Background: Talazoparib (TALA) is a highly potent, dual-mechanism PARP inhibitor that has demonstrated clinical benefit in EMBRACA Phase III trial for patients with germline BRCA1/2 (BRCA1/2)-mutated locally advanced or metastatic HER2- breast cancer. Objective: The aim of the study is to ensure the effectiveness and safety of TALA in the real-world setting among patients with locally advanced or metastatic HER2- breast cancer, with somatic or germline BRCA1/2 mutation. Methods: VITAL is an ambispective, multicentric, longitudinal, phase IV study. It includes two ambispective cohorts: - Cohort 1: patients treated through the French Early Access Program and inclusion of patients with somatic BRCA1/2 mutation was allowed. - Cohort 2: patients treated according to the European Marketing Approval granted in 09/21/2021. The primary endpoint of the study is the Time to Treatment Discontinuation (TTD) which is defined as time between the date of first dose of TALA and the date of last dose or death. Results: From November 2018 to May 2021, 85 patients were included in Cohort 2, Patients' characteristics are: - a median age of 49.0 years; - 65.8% ER+ BC / 34.2% TNBC; - 42.1% mBRCA1 / 55.3 % mBRCA2 / 2,6% mBRCA1 and mBRCA2. - 85.7% ECOG PS 0 or 1; - 23.4% de novo mBC. - Visceral, bones and CNS metastases were found in 59.0%, 61.5% and 10.3% of patients respectively. - No breast or ovarian cancer family history at 1st degree was found in 39 patients (50.0%). - 38.5% were chemo-naïve; - 21.8% received prior platinum in (neo)adjuvant or metastatic setting, with a median of prior cytotoxic regimen of 1 - For patients with ER+/HER2- ABC the median number of prior endocrine therapy was 1 and 62.0% of these patients received a CDK4/6 inhibitor prior to TALA. - 8 patients (10.3%) had CNS metastases. Out of the 78 treated patients, 57 patients (73.0%) experienced a TALA permanent discontinuation for Progressive disease (80.7%), toxicity (12.3%), cancer-related death (1.8%), or other reasons (1.8%). The median TTD for TALA is 9.6 months [6.7;10.8] with 34.5% of patients still on treatment at 12 months. After discontinuation of TALA, 59.0% of patients received a subsequent treatment with a TTD of 3.9 months [2.1 ; 45]. The most common subsequent treatments were non-platinum chemotherapy (67.4%), platinum therapy (6.5%) and other (26.1%). The Clinical Benefit Rate assessed by the investigators is 87.6% (Complete Response for 14.1%, Partial Response for 56.3% and Stable Disease for 17.2%). The median

duration of CNS metastases control was 10.2 months, and 25.0% of patients had a control of CNS metastases. At least one adverse events (AEs) was recorded in 67.9% of patients. Hematologic adverse events (AEs) (any grade) occurred in 55.1% (anemia 37.2%, thrombocytopenia 16.7%, neutropenia 15.4%). Most common non-hematologic AEs were Nausea (15.4%) and asthenia (15.4%). Related Serious Hematologic AEs occurred in 6 patients (7.7%) including 3 (3.8%) thrombocytopenia and 3 (3.8%) anemia. Related Serious Non-hematologic AEs (metrorrhagia) were seen in 1 patient (1.3%). AEs associated with temporary drug interruption, dose modification and permanent drug discontinuation occurred in 26 (33.3%), 22 (28.2%), and 7 (12.3%) patients respectively. The mOS is not mature for this analysis. Conclusions: ViTAL is the largest study that reports real-world data with TALA. Outcomes and safety in Cohort 2 (patients treated with TALA according to the European Marketing Approval), are consistent with the results of EMBRACA study and with the Cohort 1. (Litton et al. NEJM 2018)

Background: Predicting the probability of tumor progression and tolerability with sufficient accuracy remains a significant challenge in advanced breast cancer. The objective of AI4ANNA study was to assess the predictive potential of machine learning (ML) methods with respect to tumor control and safety outcomes using German study data (RIBECCA, RIBANNA) and to identify the most relevant baseline factors for prediction. Methods: Anonymized study data from two studies of ribociclib and endocrine therapy in patients with advanced HR+, HER2– breast cancer were used for predictive analysis. RIBECCA (N=487) was a multicenter, open-label, single-arm, phase 3b trial, and RIBANNA (N=1904) is an ongoing non-interventional study evaluating the real-world efficacy and safety of first-line ribociclib in combination with aromatase inhibitor/fulvestrant, endocrine monotherapy or chemotherapy. Study baseline features were used to develop prediction models for a variety of tumor control (including progression-free survival (PFS), overall response rate (ORR) at week 24, death) and safety outcomes (including general number of adverse events (AEs) as well as selected AEs belonging to blood system, cardiac, hepatobiliary, and gastrointestinal disorders). LASSO (Least Absolute Shrinkage and Selection Operator) and XGBoost (eXtreme Gradient Boosting) ML algorithms were employed

to train prediction models. LASSO was selected as a representative of fully interpretable, linear models and XGBoost as a representative of highly flexible, nonlinear models. Predictive performance of these two algorithms was compared and predictive value of single baseline features was assessed using feature permutation importance method. Results were validated internally within the training study (10 times repeated 5-fold stratified cross-validation) as well as externally, ie, implementation and training of the prediction models on one study and validation on the other and vice versa. Results: Moderate predictive signal (at baseline) could be identified for the following two outcomes: ORR (area under the curve [AUC] mean 0.628 [RIBANNA] and 0.626 [RIBECCA]) and PFS (AUC mean 0.626 [RIBANNA], 0.604 [RIBECCA]). Model performance could be validated with very similar AUCs by cross-study evaluation. Patients could be assigned to one of three risk groups. The most important features for ORR prediction included the presence of locally advanced cancer and metastases presenting as bone only disease and for PFS the presence of liver metastases, histological grade and prior (neo)adjuvant treatment. For three safety endpoints, a predictive signal (AUC >0.6) was identified only in one study but not in the other (AEs "QT prolongation", "leukopenia grade 3/4" and serious AE "vomiting"). However, insufficient predictive signals were found for all other outcomes. Conclusion: Prediction models for tumor control and safety outcomes were trained on a broad number of clinical baseline features. Moderate predictive signals could be identified for ORR and PFS. Even though the predictive performance (AUC) seems to be limited, patients could be assigned to one of three differently behaving risk groups at the baseline. The key predictive features for PFS included clinically known prognostic factors like liver metastasis, histological grade and prior (neo)adjuvant treatment.

Triple-negative breast cancer (TNBC) is the most aggressive subtype of breast cancer accounting for approximately 15% to 20% of all newly diagnosed breast cancer cases. TNBCs are defined by lack of expression of estrogen receptor (ER), progesterone receptor (PR) and human epidermal growth factor receptor 2 (HER-2). Due to its special molecular phenotype, it is not sensitive to endocrine therapy or targeted therapy. Therefore, chemotherapy such as anthracyclines or taxanes is the main systemic treatment, but the efficacy of conventional postoperative adjuvant chemoradiotherapy is poor. ~35% of TNBC tumors show abnormalities in the HR pathway, making them sensitive to poly (ADP-ribose) polymerase (PARP) inhibitors (PARPi) and DNA-damaging agents. Although more than 40% BRCA1/2-deficient patients fail to respond to PARPi and a substantial proportion of patients acquire PARPi resistance over time. TNBCs heterogeneous nature, poor prognosis and limited treatment options presents the urgent need of development of novel agents targeting tumor specific alterations. Lantern Pharma is advancing LP-184, an acylfulvene-derived prodrug that is specifically activated in tumors that overexpress the oxidoreductase enzyme Prostaglandin Reductase 1 (PTGR1), for the treatment of solid tumor indications including TNBC. LP-184 has multiple mechanisms of action (MOA). While It is synthetically lethal in tumors harboring DNA damage repair defects including Homologous Recombination (HR) deficiencies, it can also interrupt transcription. LP-184 efficacy was tested in a panel of breast cancer cell lines and patient derived TNBC xenografts models, both sensitive as well as resistant to PARP inhibitors and anthracyclines. LP-184 demonstrated nanomolar potency in six NCI-60 breast cancer cell lines (median IC50 = 327 nM). Subcutaneous patient-derived TNBC xenograft mouse models were used to determine tumor volume responses to LP-184 treatment in vivo. Xenograft tumors were derived from 10 treatment-naive HR deficient (HRD score > 50) primary TNBC patients with known BRCA1/2 loss of heterozygosity (LOH), 7 of which subsequently progressed on PARP inhibitor Olaparib. LP-184 (4mg/kg i.v., (q2d x 5 then 7 days off)x2) led to complete and durable regression in all 10 TNBC HRD-PDX models tested as compared to control (p < 0.0001). A tumor growth inhibition range of 107-141% was achieved across all the 10 models. For LP-184, T/C at the control group end day was 0% in 10/10 models, whereas across the same models for Olaparib, T/C was 0% in 2/10 models and ranged from 15 - 90% in 8/10 models. Terminal

body weight change was only a transient weight loss < 4% with LP-184 treatment across all models. LP-184 exhibited superior potency than olaparib in TNBC PDX models that carry HRD mutations including PARP resistant models and was well tolerated in mice. As acylfulvene-induced damage is primarily repaired by transcription-coupled nucleotide-excision repair (TC-NER) and HR pathways, response to LP-184 is influenced by tumor DNA damage repair pathway status. Recent data highlight an important role of super enhancer driven core transcription regulatory circuits in the pathogenesis of TNBCs. Our results support the superior efficacy of LP-184 in TNBCs, likely linked to the multiple MOAs, and establish LP-184 as a promising new agent for future clinical testing in TNBC patients. We finally propose that LP-184 may be broadly efficacious in solid tumors with HR and/or TC-NER pathway defects, such as pancreatic, prostate, ovarian and bladder cancers.

Background: FS-1502 is a HER2-targeting antibody drug-conjugate with a cleavable β -glucuronide linker and an antimitotic agent (monomethyl auristatin F) which showed promising antitumor activity in preclinical studies. We are evaluating the safety and tolerability of FS-1502 in patients with HER2-expressing advanced solid tumors (NCT03944499). Methods: Patients with HER2-expressing advanced solid tumors who had failed prior standard of care therapies were enrolled in a single-arm, open-label, dose-escalation phase Ia study in China. FS-1502 was given IV once in 21-day or 28-day cycles. The primary endpoint was incidence of dose-limiting toxicity (DLT). Adverse events (AEs), objective response rate (ORR) and duration of response (DoR) were also assessed. Data cutoff was December 30, 2021. Results: A total of 67 patients, 64 with breast cancer and 3 with other solid tumors, with median 3 prior therapies (range 1-10), were enrolled in 5 sites and treated with FS-1502 at doses of 0.1-3.5 mg/kg. Two DLTs, as defined by the protocol, were observed, with one G2 decrease in creatinine clearance at 3.0 mg/kg and one G3 thrombocytopenia with hemorrhage at 3.5 mg/kg. No Grade 4/5 events were observed. Grade 3 TRAEs were observed in 24 (35.8%) patients with the most common AEs of hypokalemia (14.9%) and decreased platelet count (9.0%). ORRs were observed at doses at or above 1.0 mg/kg with an ORR of 66.7% (4/6) at the recommended phase 2 dose (RP2D) of 2.3 mg/kg. Median duration of response (DoR) across all dose levels was 9.2 months (95%CI 5.6-NR). ORR for HER2-low patients was 42.9% (3/7). Plasma concentration and exposure (AUC) based on total ADC and total antibody increased dose proportionally at ≥ 1.0 mg/kg, with a T1/2 of 2.4-4.9 days. The incidence and magnitude of immunogenicity were low. While no MTD was determined, the 2.3mg/kg dose once in a 21-day cycle was selected as the RP2D based on safety, antitumor activity and PK data. Conclusions: FS-1502 was well-tolerated and demonstrated encouraging antitumor activity in both HER2-high and -low patients. Phase Ib and phase II clinical trials with FS-1502 are currently ongoing in various solid tumor indications including breast, gastric, and colorectal cancer.

Background: Approximately 5% of breast cancer patients carry a deleterious germline BRCA1/2 mutation, which leads malignant cells to be deficient in the repair of DNA double-strand breaks via homologous recombination. The poly(adenosine diphosphate–ribose) polymerase (PARP) enzymes are important on DNA single-strand break repair and PARP inhibitors (PARPi) cause an accumulation of unresolved DNA damage in tumors with BRCA1/2 mutations, resulting in cell death. However, because platinum salts also ultimately cause double-strand DNA breaks and may have overlapping mechanisms of resistance with PARPi, the efficacy of PARPi in patients with prior platinum therapy is unknown. We sought to evaluate the efficacy of PARPi in patients with BRCA1/2-related breast cancer and previous platinum exposure. Methods: We performed a systematic review and meta-analysis of studies that evaluated the efficacy of PARPi in patients with advanced or metastatic breast cancer and germline BRCA1/2 mutations.

Two independent investigators identified double-blind, randomized controlled trials (RCTs) that included the subgroup of previous exposure to platinum. PubMed, Embase, and Cochrane databases were searched for papers up to June 26, 2022. Data extraction from published reports and quality assessment were performed under Cochrane recommendations. Hazard ratios (HRs) with a 95% confidence interval (CI) were pooled, and a p-value of < 0.05 was considered statistically significant. The software Review Manager 5.3 was selected for conducting the statistical analysis. The primary endpoint of interest was progression-free survival (PFS). Results: Out of 2069 database results (487 on PubMed; 1376 on Embase; and 206 on Cochrane), 42 studies were selected for full review, and 4 RCTs, with a total of 249 patients, were included in the final investigation. The PARPi included were Olaparib, Talazoparib, Niraparib, and Veliparib. Pooled analysis showed that PARPi improved PFS in breast cancer patients with prior treatment with platinum-based therapy compared to the control group [HR = 0.72; 95% CI, 0.53-0.97; p = 0.03]. In comparison, the population without previous platinum exposure had a similar but slightly greater benefit from PARPi [HR = 0.68; 95% CI, 0.52-0.89; p = 0.005]. A subgroup analysis containing only the three randomized trials with PARPi monotherapy confirmed the central tendency favoring PARPi over physicians' choice of single-agent chemotherapy in patients with prior platinum-therapy; however, because of small numbers and wide confidence interval it was not statistically significant [HR = 0.72; 95% CI, 0.51-1.01; p = 0.06]. Conclusions: Our findings suggest that PARPi are associated with longer PFS in patients with advanced breast cancer and previous exposure to platinum therapy, decreasing the concerns about cross-resistance between the drug classes. Nonetheless, more extensive studies are still necessary to investigate the efficacy of PARPi in patients with prior platinum exposure and truly platinum-resistant disease.

Progression-free survival of included studies

Study	Intervention	Hazard Ratio (95% CI)		Events/patients	
		PARPi	Control	PARPi	Control
BRAVO, 2021	Niraparib	0.78 (0.39-1.58)		18/23	14/21
BROCADE3, 2020	Veliparib*	0.70 (0.34-1.44)		19/27	14/16
EMBRACA, 2018	Talazoparib	0.76 (0.40-1.45)		38/46	25/30
OlympiAD, 2017	Olaparib	0.67 (0.41-1.14)		50/60	21/26

* Veliparib plus carboplatin-paclitaxel

Background Approximately 15% of patients (pts) with hormone receptor (HR)+ human epidermal growth factor receptor 2 (HER2)- breast cancer will develop brain metastases (BM) (Kuksis et al, *NeuroOnc* 2021). Cyclin dependent kinase 4/6 inhibitors (CDK4/6i) with an endocrine therapy partner are recommended 1st line treatments in HR+HER2- metastatic breast cancer (MBC). Preclinical models show that CDK4/6i can cross the blood brain barrier (BBB). In vitro assays have shown that abemaciclib crosses the BBB more effectively than palbociclib or ribociclib (George et al, *Front Oncol* 2021). The efficacy of CDK4/6i in patients with breast cancer BM is not well described. **Methods** We examined prior treatment data for 368 pts with HR+HER2- BM who received a CDK4/6i between 2015 to 2021. The primary endpoint was overall survival (OS) from the time of starting CDK4/6i after BM development. CNS progression free survival (PFS) was assessed in pts who received CDK4/6i after BM development. We examined the relationship between OS, type and timing of CDK4/6i in multivariate analyses. Statistical analyses were conducted using R 4.1.2 software. **Results** Of the total cohort of 368 pts, 23% (n=86) had de novo MBC and 77% (n=282) had relapsed MBC. At initial presentation of MBC 79% (n=290) of pts had no BM, 19% (n=71) had BM and extracranial disease and 2% (n=7) had BM only. 56% (n=205) received a CDK4/6i before BM development, 37% (n=136) received a CDK4/6i after BM development and 7% (n=27) received a CDK 4/6i both before and after BM development. The most common CDK4/6i used first was palbociclib (85%, n=312) followed by abemaciclib (13%, n=47) and ribociclib (2%, n=9). At the time of data cutoff 277 pts were dead, 55 were alive and 36 were lost to follow up. The median follow-up of surviving pts from BM development was 32 months. 163 pts received a CDK4/6i post BM: palbociclib (66%, n=108), abemaciclib (31%, n=51) and ribociclib (3%, n=4). Of these 163 pts 83% (n=136) received a CDK4/6i as their 1st or 2nd systemic treatment post BM. In the cohort of 163 pts who received a CDK4/6i post BM, 9% did not receive local BM therapy, 40% had whole brain radiotherapy (WBRT), 34% had stereotactic surgery (SRS) alone and 17% had surgery +/- SRS. The median CNS PFS for pts who received a CDK4/6i after BM was 21

months with palbociclib and 14 months with abemaciclib (p value 0.11). Too few pts received ribociclib for analysis. CNS PFS was 21 months for pts receiving a CDK4/6i only after BM development and 10 months for those who received CDK4/6i both before and after BM diagnosis (p = 0.01). Pts who died prior to CNS progression were censored. Median OS from the time of starting CDK4/6i after BM development for pts receiving a CDK4/6i only after BM development was 25 months versus 12 months for those who received it both before and after BM development (p = 0.03). There was no statistically significant difference in OS when adjusting for the type of local BM treatment received, time from initial MBC diagnosis to BM, or the Breast Graded Prognostic Assessment (GPA) score (Sperduto et al, IJROBP 2020). Conclusions This observation suggests that there is a greater OS benefit from the time of starting CDK4/6i after BM development in pts who receive CDK4/6i solely after BM development compared to pts who received a CDK4/6i both before and after BM development. This is not unexpected given the known OS benefit associated with early use of these agents. Our unique observation of longer CNS PFS for patients who did not receive CDK4/6i prior to BM but who received it afterward suggests that CDK4/6i exposure prior to BM development may lead to development of resistance mechanisms that reduces CNS efficacy upon rechallenging with CDK4/6i after BM development. There was no statistically significant difference in post-BM CNS PFS by type of CDK4/6i received. This motivates investigation of biomarkers for patient selection and our ongoing work in collecting a matched comparison cohort of HR+HER2- pts with BM who never received CDK4/6i.

Background: Tucatinib, a highly selective tyrosine kinase inhibitor (TKI) for human epidermal growth factor 2 (HER2) receptor, received FDA approval in combination with trastuzumab and capecitabine for metastatic HER2-positive breast cancer based on the HER2CLIMB trial. While the efficacy data is promising, the tucatinib-containing triplet regimen is associated with significant toxicity and many drug-drug interactions (DDIs). The toxicity profile of tucatinib in regards to adverse events (AEs) and DDIs has not been reported outside of the HER2CLIMB trial. Additionally, with the development of many new HER2 targeted therapies including antibody-drug conjugates (ADCs) such as trastuzumab deruxtecan, efficacy in regards to therapy sequence is still unknown. Here, we describe the safety and efficacy of tucatinib in a real-world setting. Methods: This single-center, retrospective, cohort study included patients (pts) with a diagnosis of HER2- positive locally advanced or metastatic breast cancer pts that were newly initiated on tucatinib therapy at the Duke Breast Oncology Clinic following FDA approval from April 17, 2020 to June 9, 2021. Pts were evaluated for the pre-specified outcomes for the duration of tucatinib therapy, until progression of disease, or for at least 6 months follow-up. AEs reviewed included palmar-plantar erythrodysesthesia syndrome (PPE), diarrhea, fatigue, rash, anemia, thrombocytopenia, neutropenia, nausea, vomiting, mucositis, hepatotoxicity, and nephrotoxicity, defined according to the Common Terminology Criteria for Adverse Events (CTCAE) grading criteria. Overall response was categorized as complete response, partial response, stable disease, or progressive disease, defined according to the Response Evaluation Criteria in Solid Tumors (RECIST) criteria, at first staging after therapy

initiation. The overall response rate was stratified by prior standard therapies, pts who did not receive capecitabine therapy with tucatinib, and the presence or absence of brain metastases. Results: A total of 23 pts (N=23) were included in the cohort, 52% of which had brain metastases and 9% with leptomeningeal disease. Pts had a median of 3 prior lines of therapy in the metastatic setting including: lapatinib (9%), neratinib (30%), trastuzumab deruxtecan (13%), trastuzumab emtansine (74%). All pts experienced AEs, most of which were mild or moderate severity. The most common AEs reported were fatigue (70%), PPE (61%), nausea (61%), and anemia (61%). Severe AEs occurred in 6 pts (26%) with grade 3 or 4 hepatotoxicity in 13%. Only 2 pts discontinued therapy due to AEs (grade 4 hepatotoxicity, grade 2 fatigue). Due to capecitabine intolerance, 13% received tucatinib and trastuzumab doublet therapy. There were 9 pts (39%) that experienced a DDI with tucatinib requiring therapy modification or close monitoring. At first staging, partial response was seen in 26% while 35% demonstrated stable disease and 30% progressive disease. Pts with previous neratinib therapy demonstrated a partial response of 14% and a stable disease response of 29%. No pts with previous trastuzumab deruxtecan or omission of capecitabine therapy experienced a partial or stable disease response. Conclusions: The rate of AEs were similar in a real-world setting compared to the HER2CLIMB trial with a lower rate of severe adverse events, however, a higher rate of hepatotoxicity. Given the high rate of drug interactions identified with tucatinib, concurrent medications should be reviewed for appropriate therapy adjustments and monitoring. Additional data is needed in regards to sequencing and impact on therapy efficacy.

FR α is overexpressed in a number of cancers, including ovarian , breast, lung cancer, and endometrial carcinoma, yet limited expression in normal tissue. Efficacy of anti-FR α ADC have been demonstrated in clinical trials for high FR α expression ovarian cancer. These results validate FR α as a viable target for cancer treatment. We have developed a novel FR α ADC with strong bystander killing effect, BAT8006, which consists of a high-affinity antibody, an enzymatically cleavable linker and a topoisomerase I inhibitor as the payload, with DAR of 8. BAT8006 shows high affinity for the FR α antigen (KD < 0.5 nM) and FR α -expressing tumor cells. Upon binding to FR α on cell surface, BAT8006 internalizes effectively and traffics to the lysosome where payload is proteolytically released. BAT8006 demonstrated potent in vitro cell

growth inhibitory activity to FR α -positive cells with IC50 values of ~ 1 nM. In an in vitro bystander killing assay, proliferation of FR α -negative cells was potently inhibited by addition of culture medium of BAT8006-treated FR α -positive cells, but not that of BAT8006-treated FR α -negative cells, indicating the bystander killing effect of the released payload in the culture medium. Less than 0.03% of the payload was released from BAT8006 when incubated with human or monkey plasma for 4 days in 37°C, suggesting the stability of BAT8006 in blood circulation. BAT8006 led to potent and dose-dependent tumor regression in patient-derived xenograft (PDX) model of SCLC. Furthermore, single dose of 2.5 mg/kg of BAT8006 showed complete eradication of tumor in choriocarcinoma JeG-3 xenograft mice model. In PDX of ovarian cancer, 2.5 mg/kg of BAT8006 (DAR8) demonstrated superior tumor inhibition activity than 5 mg/kg of BAT8006 with DAR4, suggesting the high DAR approach of BAT8006 would be more effective. In addition, BAT8006 showed favorable pharmacokinetic and safety profiles in cynomolgus monkeys with the highest non-severely toxic dose (HNSTD) of 30 mg/kg when dosed once every three weeks for 3 times. Together these results indicate that BAT8006 could potentially provide a therapeutic benefit to treat FR α -positive tumors including breast cancer in clinical trial.

Background: Anlotinib is a novel small molecule antiangiogenic drug that can inhibit multiple tyrosine kinase receptor activities. It has demonstrated antitumor activity in various cancers. This retrospective study explored the efficacy and safety of anlotinib combined chemotherapy in HER-2 negative metastatic breast cancer patients who have disease progressed after prior two or more lines of therapy. Methods: This retrospective study enrolled twenty-two HER-2 negative metastatic breast cancer patients including TNBC and HR+ subtypes. These patients pretreated with at least two lines of chemotherapy and/or endocrine drugs before receiving anlotinib. These patients received anlotinib combination with investigator-selected chemotherapy agents, including docetaxel, vinorelbine, gemcitabine, etoposide, alibrine and so on. Anlotinib was administered 12mg d1-d14 for a 21-day cycle. The primary end point of this study was progression free survival (PFS). Secondary end points included objective response rate (ORR), disease control rate (DCR), overall survival (OS), and toxicity. The treatment continued until disease progression or intolerance or the patient withdraw informed consent. Results: The enrolled breast cancer patients received anlotinib with a median age of 52.5 (rang 30 to 73). The patients with multiple metastases were 59.1% (13/22). All patients were

evaluated and the ORR was 50% (95% CI 0.282-0.718), DCR 95.5% (95% CI 0.772-0.999) and the mPFS was 8 months (95% CI 5.15-10.85). We also analyzed the efficacy of anlotinib combination with chemotherapy in different subtypes. For HR+HER2- metastatic breast cancer patients, the ORR was 77.8% (95% CI 0.4-0.972), DCR 100% (95% CI 0.664-1.0) and the mPFS was 8.5 months (95% CI 7.217-9.783). And for TNBC patients, the ORR was 30.8% (95% CI 0.091-0.614), DCR 92.3% (95% CI 0.640-0.998) and the mPFS was 6 months (95%CI 4.405-7.595). The most common adverse events were grade 1/2 including fatigue, hand-foot syndrome and thrombocytopenia et.al., and no serious adverse events occurred. Conclusion: Anlotinib is safe and effective in patients with HER-2 negative metastatic breast cancer after prior two or more lines treatments, and it is well tolerated.

Background: Serial cell free DNA (cfDNA) analysis in metastatic breast cancer (MBC) is a noninvasive method for tracking tumor evolution and the emergence of new somatic alterations through the course of the disease. The detection of new actionable alterations may impact treatment selection; thus, serial cfDNA collection is increasingly being performed in the clinic. However, it is not well-understood how often serial cfDNA testing identifies new actionable alterations. We evaluated changes in the genomic spectrum of actionable alterations in serial cfDNA analysis of HER2 negative (HER2-) MBC.

Method: Patients with HER2- MBC who underwent plasma-based cfDNA testing (Guardant360, 74-gene assay) between February 2015 and February 2021 at an academic institution were included. A retrospective review of records was conducted to identify subtype, demographics, lines of therapy, and cfDNA results. At baseline cfDNA testing, all cfDNA alterations were considered new. For patients with serial draws, new cfDNA alterations in each draw, compared to previous draws, were quantified and characterized. The pathogenicity of new alterations was determined using the OncoKB precision oncology database. New pathogenic alterations were further classified as actionable alterations (AA) using the ESMO Scale for Clinical Actionability of Molecular Targets (ESCAT). Alterations that met the ESCAT I (alteration-drug match was associated with improved outcomes in clinical trials) or ESCAT II (alteration-drug match was associated with antitumor activity) criteria were considered as AA.

Results: 344 patients with hormone receptor positive (HR+) MBC and 95 patients with triple negative (TN) MBC had a baseline cfDNA draw. Among the HR+ cohort, 139, 79 and 48 patients had 2nd, 3rd, and 4th serial cfDNA draws, respectively. Among the TN cohort, 33 and 18 patients had 2nd and 3rd serial cfDNA draws, respectively. Table 1 depicts the prevalence of AA found in each of these draws, as well as the median number of prior therapies at each point of collection and the mean time between serial draws. The median number of new genomic alterations was lower in subsequent draws compared to the baseline, regardless of subtype (HR+: 4 vs. 2, TN: 4 vs. 1.5-3, at baseline vs. subsequent draws, respectively). In the HR+ cohort the proportion of patients with new AA (ESCAT I/II) decreased from 63% at baseline to 27-33% in the 2nd-4th draws. While some of the new AA in subsequent draws were new actionable variants in the same genes that were known to be altered in previous draws (in 19%, 68% and 57% of patients with new AA in the 2nd, 3rd and 4th draws, respectively), the remainder were new AA in previously unaltered genes. In the TN cohort 25% of patients had new AA at baseline and this proportion of TN patients with new AA continued to decrease in subsequent draws (9% and 0% in the 2nd and 3rd draws, respectively). PIK3CA and ESR1 were the most frequent genes with new AA in the ER+ cohort, regardless of draw number. In the TN cohort, PIK3CA was the most frequent gene with new AA in the first draw, and in the second draw, new AA in PIK3CA, BRCA2, and ERBB2 were present at an equal frequency.

Conclusion: While the proportion of patients with HER2- MBC identified to have new AA in serial cfDNA decreased with time for both HR+ and TNBC, new alterations continue to emerge, particularly for patients with HR+ MBC. Further research is needed to determine the impact of serial cfDNA testing on the selection of genotype-matched therapy and outcomes.

Table 1.

Test No.	1 (Baseline)	2	3	4
HR+ MBC				
n	344	139	79	48
Median No. of prior therapies (range)	2 (0-14)	3 (1-11)	3 (1-12)	4 (1-9)
Mean time interval from prior draw, months (range)	N/A	7.8 (1-43)	6.3 (1-34)	6.4 (1-29)
% Of Pt. w/ new AA (ESCAT I/II) (95% CI)	63 (58-68)	27 (20-35)	28 (18-38)	33 (20-47)
TN MBC				
n	95	33	18	N/A
Median No. of prior therapies (range)	2 (0-7)	2 (0-7)	3 (1-7)	N/A
Mean time interval from prior draw, months (range)	N/A	5.4 (1-18)	5.1 (1-22)	N/A
% Of Pt. w/ new AA (ESCAT I/II) (95% CI)	25 (17-34)	9 (0-19)	0 (0-0)	N/A

Background: CD166 is broadly expressed in normal epithelium and overexpressed in many types of malignancies, including breast cancer. Probody® therapeutic candidates are masked antibodies, conditionally activated by tumor-associated proteases, which restricts their activity to the tumor microenvironment and minimizes 'off-tumor' toxicity. CX-2009 is a conditionally activated humanized anti-CD166 monoclonal antibody conjugated to DM4 that showed clinical activity in ABC patients in a phase 1 study (Boni et al. Clin Cancer Res. 2022). This phase 2 study (NCT04596150) evaluates CX-2009 as monotherapy in patients with advanced HR+/HER2- BC (Arm A) and TNBC (Arm B), and in combination with pacmilimab (a conditionally activated PD-L1) in TNBC (Arm C). Methods: Key eligibility criteria for all cohorts include: ECOG 0-1, acceptable end-organ function, measurable disease, willingness to receive ocular prophylaxis for DM-4 related toxicity, and available tumor tissue for CD166 evaluation. Eligibility criteria for HR+ BC include: 2-4 prior regimens (excluding single-agent hormonal therapy with up to 2 prior cytotoxic regimens) and a prior CDK 4/6 inhibitor in the metastatic setting; eligibility criteria for TNBC include CD166 by IHC >1% by central assessment, 1-3 prior regimens in the metastatic setting and prior taxane. All patients initially received 7 mg/kg Q3W; the protocol was subsequently amended to enroll patients at 6 mg/kg Q3W. The primary endpoint was overall response rate (ORR) using RECIST v1.1 assessed by central review. Other key endpoints include ORR by investigator assessment, clinical benefit rate at 24 weeks (CBR24; defined as any response, confirmed or unconfirmed, or SD for 24 weeks), duration of response, and progression-free survival by investigator. Archival tumor specimens and blood samples were collected for correlative research including genomic analyses. Results: As of 13 May 2022, 60 patients were enrolled in Arm A (all patients started at 7 mg/kg); 52 were evaluable for efficacy by investigator. Median duration of follow-up was 29.1 weeks (range: 3.6-60.7). Median age was 60.5 years (36, 83); pts received a median of 3.5 (1, 6) prior treatments for ABC. CD166 H-Score > 200 was reported in 53.3% of patients. Arm A met the primary efficacy endpoint with a confirmed ORR by central radiology of 14.9% (n=47); by investigator, ORR was similar at 15.4% (n=52); an additional 9 patients (17.3%) had an unconfirmed response. CBR24 was 40.4%; using only confirmed responses, CBR24 was 23.1%. Median PFS was 11.4 weeks (95% CI 9.0, 13.9). Common treatment-related all-grade adverse events (TRAEs) included blurred vision (42%), nausea (35%), fatigue (35%), diarrhea (25%), peripheral neuropathy (27%), infusion-related reaction (23%) and decreased appetite (20%).

Grade ≥ 3 ocular and neuropathic TRAEs were 15% and 10%, respectively. AEs resulting in treatment discontinuation (AEDC) were 25%. For Arm B and C, 55 and 10 patients were enrolled (the majority received a starting dose of 6 mg/kg). For Arm B, the futility boundary was crossed (ORR < 10%). Grade ≥ 3 ocular and neuropathic TRAEs and AEDC at 7 mg/kg in Arm B were similar to Arm A (11%, 11% and 21% respectively); whereas at 6 mg/kg, they were reduced at 3%, 0% and 0%, respectively. Biomarker data and correlation with outcomes will be presented. Conclusions: Praluzatamab ravtansine demonstrated single-agent activity in unselected heavily pretreated patients with HR+/HER2- ABC. Time to event analyses, such as PFS, were confounded by higher-than-expected toxicity at a starting dose of 7 mg/kg. The toxicity profile was generally consistent with a DM4 payload. The lower dose of 6 mg/kg appears to be better tolerated. Additional clinical studies in HR+ABC, incorporating a starting dose of 6 mg/kg and potentially including a biomarker strategy, are warranted.

Background: Breast cancer (BC) is the most common malignancy in women and metastatic triple negative breast cancer (mTNBC) remains one of the most difficult to treat cancers with few targeted treatment options. RSK is recognized as a critical signaling component in the MAPK /PDK-1 pathways, is an important driver for BC and a signature of poor prognosis. PMD-026 is the first RSK inhibitor to enter clinical trials and is being developed alongside an immunohistochemistry (IHC) companion diagnostic to select patients with increased activated RSK2 in tumor tissue. A Phase 1/1b trial of PMD-026 in patients with metastatic breast cancer (mBC) or metastatic triple negative breast cancer (mTNBC) established safety at a dose of 200 mg Q12h. Efficacy signals in patients with heavily pretreated mBC/mTNBC are explored in this analysis along with evaluation of the effect of food (FE) on systemic exposure to treatment. Methods: PMD-026 was administered to 41 patients as a single agent in this phase 1/1b open-label study, with 30 patients evaluable for efficacy. Exploratory objectives were to identify subgroups of patients who may optimally benefit from PMD-026. Subgroup analysis of patients included 1) comparing BC patients who received ≤ 5 vs > 5 prior therapies; 2) comparing TNBC patients (de novo vs secondary subtypes)¹, and 3) comparing patients with low RSK2 H-scores (< 180) vs high (≥ 180). In addition, PMD 026 PK was evaluated at the 200 mg Q12h dose and a FE sub-study enrolled 12 patients administered a single 200 mg dose. Results: PMD-026 monotherapy was generally well-tolerated in the 41 mBC patients who were enrolled and treated. Kaplan-Meier PFS analysis of 30 evaluable BC patients who were dosed with PMD-026 showed that patients with less prior therapy (≤ 5) did significantly better (HR, 0.19; 95% CI [0.06–0.52], $p=0.0014$) than those with > 5 prior therapies. Subgroup analysis of PFS in those with TNBC demonstrated that de novo TNBC ($n=17$) had longer time on treatment with PMD-026 compared with secondary TNBC ($n=9$) (HR, 0.31; 95% CI [0.10-0.99], $p=0.0476$). In those with de novo TNBC with ≤ 5 prior therapies, a high RSK2 H-score was associated with significantly longer PFS at the RP2D (4.2 vs 1.3 months, HR, 0.17; 95% CI [0.03-0.80], $p=0.0254$) than patients with a low RSK2 H-score. In patients with CDK4/6 resistant HR+ BC ($n=3$), PFS was 5.2 (RSK2 high) vs 1.3 months (RSK2 low). Stable disease was observed in 53% (9/17) of patients with de novo TNBC and in 67% (6/9) of de novo TNBC patients with high RSK2. Tumor necrosis or target lesion reduction ($< 30\%$) was observed in 17% of patients (5/30), all of whom had high RSK2 expression. In the FE sub-study, increased interpatient variability in PMD-026 C_{max} and T_{max} but not AUC, was observed when administered with food, favored dosing in a fasted state, which is consistent with the pH dependent solubility of PMD-026. Notably, all FE patients (12/12) achieved the target concentration of 1 μ M (IC₉₀ in preclinical studies) within 4 hours when PMD-026 was taken without food. At the RP2D, PMD-026 taken without food showed relatively consistent exposure among patients over 24 hr timeframe. Conclusions: These findings demonstrate that in patients treated with PMD-026 who had received < 5 prior treatment regimens, had de novo TNBC or CDK4/6 refractory HR+ disease and had high RSK2 scores had longer PFS. Overall, PMD-026 is a well-tolerated, orally available RSK2 inhibitor that will be evaluated further for efficacy in TNBC and CDK4/6i refractory HR+ mBC, in a trial that will prospectively enroll patients based on RSK2 activation as defined by the RSK2 IHC H-scores. Clinical trial information: NCT04115306. 1 Patients diagnosed and treated for TNBC from their initial diagnosis (de novo TNBC) vs patients previously treated for hormone receptor positive (HR+) or human epidermal growth factor 2 receptor positive (HER2+) BC, but became HR or HER2 negative (secondary TNBC)

Background: Previous studies demonstrated that activation of the RAS/MAPK pathway is associated with reduced tumor-infiltrating lymphocytes and poor response to neoadjuvant chemotherapy in triple-negative breast cancer (TNBC). Further in vivo study showed that inhibition of the MAPK pathway with a MEK inhibitor is synergistic with immune checkpoint inhibitors (ICIs). Methods: Patients with unresectable locally advanced or metastatic TNBC with ≤ 3 prior lines of therapy were treated with pembrolizumab 200 mg every 3 weeks plus an oral MEK inhibitor binimetinib. Treatment was started with a 2-week run-in period with single-agent binimetinib. There were 2 dose levels in phase I, including dose level 0 (DL 0) with binimetinib

at 45 mg orally twice daily continuously and dose level -1 (DL -1) at 30 mg twice daily. A standard 3+3 design was used in phase I to identify the recommended phase II dose (RP2D) and Simon's two-stage Optimal design was used in phase II. Results: A total of 22 patients were enrolled. The median age was 58 years old (range 37-77). 14 (63.6%) patients had no prior systemic therapy in the metastatic setting and 8 (36.4%) patients had 1-2 prior lines of therapy. There were 4 patients treated in DL 0. Dose-limiting toxicity (DLT) was observed in 2 out of 4 patients in DL 0 with grade 3 ALT abnormality in one patient and grade 3 flank pain together with grade 3 nausea and vomiting > 48 hours despite anti-emetic therapy in the other patient. Binimetinib dose was reduced to DL -1. In the next 6 patients, there was 1 DLT observed with grade 3 AST/ALT abnormality. Thus, DL -1 was the RP2D, and an additional 12 patients were treated with DL -1 in phase II. Overall, 18 patients were treated in DL -1 and were included in phase II efficacy evaluation. 17 patients were evaluable for response. Objective responses were observed in 5 patients (29.41%, 95% CI: 10.31 - 55.96) with 1 complete response (CR) and 4 partial responses (PR). The clinical benefit rate (CBR) was 35.29% (95% CI: 14.21 - 61.67) with 6 out of 17 having had CR, PR, or stable disease \geq 24 weeks. Since previous studies showed poor responses to ICIs in patients with liver metastases due to macrophage-mediated T cell elimination, we further conduct exploratory analysis to evaluate responses among patients with and without liver metastases. Among all 5 patients with liver metastases, no response was observed. The objective response rate (ORR) in patients without liver metastases was 55.56% (95% CI: 21.20 - 86.30) and CBR was 66.67% (95% CI: 29.93-92.51), when excluding 3 patients who discontinued treatment due to adverse events prior to follow-up scans. Median progression-free survival in DL 0 was 2.4 (95%CI: 0.5-NE) and in DL -1 was 8.3 (95% CI: 3.9-NE) months. Median overall survival in DL 0 was 7 (95%CI: 0.5-NE) and in DL -1 was 33.2 (95% CI: 10.3-NE) months. Among patients who responded, 3 out of 5 (60%) had a duration of response greater than 12 months and ongoing even after stopping treatment (range: 5.4 - 32.0 months). Adverse events (AEs) were mostly grade 1-2 including anemia, CPK increase, fatigue, diarrhea, nausea, peripheral neuropathy, acneiform rash, AST increase, cardiac troponin increase, and constipation. Additional correlative studies are ongoing and will be presented at the meeting. Conclusions: Pembrolizumab in combination with binimetinib at 30 mg twice daily appears to be safe with manageable toxicities. Promising activity with durable responses was observed with this combination without chemotherapy, particularly in patients without liver metastases. Future studies are warranted to further evaluate the efficacy of this combination.

Real-world second-line treatment patterns and associated clinical outcomes for 2795 patients with advanced HR+ HER2- breast cancer treated with first-line CDK4/6 inhibitors

Background: CDK4/6 inhibitors (CDK4/6i) are standard first-line (1L) regimens for HR+/HER2- advanced breast cancer (aBC). Recent data from the randomized phase II MAINTAIN trial reported a PFS benefit for patients (pts) who received a new endocrine therapy plus ribociclib (ribo) versus new endocrine therapy alone) following progression on CDK4/6i as compared to pts who received endocrine therapy alone. However, second-line (2L) treatment patterns and patient outcomes following 1L CDK4/6i are relatively undescribed. Here we describe real-world 2L treatment patterns following 1L CDK4/6i and associated clinical outcomes from a large clinical genomics database.

Methods: Real-world evidence (RWE) was sourced from the GuardantINFORM (Guardant Health) database which comprises aggregated commercial payer health claims and de-identified records from over 207,000 pts with comprehensive circulating tumor DNA (ctDNA) results via Guardant360 (G360) from 2014 to 2021. Pts with HR+/HER2- aBC with >1 claim of CDK4/6i and >1 claim for treatment after the index G360 test were included. Real-world time to treatment discontinuation (rwTTD) and real-world time to next treatment (rwTTNT) were assessed in months as proxies for progression-free survival. Real-world overall survival (rwOS) was also reported in months.

Results: 2,795 pts met criteria for inclusion; 2,361 (84.5%) were treated with 1L palbociclib (palbo), 271 (9.7%) with 1L abemaciclib (abema) and 163 (5.8%) with 1L ribo. Chemotherapy

(chemo,35.5%) and endocrine-only therapy (32.8%) were the most common 2L therapy regardless of the 1L CDK4/6i agent (Table 1). Other 2L agents included endocrine backbone change (14.7%) or CDK4/6i change (7.7%). Endocrine backbone changes were observed more frequently (15.6%) in pts receiving 1L palbo while CDK4/6i changes were more frequent in pts receiving abema (14.0%) or ribo (22.0%). Pts treated with 2L CDK4/6i had improved rwTTNT, rwTTD and rwOS compared to 2L chemo regardless of 1L agent [rwTTNT: 10.2 (95% CI: 7.2-11.7) vs. 7.2 (6.5-8.1); rwTTD: 6.8 (95% CI: 5.8-8.5) vs. 4.3 (95% CI:3.9-4.7); rwOS: NR (95% CI: 40.0-NR) vs. 34.8 (95% CI: 31.3-37.2)]; improvement in rwTTNT, rwTTD and rwOS were also observed for pts with 2L endocrine backbone changes compared to chemo [rwTTNT: 8.5 (95% CI: 7.2-9.6) vs. 7.2 (6.5-8.1); rwTTD: 6.9 (95% CI: 5.8-7.9) vs. 4.3 (95% CI:3.9-4.7); rwOS: 63.4 (95% CI: 51.2-NR) vs. 34.8 (95% CI: 31.3-37.2)]. Pts treated with 2L alpelisib had the shortest rwOS regardless of 1L CDK4/6i agent used [any 1L: NR (95% CI: 23.6-NR)].

Conclusions: A variety of 2L regimens following 1L CDK4/6i were observed, with an improvement in rwTTNT, rwTTD and rwOS in pts receiving 2L CDK4/6i or 2L endocrine backbone change only relative to 2L chemo. These data are hypothesis generating, and the observed improvement may be secondary to therapy choice versus pts who received 2L chemo having more aggressive disease. Larger randomized trials are ongoing to study sequencing and efficacy of 2L treatments following 1L CDK4/6i.

Table 1. Distribution of 2L therapies by 1L CDK4/6i agent

	ANY 1L CDK4/6i		1L Palbociclib		1L Abemaciclib		1L Ribociclib	
2L Chemotherapy	992	35.5%	845	35.8%	100	36.9%	47	28.8%
2L Endocrine only	917	32.8%	808	34.2%	67	24.7%	42	25.8%
2L Endocrine Backbone change	412	14.7%	369	15.6%	24	8.9%	19	11.7%
2L CDK4/6i	214	7.7%	140	5.9%	38	14.0%	36	22.1%
2L Alpelisib	134	4.8%	105	4.5%	19	7.0%	10	6.1%
2L PARP inhibitor	31	1.1%	24	1.0%	5	1.9%	2	1.2%
2L Anti-HER2	79	2.8%	61	2.6%	13	4.8%	5	3.1%
2L Immunotherapy	16	0.6%	9	0.4%	5	1.9%	2	1.2%
	2795		2361	84.4%	271	9.7%	163	5.8%

Background:

Combining CDK 4/6 inhibitors with hormone directed therapy using aromatase inhibitors (AI) or selective estrogen receptor down-regulators (SERD) is considered first line therapy for treatment of hormone receptor positive (HR+) human epidermal receptor 2 negative (HER2-) metastatic breast cancer (mBC). Here we aim to evaluate first line CDK 4/6 inhibitor practice patterns both nationally and locally (Wisconsin) in HR+ HER2- mBC patients and evaluate age as a potential factor impacting practice patterns.

Methods:

A retrospective analysis was performed utilizing IQVIA Anonymized Patient Longitudinal Data. The data base captures 60-85% of cancer patients across all 50 states in the United States and relies on diagnostic coding used in service or treatment claim filing. Patients queried were greater than 18 years old and were identified by a code indicating CDK4/6 inhibitor therapy or a combination of codes indicating mBC, HR+ status and HER- status. First line treatment was

categorized as CDK4/6 inhibitor combination therapy, AI monotherapy, SERD, selective estrogen receptor modulator (SERM) monotherapy, chemotherapy, or other. Patients were further filtered by year, location, practice type (academic vs community), and age.

Results:

A total of 313,978 patients with mBC receiving first-line therapy were identified nationally between 2015 and 2021. The proportion of patients on first line CDK4/6 inhibitor combination therapy nationally significantly improved from 20% in 2015 (N=27,063) when palbociclib was first approved, to 53% in 2021 (N=54,023) (Table 1.) In 2021, first line use of CDK 4/6 inhibitor combination therapy was higher at 59% both in WI and our institution Froedtert Hospital and the Medical College of Wisconsin Cancer Center (Table 2.) At our center in 2021, the use of first line CDK4/6 inhibitor combination therapy in patients greater than age 65 was significantly lower at 35% (N=39) compared to patients less than 65 at 75% (N=64.) Further delineating the age groups at our center (Table 3,) use of CDK4/6 inhibitor combination therapy in patients aged 70-79 was 35% (N=20) and fell to 20% in patients greater than 80 in age (N=8.)

Conclusion:

Despite significant improvement in long-term outcomes with first line CDK4/6 inhibitor combination therapy in HR+ HER2- mBC patients, overall national usage is suboptimal. At our center, this was particularly apparent in patients older than 70. Identifying barriers to optimal use is critical to improve utilization of this important and effective class of drugs.

National Percentages of HR+ HER2- mBC Patients Stratified by First Line Treatment Between 2015-2021

		Year							
		2015	2016	2017	2018	2019	2020	2021

Background: Talazoparib (TALA) is a highly potent, dual-mechanism PARP inhibitor that has demonstrated clinical benefit in EMBRACA Phase III trial for patients with germline BRCA1/2 mutated locally advanced or metastatic HER2- breast cancer.

Objective: The aim of the study is to ensure the effectiveness and safety of TALA in real-life setting among patients with locally advanced or metastatic HER2- breast cancer, with somatic or germline BRCA1/2 mutation.

Methods: ViTAL is an ambispective, multicentric, longitudinal, phase IV study. It includes two ambispective cohorts:

- Cohort 1: patients treated through the French Early Access Program and inclusion of patients with somatic BRCA1/2 mutation was allowed.
- Cohort 2: patients treated according to the European Marketing Approval granted in 09/21/2021.

Here we present the results of the primary and some secondary endpoints for cohort 1.

Results: From November 2018 to May 2021, 86 patients were included in Cohort 1, with updated results after a median follow-up of 17.3 months (11.2 - 24.4).

Patients' characteristics are 53.5% of ER+ BC / 46.5% of TNBC (refer to the table).

The median Time to Treatment Discontinuation (mTTD) was 9.0 months [range 6.0 ; 11.5] with 37.7% of patients still on treatment at 12 months. Subgroup analysis shows similar mTTD according HR status, germline vs somatic mutation and prior platinum exposure (refer to the table).

The Clinical Benefit Rate assessed by the investigators is 82.4% (Complete Response for 25.7%, Partial response R for 32.4% and stable disease for 24.3%). The median of duration of CNS metastases control was 6.6 months, and 80.0% of patients had control of CNS metastases during TALA.

Out of the 85 treated patients, 69 patients (80.2%) experienced a TALA permanent discontinuation for progressive disease (84.1%), toxicity (10.1%), cancer-related death (1.4%), or other reasons (1.4%).

After discontinuation of TALA, 65.1% of patients received a subsequent treatment with a TTD of 2.3 months [1.7 ; 2.7]. The most common subsequent treatments were non-platinum chemotherapy (64.3%), platinum chemotherapy (19.6%) and others (19.1%).

At least one adverse events (AEs) was recorded in 74.4% of patients. Hematologic AEs (any grade) occurred in 48.8% (anemia 27.9%, thrombocytopenia 12.8%, neutropenia 10.5%).

Most common non-hematologic AEs were alopecia (8.1%) and asthenia (7.0%). Related Serious Hematologic AEs occurred in 10 patients (11.6%) including 7 (8.1%) Anemia.

Related Serious Non-hematologic AEs (vomiting, pyelonephritis and ascitis) were seen in 3 patients (3.6%). AEs associated with temporary drug interruption, dose modification and permanent drug discontinuation occurred in 36 (41.9%), 24 (27.9%), and 7 (10.1%) patients respectively.

The mOS is expected to be reached at the time of the congress, with 51.9% of patients still alive at 24 months.

Conclusions: ViTAL is the largest study that reports real-world data with TALA. Outcomes and safety in Cohort 1 are consistent with the results of EMBRACA study and give additional data on subgroups of interest (ie patients previously treated with carboplatin, presence of CNS). (Litton et al. NEJM 2018)

mTTD on subgroups of interest

mTTD by :		N (%)	Months [95% C.I.]
BRCA mutation	BRCA1	42 (48.8)	6.5 [4.8 ; 9.1]
	BRCA2	44 (51.2)	12.0 [6.1 ; 21.0]

Background: FCN-437c is a second-generation CDK4/6 inhibitor. Phase 1b clinical results indicated improved antitumor activity in patients (pts) with HR+, HER2– advanced breast cancer (ABC), treated with FCN-437c + letrozole.

Methods: This Phase 2, multicenter, open-label clinical study evaluated the antitumor activity, pharmacokinetics (PK), and safety of FCN-437c + fulvestrant in post-menopausal pts (Cohort 1, treatment-naïve or 2L), FCN-437c + letrozole + goserelin in pre-menopausal pts (Cohort 2, treatment-naïve). Pts received FCN-437c (200 mg QD) in a 21-day-on and 7-day-off schedule either in combination with fulvestrant (500 mg D1) or letrozole (2.5 mg QD) + goserelin (3.6 mg once per cycle) in 28-day cycles. The primary endpoint was overall response rate (ORR) and secondary endpoints were progression-free survival (PFS), overall survival (OS), PK, and

safety.

Results: At study cutoff (Feb 7, 2022), 36 pts were enrolled in Cohort 1 and 31 pts were in Cohort 2; 42 (62.7%) pts had visceral metastases and 9 (13.4%) pts had bone-only metastases. In Cohort 1, 18 pts were treatment-naïve, 15 pts had received 1L treatment, and 3 pts had received ≥2L treatment. In Cohort 2, 25 pts were treatment-naïve and 6 pts had received 1L treatment. Overall, 27 pts in the per-protocol set achieved partial response (PR), resulting in an ORR of 40.9% (95% CI, 29.0-53.7). Median follow-up was 12.8 months, and median PFS (mPFS), OS, and DOR were not reached. However, at 12 months, the PFS rate was 67.7% (95% CI, 53.2-78.6) and the OS rate was 95.9% (95% CI, 84.5-99.0); the 6-month DOR rate was 96.0% (95% CI, 74.8-99.4). In Cohort 1 (n=35), 11 pts achieved PR: the ORR was 31.4% (16.9-49.3%) and mPFS was 12.9 months (95% CI, 9.2-NR); the 6-month DOR rate was 100%. In Cohort 2 (n=31), 16 pts achieved PR: the ORR was 51.6% (95% CI, 33.1-69.9%). mPFS, OS, and DOR were not reached; the 6-month DOR rate was 92.9% (95% CI, 59.08-98.96) (Table). Treatment-emergent adverse events (TEAEs) were observed in all pts. Majority of AE were G1 or 2 except for hematological TEAE. 58 (86.6%) pts reported grade ≥3 TEAEs, mainly neutropenia (74.6%), leukopenia (49.3%), hypertriglyceridemia (6.0%), lymphocyte count decrease (4.5%), and γ-glutamyltransferase increase (3.0%): most were reversed through dose interruption and symptomatic therapy. Steady-state PK parameters were analyzed after 15-21 days of QD administration: Cohort 1: median Tmax was 3 h, geomean T1/2 was 44.6 h, geomean Cmax was 1650.7 ng/mL, and geomean AUC0-24h was 29,148.08 h*ng/mL; the geomean accumulation ratios of AUC0-24h and RCmax were 2.18 and 1.74, respectively, compared with first dose. Cohort 2: median Tmax was 4 h, geomean T1/2 was 35.7 h, geomean Cmax was 1314.34 ng/mL, and geomean AUC0-24h was 22,889.96 h*ng/mL; the geomean accumulation ratios of AUC0-24h and RCmax were 1.95 and 1.63, respectively, compared with first dose.

Conclusion: FCN-437c in combination with fulvestrant or letrozole + goserelin demonstrates antitumor activity and safety and is well tolerated in pts with HR+, HER2- ABC. This combination therapy will be further investigated in 2 ongoing Phase 3 trials (NCT05438810 and NCT05439499).

Clinical trial number: NCT05004142. Research Sponsor: Avanc Pharmaceutical Co., Ltd

Table. Clinical outcomes for patients in the per-protocol set

	Cohort 1: FCN-437c 200 mg + fulvestrant 500 mg (N=35)	Cohort 2: FCN-437c 200 mg + letrozole 2.5 mg + goserelin 3.6 mg (N=31)	Total (N=66)

Background: Two poly (adenosine diphosphate-ribose) polymerase inhibitors (PARPi) are currently FDA-approved for the treatment of HER2-negative metastatic breast cancer (MBC) in carriers of germline pathogenic variants (PVs) in BRCA1 or BRCA2 (BRCA1/2). This study explores the clinical outcomes of MBC patients treated with a PARPi. Methods: In this retrospective study, we included MBC patients treated with a PARPi between January 2017 and February 2022 at Mayo Clinic (Minnesota, Arizona, Florida, and Mayo Clinic Health Systems). We used the Kaplan Meier method to estimate the time-to-treatment-failure (TTF) and the log-rank test to compare different subsets. In addition, predictors of TTF were identified in a multivariate cox-proportional hazard regression model, including age at PARPi initiation, race, ethnicity, histology, estrogen receptor (ER), progesterone receptor (PR), and HER2 expression of the tumor, the number of prior therapies, type of PARPi, and PV carrier status (germline BRCA1/2 or PALB2 vs. somatic BRCA1/2 vs. other). Results: Sixty-five patients treated with PARPi (olaparib: 51; talazoparib: 14) were included in the final analysis. Fifty-five patients were carriers of germline PVs in BRCA1 (n=24, 37%), BRCA2 (n=27, 42%) or PALB2 (n=4, 6%), whereas ten patients (15%) had no germline PVs but the tumor had a somatic mutation in the homologous recombination-related (HRR) genes (7 in BRCA1/2, 2 in ATM, and 1 in CDKN2A and CDH1). At the data cutoff, 48 (74%) patients had discontinued PARPi due to progression or death. Fifteen (23%) patients required a dose reduction due to side effects. Occurrence of grade ≥ 3 side effects: anemia in 8, fatigue in 4, neutropenia in 2, and thrombocytopenia in 2 patients. Eight (15.7%) patients in the olaparib group and seven (50%) patients in the talazoparib group required a dose reduction for side effects. No patient on olaparib required drug discontinuation due to side effects, whereas two patients on talazoparib were switched to olaparib due to cytopenias and could tolerate olaparib. Median TTF in the overall population was 8 months (95% confidence interval [CI]: 6.4 – 9.6), and there was no difference ($p=0.64$) in TTF between the olaparib and talazoparib groups. Median TTF in the germline BRCA1, BRCA2, and PALB2 PV carriers were 7, 8, and 11 months, respectively ($p=0.57$). Among patients with somatic BRCA1/2 mutations, the median TTF was 4 months. Numerically, patients with HER2-positive tumors (n=8) had a shorter TTF compared to HER2-negative tumors (Median TTF: 4 vs. 8 months, $p=0.098$). No significant difference in TTF was observed by ER or PR status of the tumor, age at initiation of PARPi, the number of prior therapies, and prior use of platinum-based chemotherapy or CDK4/6 inhibitors. In multivariate analysis, HER2 positivity (hazard ratio [HR]: 8.0, 95% CI: 2.2 – 29.4, $p=0.002$), somatic BRCA1/2 mutations (HR: 7.6, 95% CI: 1.2 – 50.0, $p=0.03$) and somatic mutations in other HRR genes (HR: 19.1, 95% CI: 3.1 – 118.6, $p=0.002$) were associated with worse TTF. Conclusions: In the real world, PARPi were well-tolerated with promising time-to-treatment-failure (TTF) benefits comparable to data from clinical trials. Notably, relatively shorter TTF was observed in

patients with somatic BRCA1/2 and other HRR gene mutations and HER2-positive MBC. These findings improve our understanding of the role of PARPi in MBC and will help to guide treatment decisions with PARPi in the clinical setting.

Background: Patients with HER2 positive (+) breast cancer and central nervous system (CNS) metastases often have poor prognoses. DZD1516 is designed as a reversible and selective HER2 tyrosine kinase inhibitor (TKI) with full blood-brain barrier (BBB) penetration. Methods: DZD1516 is being developed in a phase 1 study (NCT04509596) in patients with HER2+ advanced or metastatic breast cancer relapsed from the standard of care. Key overall eligibility criteria were previously presented. DZD1516 was given orally twice daily (BID) in a continuous 21-day cycle (except Cycle 0). The primary objective is to evaluate the safety and tolerability of DZD1516 monotherapy and define the maximum tolerated dose (MTD). Results: As of June 23, 2022, twenty-three patients with HER2+ MBC from the USA and China were enrolled and dosed with DZD1516 monotherapy (25 mg ~ 300 mg, BID). Fifteen patients (65.2%) had baseline CNS metastases. Patients were heavily pre-treated, with a median of 7 lines of prior systemic treatment. All patients had been treated with HER2 large molecules, and 82.6% of patients also received prior HER2 TKI treatment. DZD1516 was well tolerated at doses up to 250 mg BID. Two dose-limiting toxicities were reported in the 300 mg cohort. As a result, 250 mg was defined as the MTD. Treatment-emergent adverse events (TEAEs) were reported in 91.3% of patients. Grade 3 drug-related TEAEs were reported in two patients. No grade 4 or 5 TEAEs were reported. The most common TEAEs included headache, vomiting, and hemoglobin decreased. The majority of the TEAEs could be managed and were reversible. The longest treatment duration was > 3 months. Following single oral dosing, DZD1516 was eliminated with a mean half-life of 13.4 – 22.5 hrs. After twice-daily dosing for 15 days, moderate accumulation of DZD1516 systemic exposure was observed at doses ≤ 200 mg BID and negligible accumulation at 250 mg BID. The combined molar exposure of DZD1516 and its active metabolite DZ2678 increased with dose between 50 mg to 250 mg dose range. In patients (n = 6), mean K_{puu},CSF was 2.1 for DZD1516 and 0.76 for DZ2678 across the dose range, indicating full penetration of DZD1516 and DZ2678 into human CNS. Nineteen patients (82.6%) had at least one post-treatment RECIST assessment. With a median of 7 lines of prior systemic treatment, the best antitumor efficacy in intracranial, extracranial, and overall lesions

was stable disease. Conclusion: DZD1516 is a full BBB-penetrant HER2 inhibitor. Consistent with its high selectivity, no wild-type EGFR-related AEs have been reported. The updated data will be presented at the meeting.

Objective: The molecular hallmark of invasive lobular cancer (ILC) is the loss of E-cadherin, resulting in the unique morphology, low mitotic index and unusual metastatic spread to ovaries, gut, and peritoneum. Patients with ILC face delayed, and higher stage at diagnosis, worse disease-free and overall survival¹. The most frustrating challenge is the delayed recurrence, likely due to resistance and induction of dormancy². Despite these unique features, ILC is lumped with hormone receptor-positive invasive ductal cancers (IDC); consequently, management strategies are based on data from IDC. Hence there is an unmet need to address the unique challenges of ILC. We generated Tamoxifen-resistant (TAMR) ILC cell lines with the aim to study the distinct characteristics, dormancy, differentially activated pathways, and response to drugs targeting such pathways in the resistant cells. Methods: We used MDA-MB-134-VI and SUM44-PE cells to study the effect of tamoxifen in combination with multi-targeted receptor tyrosine kinase inhibitor, Lenvatinib. TAMR cells from both MB-134 and SUM44PE cells were generated by growing them in increasing concentrations of 4-hydroxy tamoxifen (4-HT) up to 500nM, for 6 months. Total RNA from parental and TAMR cells were subjected to RNA-seq. Whole cell extracts were analyzed for specific phospho proteins by Western Blot analysis. Growth kinetics and effect of drugs on cell viability was measured using MTT assay (Roche). Cell migration was measured using Transwell migration assay. Novel engineered 2D and 3D cultures were used to study dormancy and the effect of the drug combination. Orthotopic tumor induction in NSG mice is ongoing to determine the effect of drug combination in vivo. Results: The TAMR cell lines show distinct morphological features, small but significant increase in growth rate ($p=0.05$) and remarkably higher migration (MB-134TAMR:11.5-fold, $p<0.005$ and SUM44TAMR:>100-fold, $p<0.005$). The IC₅₀ for tamoxifen increased from 8.1 μ M (MB-134) to 16.8 μ M (MB-134TAMR) and from 11.3 μ M (SUM44) to 26.6 μ M (SUM44TAMR). RNA seq analysis revealed enrichment of PI3K-AKT, MAPK, cAMP, Rap1 signaling pathways, ECM-receptor interaction, Focal adhesion, and steroid hormone biosynthesis pathways in the

TAMR cells. Upon stimulation by endothelial growth factor, the MB-134TAMR but not the parental cells showed dose dependent increase in phospho-AKT and phospho-MAPK levels. Using novel 2D/3D cultures, we show differential morphologies between IDC (MCF7) cells, MB-134TAMR, and the parental cells. MCF7 and MB-134TAMR cells are more adherent to fibronectin ($p < 0.0001$), whereas the parental ILC cells are more adherent to COL3A1 ($p < 0.0001$), a feature observed in dormancy³. Further, the administration of 5 μ M 4-HT induced a cessation of growth in the parental cell line, with a sub-population of apparent dormant cells. The combination of Lenvatinib (5 μ M) and 4-HT (7.5 μ M) synergistically inhibited both the parental cell lines by ~60%. Lenvatinib (5 μ M) and 4-HT (15 μ M) inhibited the MB-134TAMR and SUM44TAMR cell lines synergistically by 65% and 45% respectively. In vivo, the growth of MB-134 induced tumors were completely suppressed when 5mg sustained release pellet of TAM citrate was injected in the subscapular region of tumor bearing mice (tumor @100cm³). The results of the combination using in vivo models and 2D/3D cultures will be reported. Conclusion and significance: Lenvatinib with tamoxifen is active and synergistic against parental and TAMR ILC cell lines. Our novel 2D/3D cultures show distinct pattern of growth for ILC cells and a possible induction of a dormant subpopulation upon 4-HT treatment. Overcoming resistance to conventional therapies and preventing induction of dormancy will improve long-term outcomes of patients with ILC. 1. PMID:33641217 2. PMID: 34388695 3. PMID: 35121989

Background: The SAKK 22/99 is a phase III randomized clinical trial launched by the Swiss Group for Clinical Cancer Research and the European Institute of Oncology in Milan in 99 for women with HER2-positive advanced breast cancer (ABC). 175 patients were randomized 1:1 from Sept 99 to Jan 2013 to receive first-line trastuzumab (T) alone followed at disease progression by the combination with chemo (Arm A) vs the upfront combination of T and chemo (Arm B). The results were published in 2017 (O. Pagani et al Ann Onc 28: 305–312, 2017). The outcome was similar for sequential T-chemo or upfront combination

The patients' treatment and FU continued until March 2022 and we now report the safety data after 135.2 months of median FU.

Patients and methods: at the time of study termination 1 patient with SD was still receiving T alone in the study and T was continued after trial closure. The safety analyses include 86 pts allocated to arm A and 88 to arm B. 1 pt did not receive any trial treatment and was excluded from this analyses.

19 of the 86 patients in arm A stopped trial treatment after T alone, 67 continued with T+chemo. Baseline characteristics were well balanced and are summarized in Table 1.

Treatment

The T loading dose of 4 mg/kg/iv was followed by 2 mg/kg/iv weekly. In the 1st-line population (84) chemo was weekly paclitaxel (90 mg/m²/iv-3/4 weeks). After amendment 1 chemo was at investigator's choice (taxanes, vinorelbine, platin) according to label indications and could be stopped after 24 weeks (6–8 cycles) in responding patients or after unacceptable toxicity.

Results:

7 patients in arm A (8%) and 11 in arm B (13%) stopped trial treatment due to toxicities (Fisher's exact test, p=0.46). 3 of the 7 patients in arm A stopped under T alone and 4 under T+chemo (all paclitaxel weekly)

Treatment durations of these 7 and 11 patients were 7.7 months (range 0.5 – 49) in arm A and 5.5 months (range 0.6 – 31 months) in arm B, respectively.

Cardiovascular toxicities: The most common toxicities were thromboembolic events, blood pressure disorders and arrhythmia. 6 patients (7%) in arm A and 10 (11%) in arm B had cardiac

events (Fisher's exact test, $p=0.43$). G1-3 toxicities occurred in 2 (2%), 2 (2%) and 2 (2%) patients of arm A and in 5 (7%), 2 (2%) and 3 (3%) of arm B. We observed no grade 4 events. Split by treatment phase in arm A, G1-3 toxicities were seen in 1 (1%), 2 (2%) and 1 (1%) patient under T alone (N=86) and in 1 (1%), 0 (0%) and 2 (3%) under T+chemo (N=67). LVEF-decline: 78 patients in arm A and 74 in arm B had sequential LVEF measurements. A decline $\geq 10\%$ was found in 35 patients (45%) in arm A and in 20 (27%) in arm B (Fisher's exact test, $p=0.028$). Among the 35 patients in arm A, 12 had the decline under T alone, 14 under T+chemo, and 9 under both T alone and T+chemo. A decline $\geq 20\%$ was found in 10 patients (13%) in arm A and in 3 (4%) in arm B (Fisher's exact test, $p=0.08$). Among the 10 patients in arm A, 7 had the decline under T alone, 3 under T+chemo.

Sensory neuropathy

43 patients (50%) in arm A and 48 (54%) in arm B had neuropathy (Fisher's exact test, $p=0.65$). G1-3 toxicity in arm A was developed by 26 (30%), 11 (13%) and 6 (7%) patients, respectively; in arm B 30 (34%), 12 (14%) and 6 (7%). No grades 4 events occurred.

Conclusion: After more than 11 years of follow-up, no relevant toxicities were found in these patients receiving T for ABC. In particular, the incidence and grade of cardiac toxicity was low. The decline in LVEF was numerically higher in the arm A and in particular in the T alone group, but was not clinically relevant. Our data potentially suggest that T+chemo followed by T maintenance could have less cardiotoxicity than T followed by T+chemo. The possible causes for the difference in LVEF decline between the two arms are unclear, but could be related to treatment duration. The women in Arm A shows a trend to longer therapy: Median treatment duration (months) in Arm A was 7.92 (0.46 - 135.98) vs 6.62 (0.56 - 71.28) in Arm B. This long-term analysis confirms the favorable safety and good tolerability of the reported regimes.

City: Nagoya

State: Aichi

Country: Japan

Background: PAL is a first-in-class cyclin-dependent kinase 4/6 inhibitor (CDK4/6i) for the treatment of HR+/HER2- ABC. Two CDK4/6is are currently available in Japan; PAL and abemaciclib (ABE). CDK4/6i+endocrine therapy (ET) has shown significant clinical benefits compared to ET alone in clinical trials. CDK4/6i combination therapy is strongly recommended as a first-line (1L) treatment in global and Japanese treatment guidelines. However, no optimal subsequent treatment has been established after discontinuing treatment with CDK4/6i+ET. Substantial data are required to determine whether the available treatment options remain effective after CDK4/6i treatment. Here, we report the treatment pattern of subsequent therapy after PAL in a real-world setting in Japan to provide insights into the optimal subsequent therapy.

Methods: This retrospective, observational study utilized a nationwide hospital-based medical claims database managed by Medical Data Vision (MDV). The MDV database, one of the largest medical databases in Japan, covers 26% of acute-care hospitals across Japan, including 226 cancer therapeutic facilities. We evaluated the data of patients who received PAL from September 2017 to June 2021 and subsequently received therapy. Any treatment for ABC initiated within 30 days was considered part of one regimen. The median time-to-treatment failure (TTF) of subsequent therapy was estimated using the Kaplan–Meier method.

Results: From the database, we identified 1,170 patients with HR+/HER2- ABC who received PAL, among which 398 (34%) received combination therapy as 1L treatment. The median age at PAL initiation was 64 years (range 53–72), and 13.0% of the patients were pre-/peri-menopausal. Among the 398 patients, 224 (56.3%) received therapy after PAL+ET. Endocrine-based therapy was commonly used as the first subsequent therapy (n=136; 60.7%), including CDK4/6i+ET (n=70; 31.2%), ET alone (n=39; 17.4%), and everolimus+ET (n=27; 12.1%). Among the 81 (36.2%) patients who received chemotherapy as the first subsequent therapy, 27 (12.1%) received bevacizumab+chemotherapy. The median TTF (95% confidence interval [CI])

of the first subsequent therapy was 7.5 months (6.5–8.4), and that of each subsequent regimen is listed in Table 1. The median TTF (95% CI) for patients received CDK4/6i+ET as first subsequent therapy after PAL+ET was the longest among the regimens, 10.9 months (6.5–15.6). Among the 70 patients, 36 changed only CDK4/6i type, 17 changed only ET type, and 12 changed both CDK4/6i and ET types. The median TTF (95% CI) was 20.1 months (6.5–not reached [NR]), 8.7 months (2.9–11.2), and 7.7 months (2.6–NR), respectively. No obvious trend was observed between the TTF of PAL+ET as a 1L treatment and the TTF of subsequent ABE after the PAL+ET treatment.

Conclusion: More than half the patients received endocrine-based therapy after PAL+ET as a 1L treatment, and the observed treatment duration was comparable to the results of clinical trials reported to date, even after PAL treatment. ET+targeted therapy and chemotherapy represent acceptable treatment options after PAL+ET. One-third of patients received CDK4/6i+ET after PAL+ET in Japanese clinical practice; however, further investigation is warranted to confirm that this treatment strategy is effective.

Table 1. Median TTF of each subsequent therapy after PAL+ET

First subsequent therapy	Median TTF (95% CI), months
ET alone	4.4 (2.8–13.7)
CDK4/6i+ET	10.9 (6.5–15.6)
changed only CDK4/6i type	20.1 (6.5–NR)
changed only ET type	8.7 (2.9–11.2)
changed both CDK4/6i and ET types	7.7 (2.6–NR)
Everolimus+ET	6.1 (5.1–7.2)
Chemotherapy alone	7.2 (4.9–8.5)
Chemotherapy plus bevacizumab	9.4 (6.1–12.1)
Chemotherapy plus ET	8.4 (5.6–NR)

Background: New anti-HER2 drugs such as tucatinib and trastuzumab deruxtecan (T-DXd) have shown to improve survival of HER2+ MBC in clinical phase III trials. To allow a future confirmation of this survival advantage in real world, we evaluated the prognosis of HER2+ MBC patients before the availability of tucatinib and T-DXd in Austria. Furthermore, we analyzed the treatment landscape and the drop-out rate between subsequent lines of therapy as documented in the MBC-Registry of the Austrian Study Group of Medical Tumor Therapy (AGMT).

Patients and methods: The AGMT-MBC-Registry is a multicenter nationwide ongoing retrospective and prospective registry for MBC patients in Austria. In this analysis, patients with known HER2 status, available survival data, at least one treatment line and diagnosis of metastatic disease after 01/04/2013 (pertuzumab available) were included. Follow-up was censored at Dec 31, 2020, when tucatinib und T-DXd became available.

Results: As of 04/05/2022, 2,235 patients have been included in the registry. Out of 2,000 evaluable patients, 362 (18.1%) were HER2+, of which 171 (47.2%) fulfilled the inclusion criteria. Out of them 69.0% were hormone-receptor positive. In patients with metachronous metastatic disease (53.2%), 61.5% had received trastuzumab-based treatment for early breast cancer. Median overall survival (OS) for all patients was 50.1 months (95%CI 40.7-73.0), and 66.1 months (95%CI 50.1-NA) for those who received a pertuzumab combination as first-line treatment. The drop-out rate from 1st- to 5th-line was 26.9%, 24.4%, 28.3% and 36.7%, respectively. This yields an estimated percentage of patients that received at least 3, 4, and 5 treatment lines for advanced disease of 55.2%, 39.6% and 25.1%, respectively. In first line, 50.9% received trastuzumab plus pertuzumab and 11.1% T- DM1. In second line, 38.9% were treated with T-DM1 and 35.6% with trastuzumab-based chemotherapy or endocrine therapy. In third line, 11.3%, 17.0% and 49.1% received T-DM1, lapatinib-based and trastuzumab-based therapy, respectively. Outcomes according to treatment line are shown in Table 1.

Table 1: Outcome according to treatment line

Conclusion: Median overall survival of HER2+ MBC in Austria who received a pertuzumab combination treatment is comparable to the results reported in the registration CLEOPATRA trial. In this analysis, only ~40% of patients are estimated to receive more than three treatment lines and treatment benefit diminished from line to line. This underlines the importance of investigating and ultimately using the most effective compounds in early treatment lines in order to allow more patients to benefit from these life prolonging drugs.

Table 1: Outcome according to treatment line

Table 1: Outcome according to treatment line

Line	Median PFS* (95%-CI)	ORR*	CBR*
1 st (n=171)	14.60 (10.90-18.80)	50%	71%
2 nd (n=90)	7.70 (5.70-12.40)	31%	62%
3 rd (n=53)	5.80 (4.90-10.10)	22%	49%

INTRODUCTION AND OBJECTIVES

Palbociclib associated with hormone therapy (HT) has shown significant benefit in progression-free survival (PFS) and response rate versus HT alone in patients with HR+, HER2- MBC. The PALBOSPAIN study evaluates the efficacy and safety of palbociclib treatment under real-life conditions. The main objective of the study was to assess PFS, and secondary objectives were overall survival (OS), response rate, time to next line of treatment, percentage of dose reduction and safety.

MATERIAL AND METHODS

This is an observational, ambispective, multicenter, nation-wide study. Patients diagnosed with

HR+/HER2- MBC who had started first-line treatment with palbociclib between November 2017 and November 2019 were included. Patients treated within a clinical trial were excluded, as were those who had received any previous systemic treatment for advanced disease.

RESULTS

762 patients from 35 centers were included. 79% (n=600) were postmenopausal, 54.9% (n=418) had visceral disease, and 30.6% (n=233) had de-novo metastatic disease. Palbociclib was combined with an aromatase inhibitor in 69.6% of patients and fulvestrant in 30.2%. Four groups were established to assess efficacy (table 1): overall population; patients with de-novo metastatic disease (cohort A); patients relapsing >12 months after the end of adjuvant hormonal therapy (cohort B); and patients relapsing within 12 months after the end of adjuvant hormonal therapy (cohort C). Median PFS was 24 months (CI 95%; 25-27) overall and 28 (IC 95%; 23-39), 29 (IC 95% ;25-35) and 14 months (IC 95% ;11-17) for cohorts a, B and C, respectively. Median overall survival was 42 months (40-NA).

The most common side effects were neutropenia (71.3%, grade 3-4 in 52.5%, no episodes of febrile neutropenia), fatigue (38.6%), leucopenia (29.8%), anemia (28.9%), articular pain (19%), and thrombocytopenia (2,2%). 49% (n=385) of patients required dose reduction of palbociclib (one level in 27.6% and two levels in 21.4%).

CONCLUSION

In the first two years after its approval in Spain, palbociclib in first line of HR+/HER2- MBC in real-life conditions yielded PFS and safety results comparable to those of PALOMA 2 and PALOMA 3 clinical trials. OS results were poorer, although the population included in this retrospective study is heterogeneous and median survival values have not been reached in some subgroups.

Table 1. Efficacy results of palbociclib in real world

Background The combination of CDK4/6 inhibitors and endocrine therapy is the current standard first-line therapy for patients with HR+/HER2- metastatic breast cancer (mBC). Preliminary data suggest that CDK4/6 inhibitors not only induce tumor response by blocking CDK-dependent cell growth but that they can also alter the host immune function and stimulate tumor cell-directed immunity. However, clinical data are scarce, and no data exist about the impact of age and frailty, which are known to impact host immunity (immunosenescence). **Materials and methods** This prospective ongoing study is evaluating the efficacy and toxicity of the CDK4/6 inhibitor ribociclib and letrozole in older (≥ 70 years) patients with HR+/HER2- mBC (RIBOB, NCT03956654). In the associated blood biomarker sub-study, we investigate the impact of ribociclib and letrozole on the immune subset composition. Immune cell subsets were analyzed using flowcytometry (BD FACSVerserTM) of peripheral blood mononuclear cells isolated at baseline (before ribociclib administration) and after three months of ribociclib treatment. In total, six multicolor flow cytometry staining panels were set up to investigate the changes in the immune cell subsets (CD4+ T-cell subsets, CD8+ T-cell subsets, general immune cell subsets, T-regulatory cell subsets, T-cell activation status subsets, and myeloid-derived suppressor cells subsets). Frailty status was assessed at baseline using the G8 screening tool (range score: 0-17) as a proxy. The paired t-test and matched-pairs Wilcoxon signed-rank test are used to evaluate changes in immune subset composition between baseline and after three months. The unpaired t-test and Mann-Whitney U test are used to evaluate differences in immune subset composition between frail and fit patients. **Results** Immune cell subset distribution and evolution were available for 15 older patients (median age: 77 yrs.; IQR 74-83), 4 considered fit (G8-score >14), and 11 frail (G8-score ≤ 14). Firstly, we analyzed the difference in immune subset composition between baseline and three months for the whole cohort. There was a significant increase of naïve T-regulatory cells ($p=0.0012$) and a significant increase in CD8+ T-cell activation indicated by an upregulation of HLA-DR+ ($p=0.0055$) and CD38+ ($p=0.0203$). Secondly, the difference in immune subset composition between fit and frail persons was assessed showing a lower activation status of CD4+ and CD8+ T-cell subsets in frail persons at baseline, as assessed by several activation markers: CD4+PD1+ ($p=0.0051$), CD4+PD1+CD69+ ($p=0.0013$), CD8+PD1+ ($p=0.0073$), and CD8+PD1+CD69+ ($p=0.0339$). These significant differences between fit and frail disappeared after three months, largely because of increased T-cell activation in the frail subset. **Conclusion** Ribociclib plus letrozole treatment for three months results in an upregulation of the T-regulatory cells' naïve subset, suggesting an expansion of the T-cell repertoire, which is compatible with immune cell activation. Furthermore, the activation status of the CD8+ T-cells was upregulated. These observations confirm recent findings reported by Scirocchi F. et al. (Lancet, 2022). In addition, frail older patients show a lower baseline T-cell activation status compared to fit older patients but seem to have increased T-cell activation after treatment exposure. In the future, correlations with treatment response will be evaluated when follow-up data matures. Our data encourage

the further assessment of immune cell modulation in combination with CDK4/6 inhibitors in the treatment of patients with metastatic breast cancer.

Background: Limited information is available about real-world treatment patterns and survival among patients with metastatic breast cancer (mBC) with BRCA1/2 mutations. BRCA1/2 mutations, which are involved in the repair of DNA double-strand breaks, are rare. Since 2018, PARP inhibitors (olaparib and talazoparib) have been approved for the treatment of patients with germline BRCA-mutated HER2-negative locally advanced and/or mBC.

Methods: This retrospective chart review study included adults diagnosed with mBC with ≥ 1 oncogenic somatic BRCA1/2 mutation detected by tumor comprehensive genomic profiling who began a line of therapy on or after July 1, 2014, at 3 oncology centers in the American Association for Cancer Research (AACR) Project Genomics Evidence Neoplasia Information Exchange (GENIE) consortium. The index date was the first initiation of a new therapy for mBC in this period (which could be first-line [1L] or subsequent line of therapy). Data on all available lines of therapy post-index were collected. Treatments received in different lines of therapy for mBC and overall survival (OS) were described separately for patients with HR-positive/HER2-negative (HR+/HER2-) mBC, triple negative mBC (TNBC), and HER2-positive (HER2+) mBC. OS from the start of each line of therapy was assessed using Kaplan-Meier analysis.

Results: A total of 48 women with mBC met the inclusion criteria. The mean age at index was 58 years; 73% of women were White. Common sites of metastases included lymph nodes (56%), bone (52%), and lungs (31%). Somatic BRCA1 mutation was detected in 48% and BRCA2 mutation was detected in 54% of women. Assessment of germline BRCA mutations was conducted in 25 (52%) women; 2 (8%) of assessed women tested positive for germline BRCA mutations. 29 (60%) of women had HR+/HER2- mBC, 9 (19%) had TNBC, 9 (19%) had HER2+ mBC, and 1 woman had unknown HER2 status. Treatments received in different lines of therapy for mBC and OS from start of each line of therapy by HR and HER2 status are reported in Table 1. Common treatments for women with HR+/HER2- mBC included endocrine-based therapy, and chemotherapy. Women with TNBC were most often treated with chemotherapy. Women with HER2+ mBC most often received endocrine-based therapy in 1L; chemotherapy or HER2-targeted combination therapy in second-line (2L); and chemotherapy or HER2-targeted monotherapy in third-line (3L). Median OS from the start of 1L therapy was 37.5

months among women with HR+/HER2- disease; 20.0 months for women with TNBC; and 51.7 months for women with HER2+ disease.

Conclusions: These findings provide real-world insights about treatment patterns and survival among women with mBC and BRCA1/2 mutations. Further studies with larger sample sizes are needed to confirm these findings.

CDK4/6 inhibitors (CDK4/6i) is well established as the current standard of care for hormone positive (HR(+)) metastatic breast cancer (mBC), in combination with endocrine therapy. CDK4/6i extend a chemotherapy-free, progression free survival (PFS) that preserves quality of life in patients. The most common side effect of CDK4/6i is myelosuppression, with neutropenia the most prevalent adverse effect, especially for palbociclib and ribociclib. In PALOMA-2 and MONALEESA-2, where neutropenia was prevalent (any grade neutropenia 79.5%, grade 3/4 neutropenia 66.5% in PALOMA-2, and any grade neutropenia: 74.3%, grade 3/4 55.3% in MONALEESA-2), although febrile neutropenia seldom occurred (1.8%). Several studies have proposed different genetic factors predisposing to CDK4/6 inhibitor induced neutropenia, including Duffy antigen polymorphisms, ABCB1 and ERCC1 polymorphisms (ABCB1_rs1128503, ABCB1_rs1045642, ERCC1_rs11615, ERCC1_rs3212986), CDK6 polymorphisms, and others. Subgroup studies from the PALOMA trials have suggested that Asian patients receiving palbociclib have higher rates of neutropenia, although the exact

explanation is unknown.

We conducted a retrospective analysis of 102 Taiwanese patients who received palbociclib for HR(+) mBC at the Taipei Veterans General Hospital for the clinical features, incidence and time course of neutropenia were analyzed. Significant neutropenia incidence was observed (> 95% of all grade neutropenia, 74.5% grade 3/4 neutropenia). In addition, in our clinical cohort, one of the patients was a long term peritoneal dialysis patient newly diagnosed of HR(+) mBC and started on Palbociclib, initially 125mg, later decreased dosage to 100mg after neutropenia occurrence. By Liquid chromatography–mass spectrometry (LC–MS), we quantified the levels of palbociclib in her serum and peritoneal fluid at various time points, while on different dosage use. To our knowledge, this is the first pharmacokinetics analysis on a peritoneal dialysis patient receiving CDK4/6i. To investigate a possible genetic association for the high prevalence of neutropenia, we queried the Taiwan biobank, a nationwide biospecimen repository with 129,586 healthy individual genome wide DNA sequencing data deposited. We investigated the prevalence of the 4 SNPs previously reported to be related to neutropenia in the PALOMA studies. By comparing the Taiwan biobank data to SNP databases from different ethnicities, we observed interesting findings on ethnicity differences of SNP distribution and higher prevalence of neutropenia SNPs. Collectively, in this study we report real world data, biobank genome wide analysis, and a novel report of pharmacokinetic study in a peritoneal dialysis patient, providing novel insights into the real world use of palbociclib and CDKi.

Characteristics of the clinical cohort treated with palbociclib at TVGH

	number	percentage
Patients, n	102	
Median Age, y	56.9	
Female, %	100

Trophoblast cell surface antigen 2 (Trop-2) is overexpressed on many epithelial carcinomas, yet is expressed at much lower level on normal tissue. Elevated expression of TROP-2 is often associated with tumor invasion/aggression, progression, and metastasis. Efficacy of anti-TROP2 ADC have been demonstrated in clinical trials for both TNBC (triple negative breast cancer) and HR+/HER2- breast cancer. We have developed a novel Trop-2 ADC with strong bystander killing effect, BAT8008, which consists of an enzymatically cleavable linker and a topoisomerase I inhibitor as the payload, with DAR of 6. BAT8008 demonstrated potent in vitro cell growth inhibitory activity to Trop2-positive cells with IC50 values of < 1 nM. In an in vitro bystander killing assay, proliferation of Trop-2-negative cells was potently inhibited by

addition/transfer of culture medium of BAT8008-treated Trop-2-positive cells, but not that of BAT8008-treated Trop-2-negative cells, indicating the bystander killing effect of the released payload in the culture medium. Less than 0.1% of the payload was released from BAT8008 when incubated with human or monkey plasma for 7 days in 37°C, suggesting the stability of BAT8008 in blood circulation. Single dose of BAT8008 at 1 and 2.5 mg/kg could inhibit 73% and 81% tumor growth in the Trop-2-positive MDA-MB-468 and MX-1 xenograft mice model, respectively. BAT8008 also demonstrated superior tumor inhibition activity than a modified ADC using Daiichi's ADC technology or Trodelvy in a pancreatic BxPC-3 xenograft mice model. In addition, BAT8008 showed favorable pharmacokinetic and safety profiles in cynomolgus monkeys with the highest non-severely toxic dose (HNSTD) of at least 25 mg/kg when dosed once every two weeks for 3 times. Together these results indicate that BAT8008 could potentially provide a therapeutic benefit to treat TROP2-positive breast cancers in clinical trial.

Benefits Provided by Antibody Drug Conjugates in Overall Survival Outweighs those in Progression-free Survival for Metastatic Breast Cancer: A Class Effect

Presenting Author(s) and Co-Author(s):

I-Chun Chen, M.D., Ph.D., *Clinical Assistant Professor/ Attending physician - Department of Medical Oncology, National Taiwan University Cancer Center; Graduate Institute of Oncology, National Taiwan University*

Country: United States

Country: United States

Background:

In metastatic breast cancer (MBC), the benefits of progression-free survival (PFS) and overall survival (OS) is not always proportional. This dissociation is related to the multiple other treatment options such as chemotherapy after disease progression and these treatments would contribute to the long post-progression survival. A constant improvement of PFS that translates into OS has been reported in anti-HER2 antibody containing treatments. In the era of antibody drug conjugates (ADC), we aim to examine the relationship between the increments of PFS and OS in MBC.

Methods: We have used “metastatic breast cancer” and “antibody drug conjugate” to search for clinical trials that report both PFS and OS. Hazard ratios (HR) and median survival were analyzed. Increments in PFS (delta PFS) and increments in OS (delta OS) were compared between studies.

Results: A total of 5 trials were identified and summarized in table 1. The target of ADC is HER2 (N=4) or Trop2 (N=1). In DESTINY-Breast 03 trial, the control arm is another ADC (T-DM1). The control arms in all the other 4 trials are chemotherapy. The HR of PFS ranged from 0.28 to 0.65 and the HR of OS ranged from 0.48 to 0.68. The HR of PFS is smaller than HR of OS in all of the 5 trials. The median OS was not reached in 1 of the trials (DB-03) and was thus removed from the analysis for delta PFS and delta OS. In the comparison of delta PFS, the increments of median PFS fell between 2.9 and 4.8 months. The increments of median OS were between 5.4 and 6.6 months. All the delta OS are larger than the delta PFS in the four trials.**Conclusion:** Regardless of the antibody drug targets, ADC provides consistent improvements in median OS that surpasses the improvements in median PFS in metastatic breast cancer. The mechanism warrants further investigation.

Background: Cyclin-dependent kinase 7 (CDK7) plays a significant role in the cell cycle via activation of CDKs 1, 2, 4, and 6, and regulates transcription via phosphorylation of RNA polymerase II and the estrogen receptor. CDK7 overexpression has been reported in several tumor types, including hormone receptor-positive breast cancer (HR+ BC), triple-negative BC (TNBC), small-cell lung cancer, and epithelial ovarian cancer (EOC). In all major BC subtypes, CDK7 overexpression is associated with poor prognosis. XL102 is a potent, orally bioavailable, highly selective covalent CDK7 inhibitor. QUARTZ-101 is a first-in-human, open-label trial (NCT04726332) evaluating the safety, tolerability, and optimal dose of XL102 as a single agent and in combination regimens in patients with solid tumors, with expansion in subsequent tumor cohorts of advanced HR+ BC, TNBC, EOC, and metastatic castration-resistant prostate cancer

(mCRPC). Presented here are initial results from the dose-escalation stage for single-agent XL102 (cohort A). Methods: In the single-agent dose-escalation stage, patients received XL102 orally at multiple dose levels (DLs) using a modified interval 3+3 design: once daily at 20 mg (DL A1), 40 mg (DL A2), 80 mg (DL A3), and 120 mg (DL A4); and twice daily at 40 mg (DL A5). Eligible patients had confirmed inoperable, locally advanced, metastatic, or recurrent solid tumors and ECOG performance status (PS) of 0 or 1; any CNS disease must have been adequately treated and stable for ≥ 4 weeks. Patients with previous exposure to XL102 or other selective CDK7 inhibitors were excluded, as were patients with uncontrolled, significant intercurrent or recent illness. Prior use of CDK4/6 inhibitors was allowed. The primary objective of dose escalation was to determine the maximum tolerated dose (MTD) and/or recommended dose (RD) of XL102; secondary objectives included safety and tolerability, pharmacokinetics (PK), and drug-drug interactions. Results: At data cutoff of May 13, 2022, twenty patients with various advanced solid tumors (100% stage IV) were enrolled in dose-escalation stage cohort A and treated with single-agent XL102 (DL A1 n=3; A2 n=3; A3 n=7; A4 n=4; A5 n=3). Median age was 67 (range 43–84) years, 85% were female, and 75% had an ECOG PS of 1. Six patients remained on XL102 including 2 treated for >6 months with stable disease, both had received prior CDK4/6 inhibitors (HR+BC and liposarcoma). There were no dose-limiting toxicities at any DL, and MTD/RD has not been determined. Treatment-emergent adverse events (TEAEs) occurred in 95% of patients, with 4 (20%) grade 3 and 0 grade 4 TEAEs; there were no grade 5 treatment-related AEs. Treatment discontinuations were mostly due to radiographic progression (n=8); longest treatment duration was 6.7+ months and ongoing. XL102 demonstrated rapid absorption with a T_{max} of approximately 1–2 h and elimination half-life of 5–8 h. Target occupancy was exposure-dependent and prolonged relative to XL102 PK, consistent with covalent binding to CDK7. Conclusions: Single-agent XL102 was well tolerated at the DLs tested. Updated data, as well as PK results, will be presented. Expansion cohorts in HR+BC, TNBC, EOC, and mCRPC will be initiated once a recommended dose for the expansion-cohort stage is determined.

Background: Trastuzumab deruxtecan (T-DXd) improves outcomes in HER2-positive metastatic breast cancer (MBC) patients, including patients with previously treated stable brain metastases (BMs). Our objective was to examine the characteristics of HER2-positive MBC patients with BMs prior to T-DXd use. Methods: We performed a retrospective cross-sectional study of T-DXd prior authorization (PA) approvals by OncoHealth for HER2-positive MBC patients between 1/17/2020 – 6/21/2022. Using medical records and utilization management data, we assessed the characteristics of PA approvals for 145 patients requesting T-DXd in Stage 4, HER2-positive, female MBC with BMs. Results: Brain metastases were identified in 41/145 patients with HER2-positive MBC prior to T-DXd authorization. Among the 41 patients The mean age was within the range of 50-59 years, 72% were hormone receptor-positive, and all were HER2 positive. 19/41(46%) had symptomatic BMs, 5/41(12%) had asymptomatic BMs. Prior local therapies for the BMs included craniotomy in 19.5% and brain radiotherapy in 87.8% prior to T-DXd. The median number of prior MBC therapies was 2 (range: 0-8) and 73% (30/41) did not receive tucatinib-based therapy prior to T-DXd. Tucatinib-based therapy was the most

common subsequent line of therapy among T-DXd patients with further therapy (5/8). For available data (13 metastatic patients), 8 metastatic patients received tucatinib for an average of 149 days before receiving T-DXd for an average of 238 days, compared to 5 metastatic patients who received T-DXd for an average of 295 days before receiving tucatinib for 240 days, implying improved disease management in the T-DXd-to-tucatinib sequence. Conclusions: In the real world, patients with symptomatic, progressing BMs are more likely to receive T-DXd prior to tucatinib or potential tucatinib-based therapy, with longer duration of stability and treatment. Appropriate sequencing of available treatments with activity on brain metastases such as T-DXd and tucatinib-based therapy needs to be further studied.

Abstract Title: Discontinuation of HER2+ targeted therapy among cancer survivors with metastatic HER2+ breast cancer: A case report

Background: Anti-HER2 directed therapy (aHER2tx) has significantly improved survival outcomes in patients with HER2-positive metastatic breast cancer (HMBC). Current United States (US) and European oncology practice guidelines recommend continuing aHER2tx until intolerable side effects or disease progression. It is estimated that 10-15% of treated patients (pts) may achieve prolonged complete remission (CR). Currently, the optimal duration of aHER2tx in patients achieving a CR is unknown. A PubMed literature search identified 7 case reports outside of the US that describe pts who remain in CR after discontinuation of aHER2tx. To our knowledge, this is the first analysis of similar cases in the US.

Method: We identified pts with a diagnosis of HMBC who discontinued aHER2tx between January 1, 2010, to June 30, 2021, at a large integrated healthcare system in the US. Pts were included if they had discontinued aHER2tx for at least one year. Data collection included demographics, histology, confirmed sites of metastatic disease (mets), local and systemic treatment (tx) before and after aHER2tx discontinuation, documented radiographic response, and reason to discontinue aHER2tx. Data collection ended on June 30, 2022.

Results: Our case report identified 15 pts (mean age at diagnosis 53.0 ± 13.2) based on inclusion criteria. Baseline demographics and characteristics are listed in Table 1. Common clinical characteristics of the cohort include mean age at mets diagnosis is 56 years, postmenopausal status (67%), invasive ductal carcinoma (87%), ER-negative (60%), HER2-positive 3+ by IHC (93%), de-novo mets (60%), multiple sites (93%) and multi-organ mets (87%).

Among the cohort, 6 pts (40%) received prior adjuvant therapy, then later recurred, and of these only one had received HER2-based adjuvant tx. In all pts, first line therapy for mets included chemotherapy and aHER2tx, except one pt received endocrine therapy (ET) and aHER2tx. A CR was achieved in all but one pt (93%) with one line of aHER2tx consisting of trastuzumab (H) ± pertuzumab (P). One pt (7%) received local tx to all metastatic sites. In 13 pts, the median time to first radiologic complete response (RCR) after first line therapy for mets was 4 months (Interquartile (IQR) 3-15). Two cases were not included as we were unable to determine time to initial response after tx. All pts had confirmed RCR at the time of aHER2tx discontinuation. Median duration of aHER2tx was 8.3 years (IQR 4.8-9.5), including a median of 6.3 years (IQR 2.8-8.8) on maintenance aHER2tx. Twelve pts (80%) were off all therapy, and 3 pts (20%) continued ET for ER+ disease at the last follow-up (f/u). Patient preference (47%) was the most common reason for stopping aHER2tx. The median disease-free survival off aHER2tx was 4.8 years (IQR 3.1-6.2) and all pts were alive without evidence of disease at last f/u.

Conclusion: A subset of HMBC pts successfully discontinued aHER2tx without experiencing recurrence with a median of 4.8 years off therapy in a US cohort. In this case report, common clinical features like strong HER2 overexpression, no prior aHER2tx, and achieving RCR while on first line aHER2tx with H ± P are potential indicators for prolonged CR after discontinuing aHER2tx. Future studies with a comparator group are needed to fully understand the pt population who may safely stop aHER2tx after a CR.

Table 1: Baseline Demographics and Clinical Characteristics

Background: Palbociclib is a CDK4/6 inhibitor used to treat metastatic hormone receptor-positive (HR+) breast cancer (MBC) in combination with endocrine therapy. Tamoxifen is an effective treatment for HR+ MBC, with different toxicity profile compared with aromatase inhibitors (AI) and fulvestrant. Preclinical data demonstrated synergy for the combination of tamoxifen and palbociclib, being effective in a model of acquired tamoxifen resistance.

Methods: We conducted a non-randomized, open-label, single-arm, multicenter, phase II trial of palbociclib in combination with tamoxifen in patients with HR+/HER2 - advanced BC, with no prior therapy for MBC. Ovarian suppression was recommended for pre-menopausal women.

Primary objective was progression free survival, PFS. **Secondary objectives:** objective response rate, ORR (CR or PR) based on RECIST 1.1 or MDA Criteria (for patients with bone only disease); safety and tolerability (using CTCAE v4); clinical benefit rate, CBR (CR, PR or SD lasting min 24 weeks); 2-year overall survival. **Correlative objectives:** proteomic analysis of plasma exosomes to identify mechanisms of primary and secondary resistance to tamoxifen/palbociclib.

Results: Between 6/30/2016 and 7/02/2019, we enrolled 49 patients (47 evaluable): 23 pts with de-novo metastatic disease and 24 pts with recurrent BC (12 pts were on adjuvant treatment with AI at time of recurrence and 12 pts on surveillance). As of 6/30/2022 data cut-off, 2 pts were still on treatment. This is an updated analysis with median follow-up time of 24 months (range 8-51). Median age was 60 (range 39-82). The median PFS was 19.8 months with 95% CI (8-41) for pts with de-novo MBC and 7 months (2-12) for pts with recurrent BC. The ORR was 30% overall, 39% for pts with de novo MBC, 21% for pts with recurrent BC. CBR was 64% overall, 77% for pts with de novo MBC and 50% for pts with recurrent BC. CBR was 65% for white pts and 55% for AA pts. Best response per RECIST1.1: 14 pts (34%) had PR, 18 pts (44%) had SD, 9 pts (22%) had PD. All 6 pts with bone only disease had SD. The most common drug related grade ≥ 3 AE was neutropenia (51%), transient and manageable by dose modifications, no cases of febrile neutropenia. Four patients (8%) developed thromboembolic events (grades 2, 3, 4) and discontinued treatment. One patient died while on treatment from PD. More than 800 exosome proteins were detected in the samples analyzed so far. Exosomal protein networks in pretreatment samples predicted treatment response with 89% sensitivity and 95% specificity in unsupervised clustering. Data on correlative objectives will be presented in a separate abstract.

Conclusions:

The combination of palbociclib and tamoxifen showed tolerable, expected safety profile. This may be an alternative approach for selected patients in first line treatment of HR+ MBC, especially those who present with de-novo metastatic disease and are intolerant to AI; although this small study indicates a lower PFS.

Real-world efficacy of dual antiHER2 therapy in first line metastatic HER2-positive breast cancer and the possibility of prediction of long-term response

Presenting Author(s) and Co-Author(s):

Marija Križić, n/a, MD - University Hospital Centre Zagreb
Country: United States

Tajana Silovski, n/a, MD, PhD - University Hospital Centre Zagreb

Real-world efficacy of dual antiHER2 therapy in first line metastatic HER2-positive breast cancer and possible predictors of long-term treatment response

Križić Marija¹, Silovski Tajana¹, Popović Marina¹, Dedić Plavetić Natalija^{1,2}

¹ Department of Oncology, University Hospital Centre Zagreb

² School of Medicine, University of Zagreb

Background: Although huge progress has been made in treating HER2-positive metastatic breast cancer in the last decade, it remains an incurable disease. Dual anti-HER2 therapy with pertuzumab and trastuzumab combined with chemotherapy represents the standard first line treatment of metastatic HER2-positive breast cancer, in view of the impressive CLEOPATRA study results. The aim of this study was to analyze the efficacy of dual antiHER2 therapy in real-world clinical practice and determine the differences in the clinicopathological characteristics of the long-term responders in comparison with short-term responders.

Methods: Retrospective analysis of dual antiHER2 therapy efficacy was done and correlated to clinical and pathological characteristics of patients with different duration of response (DoR) in the first line metastatic HER2-positive breast cancer. The study was conducted at the UHC Zagreb, Croatia and approved by the Ethics Committee. Long-term responders were defined as patients with a duration of response (DoR) to dual antiHER2 therapy ≥ 36 months, and short-term responders were defined as patients with DoR ≤ 12 months. Progression-free survival was estimated using the Kaplan-Meier method. The reverse Kaplan-Meier method was used to estimate median follow-up duration. The non-parametric Chi-Square test (between categorical variables) and Mann-Whitney U-test (between continuous variables) were used to determine the differences between long-term and short-term responders groups. The significance level was set at $p < 0.05$.

Results: Altogether, 128 patients treated with dual antiHER2 therapy for HER2-positive metastatic breast cancer from October 2015 to May 2022 were included in the study. By data cut-off, 50.8 % (N=63) of patients had progressed or died. The median follow-up time was 36 months. The median PFS was 31 months for the total cohort (95% CI 22.6 -39.3). Overall, 29

patients among the long-term responders and 32 patients in the short-term responders group were identified. A comparison of clinical and pathological characteristics between the two groups is shown in Table 1. Even though patients in the group of long-term responders were younger (54.5 years vs. 56.5 years), had less visceral involvement (69 % vs. 81.3%), and were more often trastuzumab "naive" (75.9% vs. 68.7%), no statistically significant differences were found between the two groups.

Conclusion: In this real-life study, the median PFS was 31 months for the total cohort, even longer than in the referent CLEOPATRA trial, which confirms the effectiveness of dual antiHER2 therapy in a real-world setting. No possible clinical or pathological predictors of long-term response were identified, but larger studies may be able to distinguish patients' characteristics associated with long-term response.

Table 1: A comparison of clinical and pathological characteristics between the group of long-term responders and short-term responders

Total cohort N=128	Long-term responders (DoR \geq 36months)	Short-term responders (DoR \leq 12months)	P-VALUE
	N= 29/128	N= 32/128	
Median age (years)	54.5	56.5	0.1055
Visceral involvement	N=20 (69.0 %)	N=26 (81.3%)	0.7198
>3 metastatic sites at initial diagnosis	N= 9 (31.0%)	N=16 (50%)	1.0
Trastuzumab "naive"	N =22 (75.9 %)	N=22 (68.7%)	0.9373
HR positivity	N=21 (72.4%)	N= 23 (71.9%)	0.3775
Brain metastasis at baseline	N=3 (10.3 %)	N= 4 (12.5%)	0.8788
De novo metastatic disease	N=16 (55.2 %)	N= 12 (37.5%)	0.4242
Recurrent disease	N= 13 (44.8%)	N= 20 (62.5%)	0.4242
Adjuvant trastuzumab	N=7 (53.8%)	N=10 (50.0 %)	0.1566

Background: Trastuzumab deruxtecan (T-DXd) improves outcomes in HER2-positive, and recently in HER2-low (IHC 1+ or IHC 2+/ISH-) previously treated metastatic breast cancer (MBC) patients. OncoHealth is a digital health care company that leverages managed care-trained, board-certified oncologists and oncology pharmacists to review the appropriateness of prior authorization (PA) requests for cancer treatment regimens. Our objective was to examine the rate of off-label PA approvals for T-DXd in MBC.

Methods: We performed a retrospective cross-sectional study of T-DXd PA approvals by OncoHealth for MBC patients between 1/17/2020 – 6/21/2022. Using medical records and utilization management data, we assessed the prevalence of PA approvals for T-DXd in HER2-low and HER2-positive MBC patients according to PA support at the time of approval, whether on-label, off-label NCCN compendium supported, off-label acceptable scientific literature-only (LIT) supported, or approved by clinical justification if off-label/off-NCCN or LIT.

Results: We identified 156 patients with MBC with a PA approval for T-DXd. The median patient age range was 60-69 years, 85% had visceral disease, 28% had brain metastases, 93.6% had

HER2-positive MBC and remaining were HER2-low MBC. The median line of T-DXd therapy was 6 (range, 1-15) for HER2-low and 3 (range, 1-10) for HER2-positive MBC. All HER2-low T-DXd cases were supported by LIT and approved prior to NCCN guidelines incorporation in 6/21/2022. Among HER2-positive MBC patients, 25% (37/146) of PA approvals were off-label. Of these, 57% (21/37) were supported by NCCN, and the remaining 43% (16/37) were approved off-label/off-NCCN or LIT. The majority of the off-label/off-NCCN or LIT cases (10/16) were approved by clinical judgement based on 2nd line HER2-positive MBC abstract data from DESTINY-Breast03 presented at ESMO on 9/19/21.

Conclusions: All off-label PA approvals for T-DXd in HER2-low MBC occurred prior to NCCN's incorporation, expanding access. One quarter of all T-DXd approvals in HER2-positive MBC were off-label. Leveraging managed care, board-certified oncology clinicians with knowledge of the latest cancer therapies and use of additional coverage determination resources such as NCCN and acceptable scientific literature can help expedite and expand access to off-label anti-cancer drugs that may be beneficial for cancer patients.

T-DXd Authorization Approvals

Approval Support	HER2-positive (n=146)	HER2-low (n=10)
On-Label, n (%)	109 (75%)	NA
Off-Label, NCCN, n (%)	21 (14%)	NA
Off-Label, Acceptable Scientific Literature-Only, n (%)	0	10 (100%)
Off-Label/Off-NCCN or Literature, n (%)	16 (11%)	0

Background: Cyclin-dependent kinase 4/6 (CDK4/6) inhibitors in combination with hormonal treatment is the standard of care in the management of hormone receptor positive, human epidermal growth factor receptor-2 (Her2) negative metastatic breast cancer (MBC) patients. Data coming from the Middle east region is very rare and our patients' population were poorly represented in the CDK4/6 inhibitors landmark clinical trials, This retrospective study is to evaluate our real-world experience with this treatment combination in our patients' population. Patients and methods: A retrospective study was conducted in a middle eastern tertiary institution, where the clinical data of treatment outcome and toxicity were collected from the electronic medical records of 164 patients with hormone receptor positive, Her2 negative MBC who were managed with CDK4/6 inhibitors in combination with hormonal treatment, at and beyond first line of treatment. Progression free survival (PFS) was the study primary objective, Objective response rate (OR), Overall survival (OS), and toxicity profile were the secondary objectives. Results: From January 2017 to April 2021, 164 patients (5 men and 159 women) were managed with CDK4/6 inhibitors in combination with hormonal treatment for MBC, median age was 52 years (IQR: 45-59), 63% of patients were postmenopausal, 60% had luminal type B tumors, 22% had Her2 expression of 2+ by IHC, 55% had de Novo metastases, 67% had visceral metastases, 61% defined to have endocrine resistant disease (13% primary and 48% secondary resistance), CDK inhibitors (46% Palbociclib, 54% Ribociclib) were given as 1st, 2nd and beyond 2nd line in (48%, 28% and 24% respectively), at a median duration of follow up of 25.3 months (IQR: 13.8-33.9 months), the median PFS for the overall group was 14.2 months (CI 09.8-18.7), it was highest for 1st line treatment 19 months vs 15 and 5 months for the 2nd and beyond 2nd line treatment respectively. The median overall survival was 51.6 months (CI

35.8-67.5) for the whole group, 50.3 and 51.6 months for 1st and 2nd line vs 33.1 months for beyond 2nd line treatment. 5% of patients had achieved complete response, 37% partial response, and 24% had stable disease, with a clinical benefit rate of 74%. A body mass index (BMI) < 30, KI67 < 20%, luminal type A, de Novo metastases, Ribociclib as a CDKi, Aromatase inhibitor (AI) as the hormonal partner, and introducing the treatment combination in early treatment lines (1st and 2nd lines) were all associated with significantly higher PFS in univariate analysis. BMI and AI were the only factors associated with significantly higher PFS in multivariate analysis. Efficacy was consistent regardless of the menopausal status, type of endocrine resistance, and site of metastases. The most common toxicities were neutropenia, fatigue, vomiting, diarrhea, QTC prolongation and hepatic toxicity, the most common G3&4 toxicity were Neutropenia 56%, hepatic toxicity 5.4% and QTC prolongation in 4.3%. Treatment was permanently stopped because of toxicity in 12 patients (7.3%). Conclusion: Our real-life data came consistent with the pivotal clinical trials' results, encouraging and supporting the use of CDK 4/6 inhibitors in combination with hormonal treatment in our patient population with metastatic breast cancer, especially in the early treatment lines, deferring the start of more toxic therapies to a later stage.

Background: The MONALEESA (ML) studies showed significant PFS & OS benefits for 1L ribociclib (RIB) + endocrine therapy (ET) in patients (pts) with pre/peri & postmenopausal advanced breast cancer. The benefit of RIB beyond study treatment (tx) was also observed, with improvements in PFS2 & delays in time to 1st subsequent chemotherapy (CT). While there is currently no preferred tx for the next line post-progression on a CDK4/6 inhibitor (CDK4/6i), except alpelisib in pts with a PIK3CA mutation, guidelines encourage multiple lines of ET or ET-based therapies before switching to CT (except for visceral crisis). This pooled exploratory analysis of the ML studies examined outcomes of various tx strategies post progression on RIB + ET.

Methods: Data from pts receiving 1L therapy in ML-2, -3, & -7 (NSAI cohort only & excluding pts with early relapse \leq 12 mo after end of (neo)adjuvant ET] whose prognosis is closer to that of 2L pts) were pooled & pts receiving 1st subsequent therapies after progression were analyzed. Three groups of subsequent therapies were assessed: ET only, CT, & targeted therapy. Subsequent CT comprises CT +/- any other therapy; targeted therapy includes CDK4/6i, mTORi, PI3Ki, AKTi, etc, +/- ET. Subsequent CT & targeted therapy groups are mutually exclusive. Median duration of study tx, 1st subsequent therapy, & OS (from randomization to death) were analyzed by KM methods. Weighted Cox regressions were performed using inversed propensity scoring matching method (inverse probability tx weighting [IPTW]) to ensure compatible pt characteristics between tx arms. These are not randomized comparisons; only baseline characteristics were used for the estimation of propensity scores in the IPTW, imbalance of prognostic factors at progression may exist.

Results: Median follow-up time was 74 mo. 461 pts treated with RIB (81%) & 440 (86%) with PBO discontinued study tx & received a subsequent therapy. In the RIB arms, the most common 1st subsequent therapies were ET only (40%), CT (29%), combination with targeted therapy (28%), & other (4%); for the PBO arms, 34% received CT as a 1st subsequent therapy & 31% each received ET only or combination with targeted therapy (5% received other). In 14% & 20% of pts in the RIB & PBO arms, the 1st subsequent therapy was a CDK4/6i, of these 31% & 12% were RIB. In general, regardless of type of 1st subsequent therapy, the duration of both the study tx & the 1st subsequent therapy was longer for pts treated with RIB vs PBO (Table). In both RIB & PBO arms, pts who received subsequent CT had the shortest duration on study tx, whereas those who received subsequent targeted therapy combination had the longest. Among pts on 1L RIB + ET, after matching pre-randomization baseline characteristics, subsequent CDK4/6i use was associated with the longest mOS (84 [84-NE] mo), followed by ET only (60 [51-68] mo), then a non-CDK4/6i targeted therapy (52 [43-72] mo); post-progression CT was associated with the shortest mOS (37 [32-48] mo).

Conclusions: This large, pooled analysis of the ML studies shows that, in general, duration of any subsequent therapy was numerically longer post-1L RIB + ET vs PBO + ET, & subsequent CT was used less frequently for pts on RIB vs PBO. Both findings confirm that upfront tx with RIB does not worsen pt outcomes. This trend in enhancement of outcomes of subsequent therapies seen with 1L RIB suggests a post-tx effect that merits further exploration.

Table.

Median Duration, mo	All	CT	ET Only	Any Targeted Therapy	Any CDK4/6i	RIB
RIB + ET, n	461	132	184	128	65	20
1L RIB + ET	19.3	13.5	17.4	24.8	29.4	47.4
First subsequent therapy	10.5	7.6	8.3	15.0	22.8	34.2
PBO + ET, n	440	150	136	134	86	10
1L PBO + ET	14.7	9.2	14.9	22.5	28.0	29.9
First subsequent therapy	8.9	9.0	7.4	9.4	14.7	21.1

Background: Approximately 10% of patients with HER2-positive breast cancer have primary resistance to trastuzumab, leading to poor prognosis. Although several trials enrolled those hard-to-treat patients, there has been no strong evidence available for the clinical decision making. This multicenter phase 2 trial aimed to investigate the activity and safety of pyrotinib plus capecitabine only in those patients with trastuzumab-resistant, HER2-positive advanced breast cancer. Methods: Patients from 17 sites in China received pyrotinib 400 mg once a day and capecitabine 1000 mg/m² twice a day on days 1-14 every 21 days until disease progression or intolerable toxicity. Based on the definitions used in prior clinical trials, primary trastuzumab resistance was defined as progression during trastuzumab treatment (Group 1) or within 12 months after completing trastuzumab treatment in the (neo)adjuvant setting (trastuzumab should have been for ≥ 9 weeks, Group 2), or progression within 6 months after the initiation of trastuzumab treatment in the advanced setting (treatment should have been for ≥ 6 weeks, Group 3). The primary endpoint was progression-free survival (PFS). The study is registered with ClinicalTrials.gov, NCT04001621. Results: Between June 2019 and September

2021, a total of 100 patients enrolled; 35 (35.0%) patients had hormone receptor (HR)-positive disease, and 65 (65.0%) had HR-negative disease. Prior use of trastuzumab, pertuzumab and antibody-drug conjugate was reported in 100%, 21.0% and 2.0% of patients, respectively. By the data cutoff on July 10, 2022, the median follow-up duration was 23.4 months (95%CI, 20.5-25.6) with 66 PFS events documented. Median PFS was 11.8 months (95%CI, 8.4-15.1) in the overall population. Patients in Group 2 (n=49) had the longest median PFS of 17.8 months (95%CI, 13.8-not reached), which was significantly different from either 8.2 months (95%CI, 3.0-20.7; p = 0.001) in Group 1 (n=21) or 5.6 months (95%CI, 4.1-6.9; p < 0.001) in Group 3 (n=30). No significant difference in median PFS was observed in subgroup by HR status (HR-positive: 9.7 months [95%CI, 6.4-18.4]; HR-negative: 12.3 months [95%CI, 8.2-17.8]; p = 0.764). Objective response rate was 70.0% (95%CI, 60.0%-78.8%). Overall survival data was immature. The most common grade ≥3 treatment-emergent adverse events included diarrhea (24.0%), palmar-plantar erythrodysesthesia syndrome (9.0%), neutrophil count decreased (7.0%), hypokalemia (5.0%), and decreased appetite (5.0%). No treatment-related deaths occurred. Conclusions: Pyrotinib plus capecitabine resulted in a promising PFS that crossed the pre-specified efficacy boundary in patients with HER2-positive advanced breast cancer who met the traditional definition of primary trastuzumab resistance. Patients in Group 2 had a significant longer PFS than those in either Group 1 or Group 3, highlighting the need to re-define primary trastuzumab resistance and to clarify efficacy of new anti-HER2 biologicals for each subpopulation.

Background: HER2 positive (HER2+) breast cancers harboring downstream MAPK or PI3K pathway alterations manifest persistent downstream signaling on anti-HER2 inhibitors with metastatic patients having worse outcomes on first line trastuzumab and pertuzumab (HP) therapy. However, HER2 antibody-drug conjugates (ADCs) are not as dependent upon potent signal transduction inhibition to exert their antitumor effects. To further investigate, we sought to determine whether MAPK and/or PI3K alterations affect the biologic or clinical outcomes of patients and models receiving HER2 ADCs. Methods: We performed prospective genomic sequencing using MSK-IMPACT on patients with advanced HER2+ breast cancer who received trastuzumab emtansine (T-DM1) in the metastatic setting between March 2013 and July 2021. We collected detailed information on clinical outcomes and correlates through our institutional IRB-approved retrieval process. HER2/ER/PR status at the time of metastatic recurrence were defined as per ASCO/CAP guidelines. Cox proportional hazard models were used to determine the association between MAPK and PI3K pathways alterations and progression-free survival (PFS) on T-DM1. Common mutations associated with outcomes were modeled in HER2+ breast cancer cell lines using short hairpin RNAs and CRISPR/Cas9, and the sensitivity to HER2 ADC was evaluated via cell proliferation and xenograft assays. Results: We identified 185 HER2+ breast cancer patients treated with T-DM1 at any line (median: 5) whose primary (N=65) or metastatic (N=120) tumor samples were sequenced. Median age was 55 (range: 20-87). The majority of the patients received T-DM1 in 2nd or 3rd line (52%) and received prior trastuzumab or HER2 TKI in metastatic setting (96%). 74/185 (40%) had de novo metastatic breast cancer and 119/185 (64%) had ER/PR+ /HER2+ disease. Pathogenic activating alterations involving the MAPK pathway were observed in 14% of patients with the most frequent alterations being ERBB2 activating mutations (42%) and NF1 loss (34%). PI3K pathway alterations were identified in 42% of the patients, the majority being activating mutations of PIK3CA (87%). MAPK alterations were significantly enriched in the metastatic tumors compared to the treatment-naïve primaries (20% vs 3%, $p=0.001$), while PI3K alterations were not (44% vs 40%, $p=0.6$). To reduce the possible confounding resistance mechanisms induced by prior treatment, we restricted the survival analyses to patients who received T-DM1 up to 3rd line of therapy (N=100). On multivariable analysis adjusted for ER/PR status (positive vs negative), stage at the presentation of metastatic disease (de novo metastatic vs recurrence), treatment line and type of sequenced sample (primary vs metastatic), patients with MAPK (N=14) and PI3K (N= 38) alterations had similar PFS compared to wild type (HR 1.20, 95%CI 0.62-2.30, $p=0.6$ and HR 1.23, 95%CI 0.77-1.95, $p=0.4$, respectively). Similar results were found in the combined analysis including alterations in either pathway (N=48, HR 1.28, 95%CI 0.81-2.04, $p=0.3$). To verify the antiproliferative effect of HER2 ADCs on breast cancer cells with MAPK pathway activation, we depleted NF1 in a panel of HER2+ breast cancer cell lines. Consistently, MAPK-altered cell lines were sensitive to FDA-approved HER2 ADCs including trastuzumab deruxtecan (T-DXd). Conclusions: In contrast to H/P therapy, T-DM1 therapy was equally effective in tumors with downstream PI3K or MAPK alterations and wild type tumors. Expanded analysis on a larger cohort, including a subgroup of patients treated with novel HER2 ADCs such as T-DXd will be presented. The characterization of PI3K and MAPK pathways status in metastatic HER2+ breast cancer may inform prioritization of treatment options.

Background: The role of adjuvant radiotherapy (RT) following breast conserving surgery (BCS) for women with ductal carcinoma in situ (DCIS) remains controversial. Although there is Level 1 evidence supporting the use of RT in reducing the risk of local recurrence, prognostic and predictive tools are needed to better stratify individual risks and benefits of RT. The DCISionRT® Test (PreludeDx, Laguna Hills, CA) is a 7-gene predictive biosignature that uses tumor biology in conjunction with clinicopathologic factors. The test provides a validated score (DS) for women receiving BCS that assesses 10-year risk of DCIS recurrence and development of invasive breast cancer with and without adjuvant RT. We established a registry to evaluate the decision impact of the 7-gene predictive biosignature on DCIS treatment recommendations.

Methods: The PREDICT study is a prospective, multi-institutional registry for patients who received DCISionRT testing as part of their routine care. The registry includes females 26 and older who are diagnosed with DCIS and are candidates for BCS and eligible for RT or systemic therapy. Treating physicians completed treatment recommendation forms before and after receiving test reports to capture surgical, radiation and hormonal treatment (HT) recommendations and patient preferences. The primary endpoint is to identify the proportion of

patients where testing led to a change in RT recommendation. Additional analyses include changes in recommendations in patient subgroups based on clinicopathologic factors or clinician specialty.

Results: Analysis was performed in 2,308 patients treated at 63 clinical sites. The median age of patients was 62 years, 18% were 50 or younger, nuclear grade was high in 33%, and tumor size was 2.5 cm or greater in 11%. Test results were DS Low Risk (DS ≤ 3) for 63% of women and 37% were DS Elevated Risk (DS > 3). Overall, RT recommendation (yes/no) was changed for 38% of women after the 7-gene biosignature testing and HT recommendation was changed for 11%. There was a net decrease in RT recommendation from 71% pre-assay to 53% post-assay (p< 0.001), where RT recommendations decreased 53% in DS Low Risk patients but increased 25% in DS Elevated Risk patients. Surgeons were more likely to change their RT recommendation (47%) than radiation oncologists (35%). When test results indicated DS Elevated Risk, both surgeons (79%) and radiation oncologists (88%) were likely to recommend RT, but when the results were DS Low risk, surgeons were more likely than radiation oncologists to recommend omitting RT (82% vs. 60%, respectively). Compared to traditional clinicopathologic features, the factor most strongly associated with RT recommendation was the biosignature result with other factors of importance being patient preference, tumor size and grade.

Conclusions: This analysis demonstrates significant changes in recommendations to add or omit RT based on the 7-gene predictive biosignature in 2,308 patients. The integration of DCISionRT into clinical decision processes has substantial impact on recommendations aimed at optimal management to prevent over- or under-treatment.

TABLE 1. Impact of the 7-gene predictive biosignature on adjuvant radiation recommended by clinicopathologic features.

Clinical Factor	N	RT Recommended			Pre- to post-test change in RT recommended		Total change in RT recommended		
		Pre-test (%)	Post-test (%)	Net change (%)	Yes, % to no (%)	No, % to yes (%)	Overall change (%)	Overall change (95% CI)	p-Value
Overall	2308	71	53	-18	40	34	38	36, 40	<0.001

Background: Epithelial-mesenchymal transition (EMT) is a well-known multistep process of cancer cell invasion and metastasis, as well as treatment resistance. Our group has been reporting the predictive role of scores generated using Gene Set Variation Analysis (GSVA) of Hallmark pathways in breast cancer. In this study, we hypothesized that EMT score high breast cancer is aggressive and is associated with poor clinical outcome. Material and Methods: The clinicopathological data and transcriptome data of breast cancer patients from three independent large publicly available databases, The Cancer Genome Atlas (TCGA, n = 1077), The Molecular Taxonomy of Breast Cancer International Consortium (METABRIC, n = 1904), and GSE96058 (n=3069) were utilized. Survival analyses; Overall survival (OS), Disease-specific survival (DSS) and Disease-free survival (DFS) were performed by comparing the high and low score groups. Tumor immune microenvironment was analyzed utilizing the values reported by Thorsson et al. Also, single sample Gene Set Enrichment analysis (ssGSEA) was performed between EMT high and low expression groups utilizing single cell sequence cohorts. Results: EMT score was generated by Gene Set Variation Analysis of a Hallmark gene set and we divided each cohort into EMT score high and low groups by utilizing median as the cutoff. To our surprise, EMT score of the primary tumor was not associated with metastasis (N and M categories of cancer staging), Nottingham histological grade, nor MKI67 expression levels consistently in TCGA, METABRIC, and GSE96058. EMT score high tumors were not associated with worse DFS, DSS, OS in TCGA and METABRIC and OS in GSE96058.

Analyses using xCell demonstrated that EMT score high tumors were associated with high infiltration of stromal cells such as adipocyte ($p < 0.001$, $p < 0.001$ and $p < 0.001$, respectively) and fibroblasts ($p < 0.001$, $p < 0.001$ and $p < 0.001$, respectively) in all three cohorts, TCGA, METABRIC, and GSE96058. Also, myeloid cells such as macrophages ($p < 0.001$, $p < 0.001$ and $p < 0.001$, respectively) and dendritic cells ($p < 0.001$, $p < 0.001$ and $p < 0.001$, respectively) were highly infiltrated with EMT score high tumors. Result of ssGSEA of single cell sequence cohorts revealed that cancer associated fibroblasts demonstrated highest EMT scores compared with the other cell types such as cancer cells, T-cells, B-cells, or myeloid cells. In other words, EMT score of a bulk tumor may reflect the signature from fibroblasts rather than cancer cells. Conclusion: We found that cancer associated fibroblasts rather than cancer cells are the major source of the transcriptomic signatures of EMT in the bulk tumor, which cautions us to be careful with the interpretation of the results of EMT signature from a bulk tumor.

Clinical decisions on precision and immuno-oncology therapies are based on predictive biomarkers commonly obtained from a single metastatic biopsy or archived primary tumor tissue. Circulating genomic biomarkers offer a minimally invasive approach to monitor intra-patient tumor heterogeneity and detect in real-time the clinically-relevant evolving clonal architecture. Although currently underutilized, we hypothesize that single-cell DNA next generation sequencing (scNGS) of circulating tumor cells (CTC) is a particularly well-suited method to complement biomarker information obtained from tissue and cell-free circulating tumor DNA (ctDNA). In this study we analyzed 113 individual CTC, 21 ctDNA, and 15 white blood cells (WBC) samples, from 15 CTC-positive lobular breast cancer patients, four of whom had CTC available at both metastatic baseline and after progression on a variety of therapies chosen at their physician's discretion. Clinical NGS data from 15 tumor tissue biopsies obtained using a ~1700-gene DNA panel and whole transcriptome sequencing were available for comparison. CTC were enriched with the CellSearch® system and isolated as single cells with the DEPArray™ system. Whole genome amplified CTC and WBC, as well as ctDNA underwent scNGS with the OncoPrint Comprehensive Assay covering ~500 genes and 1.1Mb of genomic space to detect mutations, copy number alterations, tumor mutation burden (TMB) and microsatellite instability (MSI). 99.1% of single cells and 95.2% of ctDNA samples were informative, with a mean sequencing depth of 664x. Using our previously developed, CTC-based precision medicine reporting platform, MI-CTCSeq, CTC in 9 of 15 patients (60%) had mutations that were actionable by FDA-approved targeted therapies including in the oncogenes PIK3CA and FGFR2 and HER2. 3 of these 9 patients (33%) harbored actionable alterations not shared between all 3 analyte types (tissue, CTC and ctDNA). These included 3 actionable mutations found in CTC and ctDNA only, 1 in tissue and ctDNA only, and 1 in ctDNA only. However, 2 of those ctDNA mutations were identified near the limit of detection and with a priori knowledge of their presence from tissue or CTC. Further, 1 patient with plentiful CTC had no detectable ctDNA and one patient's tissue biopsy was inadequate for sequencing while both liquid biopsy analytes were abundant. 13 patients (87%) displayed intra-patient, inter-CTC genomic heterogeneity of putative driver mutations. 1 of 4 (25%) patients with CTC available in >1 timepoint displayed fluctuations in their CTC subclonal makeup between timepoints. Data from this patient's 2 tissue biopsies, 3 ctDNA samples, and 27 individual CTC over 4 timepoints combined to reveal in unprecedented detail inter-metastatic lesion and inter-CTC heterogeneity and tumor evolution in response to endocrine and immunotherapy selective pressures. ScNGS of CTC helped provide an additional level of detail not appreciated by sequencing of the other two analyte types. In another patient, CTC were composed of 2 subclones which were indistinguishable by ctDNA, 1 of which appears to have not been sampled by the tissue biopsy. Using a novel method, we enabled detection of single-cell CTC TMB and MSI. CTC TMB scores (dichotomized as above/below 10 mutations/Mb) were 100% concordant with those measured in the corresponding tissue biopsies. Further, in a novel observation, we detected intra patient, inter-CTC heterogeneity of TMB and MSI, which has potential implications for immunotherapy response and development of resistance. Taken together, these data support the non-invasive biomarker interrogation and monitoring by liquid biopsy that incorporates CTC scNGS and complements tissue in informing precision and immuno-oncology approaches. This may have important implications for appropriate treatment selection and identification of therapeutic resistance mechanisms.

Predictors of long-term durable response in de novo HER2 positive metastatic breast cancer and the real world treatment experience at two institutions

Presenting Author(s) and Co-Author(s):

Purpose

Modern HER2-directed therapies enable some patients with de novo HER2+ metastatic breast cancer (MBC) to achieve long-term, durable responses (DR), which can be defined as no progression of disease since initial diagnosis. Clinical and pathologic factors that predict DR continue to be elucidated. Expert opinion dictates indefinite HER2-directed therapies for patients who achieve DRs, but real-world examples of this practice are lacking in the literature.

Methods

This is a retrospective study of all patients with de novo HER2+ MBC at two major academic institutions who received at least one dose of trastuzumab between 2012-2019. DR is defined as absence of progression/death at any point after diagnosis. Controls are patients with evidence of progression/death. Age, ER/PR status, sites of metastasis, surgical resection of primary tumor and initial treatment were analyzed as predictors of DR using an unpaired T test, with $p < 0.05$ chosen as threshold for significance. For patients with DR, time to complete (CR) and partial response (PR) according to RECIST 1.1 were recorded, as was the duration and treatment patterns surrounding trastuzumab and pertuzumab. Patients were defined as having cardiotoxicity if they experienced a decline in cardiac ejection fraction at any point while on trastuzumab therapy leading to treatment delays or discontinuation.

Results

96 patients with de novo HER2+ MBC, 28 with DR and 68 with progression, were identified. The average follow up of patients with DR was 90 months (range 27-224), compared to 58 months (range 1-208) in controls. The entire cohort of 96 patients had a median PFS of 23.5 months and a median OS of 88 months. Among the 28 patients with DR, 2 achieved stable disease, 10 patients had documented PR at 4 months on average (range 2-6 months), and 26 patients had CR at 7.7 months on average (range 2-19 months). Among patients with DR, nine patients have been receiving trastuzumab for over ten years with no evidence of disease and one patient opted to discontinue trastuzumab. 75% of patients with DR had a single metastatic site, compared with 47% of patients with progression (OR 3.7, $p=0.01$). 64% of patients with DR received a regimen containing trastuzumab, pertuzumab, and a taxane, while 28% of patients who progressed did (OR 4.5, $p < 0.001$). 57% of patients with DR underwent surgical removal of breast primary, compared with 24% of patients who progressed (OR 4.3, $p=0.002$.) Age, and ER/PR status did not predict DR. (Table 1) Six patients (6.3%) developed reduced ejection

fraction requiring treatment interruption or cessation, five in the group who progressed, one in the DR group.

Conclusion

Nearly a third of patients with de novo HER2+ MBC achieved DR. Factors that correlate with DR include single metastatic site, initial trastuzumab, pertuzumab and taxane therapy, and surgical resection of primary tumor. This suggests that in selected patients, a more aggressive up front approach including surgical resection, and agents such as carboplatin, and trastuzumab deruxtecan deserves further study. Among patients with DR, indefinite trastuzumab administration is the norm with minimal cardiotoxicity but the impact of this on quality of life and financial toxicity are not well described.

Background: Over the last years, the management of patients with node positive early breast cancer has gone through important innovations. On the medical side, new targeted therapies such as olaparib and abemaciclib have been introduced, with promising results on the invasive disease-free survival. Moreover, sparing axillary lymph node dissection has proven to be noninferior in terms of overall survival. However, no tools are currently available to predict lymph node involvement before definitive surgical evaluation. The aim of the study was to analyze clinical and pathological characteristics of patients with node positive early breast cancer to explore potential risk profiles associated with a ≥ 3 nodal involvement. Methods: The study retrospectively analyzed 335 node-positive breast cancer patients treated at the Breast Unit of the CRO Aviano National Cancer Institute, between 2017 and 2021. Data regarding primary tumor biological features, lymph node involvement and surgical approach were collected. Associations between clinico-pathological characteristics and ≥ 3 lymph node involvement were tested through stepwise logistic regression and the gradient boosting machine learning algorithm (GBM). Results: Among the 335 analyzed patients, 87.0% had a primary tumor < 5 cm, with a single positive lymph node in 73.3% of cases. Hormone receptors were mainly positive (respectively 93.5% and 83.4% for estrogen and progesterone receptors). Tumor grade was most frequently well differentiated (Grade 1 in 60.7%), with a Ki67 $< 20\%$ (59.5%). After multivariable logistic regression, a tumor size ≥ 3 cm (OR 3.24, CI95% 1.47-7.17, $p = 0.004$), the presence of massive lymphovascular stromal invasion (OR 2.50, CI95% 1.02-6.14, $p = 0.045$) and 2 or more positive sentinel lymph nodes at surgical evaluation (OR 6.08, CI95% 3.34-11.05, $p < 0.001$) were associated with a higher risk of identifying ≥ 3 positive lymph nodes after subsequent axillary dissection. Similar results were observed in the luminal-like cohort. A GBM machine learning model was then developed with a 0.77 Area Under the Curve. Features with the highest relative importance (RI) were single sentinel node involvement (RI 16.1873), followed by tumor size ≥ 3 cm (RI 10.2024), ≥ 2 positive sentinel lymph nodes (RI 8.5050) and lymphovascular stromal invasion (4.0217). Consistently, number of positive sentinel lymph nodes and tumor size were the predominant features in all top 20 GBM models. Conclusions: The present study explored the definition of risk profiles linked to 3 or more positive lymph nodes based on clinical and pathological features. It, moreover, tested the

feasibility of developing machine learning classifiers to support future clinical decision-making. Due to the growing complexity of the adjuvant setting, finding a balance between minimally invasive surgical and staging approaches and risk definition for treatment personalization will become increasingly critical.

Background

Around 30-40% of early breast cancer (EBC) patients relapse after curative surgery and systemic treatment. However, it is very difficult to identify the patients with high risks of relapse. Recently, circulating tumor DNA (ctDNA) is shown to be a sensitive method to evaluate the minimal residual disease (MRD) of solid tumors after surgery. Here, we explored the prognostic value of ctDNA in a large real-world study of EBC patients.

Method

346 invasive EBC patients from three hospitals in China were enrolled in this study. All patients received radical surgery and were followed up for a median of 13.1 months from surgery. 17 patients developed local and/or distant relapse during the follow-up. Primary breast cancer samples (n=346) and plasma samples (n=1059) were subjected to deep targeted sequencing using a large next-generation sequencing panel that covers 1,021 cancer-related genes.

Results

Among the 346 patients, 153 patients had detectable ctDNA in at least one of the plasma samples and 15 of them relapsed. Only two of the 193 patients with consistent negative ctDNA

relapsed, demonstrating the value of positive ctDNA in predicting RFS ($p < 0.0001$; HR=13.09; 95%CI: 2.98-57.45).

Of 334 patients who had postoperative plasma samples tested, 108 patients with positive ctDNA in at least one of the postoperative plasma samples had 11 relapse during follow-up, which had a significantly worse RFS than the 226 patients with negative postoperative ctDNA and 4 relapse ($p < 0.0005$; HR=5.98; 95%CI: 1.90-18.79).

In this study, 176 patients received neoadjuvant therapy (NAT) and 59 of them had twice or more ctDNA tests before surgery. Among them, 12 patients with negative ctDNA before NAT remained negative before surgery and had no relapse, 36 patients with positive ctDNA before NAT turned negative before surgery and had 4 relapse, while 11 patients kept positive ctDNA before surgery and had 2 relapse.

165 patients received NAT and had postoperative ctDNA tests. Of the 31 patients achieved pCR, 21 patients with negative postoperative ctDNA did not relapse and 10 patients with positive postoperative ctDNA had 1 relapse. Of the 134 non-pCR patients, 90 patients with negative postoperative ctDNA had 4 (4.4%) relapse, which is significantly better than the 44 patients with positive postoperative ctDNA and 8 (18.2%) relapse ($p < 0.05$), indicating the feasibility to further distinguish the real high-risk patients among the patients with non-pCR after NAT.

Among the 17 patients with relapse or metastasis, 11 patients had positive ctDNA after surgery before relapse and the median lead time was 74 days and a maximum of 526 days. Four patients had negative ctDNA before relapse and two patients did not test after surgery.

Conclusions

Circulating tumor DNA is a sensitive assay to predict the relapse in early breast cancer, especially in the patients who received NAT and did not achieve pCR. This may provide a window of opportunity to personalize the escalated adjuvant treatment in patients with high relapse risk.

Pre-operative endocrine therapy use in post-menopausal women with localized, ER-positive breast cancer affords comparable rates of response and breast preservation, but lower toxicity relative to chemotherapy. Pre-operative endocrine therapy exerts selective pressure on cancer cells and promote evolution and/or enrichment of pathogenic alternations such as ESR1 mutations and other cellular adaptations. How such endocrine therapy-induced adaptations alter response to radiation therapy remains poorly defined. In this study, we show that diverse mechanisms that confer endocrine therapy resistance also drive radiation resistance by reprogramming of DNA repair pathways. We also show that BRD4, a member of bromodomain and extraterminal domain (BET) family of proteins, mediates such DNA repair reprogramming. BRD4 also plays a key role in transcriptional reprogramming in ER-positive breast cancer cells that confers endocrine therapy resistance. Thus, OTX015, a BET inhibitor with a favorable safety profile in early stage clinical trials, reverses both endocrine therapy resistance and radiation resistance in ER-positive breast cancer cells and tumors. Our findings are also consistent with reports that tamoxifen-resistant breast cancer cells are resistant to DNA damaging chemotherapeutic agents such as adriamycin and cisplatin. Overall, our findings suggest that endocrine therapy resistance in the pre-operative setting serves as a biomarker for reduced response to adjuvant radiation therapy, and that pharmacological BET inhibition reverses radiation resistance in such patients. The increasing use of “window of opportunity” studies to assess response to endocrine therapy in the pre-operative setting will further facilitate personalization of radiation treatments in these patients based on their response to endocrine therapy. Thus, we provides a therapeutic rationale for personalization of radiation treatments in breast cancer patients based on their response to endocrine therapy. We also provide a molecularly targeted approach for reversing radiation resistance in such patients. Thus, our study provides a framework for advancing Precision Radiation Oncology in breast cancer patients.

Purpose: We previously demonstrated that high levels of circulating methylated DNA are associated with subsequent disease progression in women with metastatic breast cancer (MBC). In this study, we validated the clinical utility of a Liquid Biopsy-Breast Cancer Methylation (LBx-BCM) prototype assay using the GeneXpert® cartridge system for early assessment of disease progression in MBC. Study Design: The 9-marker, LBx-BCM prototype assay was evaluated in TBCRC-005, a prospective biomarker study, using plasma collected at baseline, week 4 and week 8 from 144 MBC patients. Results: At week 4 MBC patients with high cumulative methylation (CM) had a significantly shorter median PFS (2.88 months v 6.60 months, $p = 0.001$) and OS (14.52 months v 22.44 months, $p = 0.005$) compared to those with low CM. In a multivariable model, high versus low CM was also associated with shorter PFS (HR = 1.90, 95%CI 1.20-3.01; $p = 0.006$). Change in CM from baseline to week 4 (OR = 4.60, 95%CI 1.77, 11.93; $p = 0.002$) and high levels of CM at week 4 (OR = 2.78, 95%CI 1.29, 5.99; $p = 0.009$) were associated with progressive disease at the time of first restaging. A robust risk model (AUC = 0.733) based on week 4 circulating CM levels was developed to predict disease progression as early as 3 months after initiating a new treatment. Conclusion: The easy to perform and automated LBx-BCM prototype assay is a promising clinical tool for detecting disease progression early after initiating treatment in women with MBC. Further validation in larger clinical datasets is needed.

Background: MRI predictive modeling is used in the I-SPY 2 neoadjuvant clinical trial as a key component of the pre-RCB (Predicted Residual Cancer Burden) clinical workflow for re-directing “good responders” to skip AC (anthracycline) and proceed to surgery early. The current MRI model is hormone receptor (HR)- and human epidermal growth factor receptor 2 (HER2)-specific, and was trained retrospectively using data from 990 patients in I-SPY 2. Recently, new breast cancer subtypes based on gene expression and pathologic response were proposed by Wolf et al [1]. Their study predicted that drug allocation by the new response-predictive subtype (RPS) would lead to a higher pathologic complete response (pCR) rate than allocation based on HR/HER2 subtypes. In this project, we evaluated the MRI model optimized by RPS and compared it with the HR/HER2 optimized model.

Methods: A total of 990 patients enrolled in I-SPY 2 and randomized to one of 9 drug arms or control were evaluated in this analysis. Functional tumor volume (FTV) was calculated from dynamic-contrast enhanced MRI [2] performed pretreatment (T0), after 3 weeks of treatment (T1), and between sequential drug regimens (T2). pCR was assessed at surgery after treatment was completed. HR/HER2 subtype was defined by HR and HER2 +/-, which resulted in four subtypes: HR+/HER2-, HR+/HER2+, HR-/HER2+, and HR-/HER2- (triple negative). RPS subtype was defined by immune, DNA repair deficiency (DRD), HER2, and BluePrint (BP) subtype (Agendia) biomarkers to define five subtypes: HER2-/Immune-/DRD-, HER2-/Immune+, HER2-/Immune-/DRD+, HER2+/BP-HER2_or_Basal, and HER2+/BP-Luminal. A logistic regression model using at least 1 FTV variable (value at T0, percent change at T1 or T2) was analyzed for predicting pCR. AUC (area under the receiver operating characteristic curve) was used to identify the optimal logistic regression model (highest AUC) in each biomarker-defined subset. For multi-predictor analysis, 10-fold cross validation was used.

Results: 854 patients (301 pCRs, 35%) with FTV evaluations at T0, T1, and T2, HR/HER2 and RPS subtypes, and pCR outcomes were included. Numbers of patients and pCR rates in individual subtypes are listed in Table 1. Of FTV variables, percent change at T2 was selected for inclusion in almost all subtype specific optimal models except HR+/HER2+. FTV at T0 (pretreatment tumor volume) was included in triple negative, HER2-/Immune+, and HER2+/BP-HER2_or_Basal models. Using the current HR/HER2-specific model, the highest AUC (0.74) was found in triple negatives and the lowest AUC (0.68) was in HR+/HER2+. Using the proposed RPS-specific model, the highest AUC (0.84) was found in HER2-/Immune-/DRD+ and the lowest AUC (0.59) was found in HER2+/BP-Luminal cohorts. Table 1 shows AUCs estimated using predictions generated by HR/HER2- versus RPS-specific models, in the full cohort and in individual HR/HER2 sub-cohorts. AUCs were improved when RPS-specific models were used in full and in HR+/HER2-, HR+/HER2+, and triple negative cohorts. No improvement was observed in the HR-/HER2+ cohort where 97% (72/74) were HER2+/BP-HER2_or_Basal.

Conclusion: Improved prediction of pCR was observed using the RPS-specific MRI model compared to the current HR/HER2-specific model. A new preRCB workflow is being developed to combine MRI-based prediction with core biopsy assessment to re-direct “good responders” to surgery earlier and more precisely based on a patient’s biological subtype.

	N	pCR rate	AUC by HR/HER2	AUC by RPS
Full	854	35% (n=301)	0.77	0.80
HR+/HER2-	336	19% (n=65)	0.71	0.82
HER2-/Immune-/DRD-	177	5% (n=9)		
HER2-/Immune-/DRD+	29	31% (n=9)		
HER2-/Immune+	130	36% (n=47)		
HR+/HER2+	141	38% (n=54)	0.68	0.77
HER2+/BP-HER2_or_Basal	87	55% (n=48)		
HER2+/BP-Luminal	54	11% (n=6)		
HR-/HER2+	74	66% (n=49)	0.73	0.69
HER2+/BP-HER2_or_Basal	72	65% (n=47)		
HER2+/BP-Luminal	2	100% (n=2)		
Triple negative	303	44% (n=133)	0.75	0.76
HER2-/Immune-/DRD-	75	23% (n=17)		
HER2-/Immune-/DRD+	36	50% (n=18)		
HER2-/Immune+	192	51% (n=98)

Background: Adjuvant whole breast radiotherapy (RT) is provided to almost all women with early-stage invasive breast cancer after breast conserving surgery and appropriate systemic therapy. While there is increasing interest to personalize the use of RT based on molecular profiling, to date, there is no molecular signature available to reliably assess the benefit of radiotherapy after surgical resection. Here we assess the ability of a 16-gene signature named Profile for the Omission of Local Adjuvant Radiotherapy (POLAR) to identify who may be suitable candidates for radiotherapy omission in patients of the Scottish Conservation Trial. Methods: The POLAR signature was applied to archival tissue from the Scottish Conservation Trial, which randomized 585 patients with stage I-II breast cancer, tumor size < 4 cm, and age ≤70 years old to receive RT or not. The archival tissue was measured for ER (ER+ >10%), PgR (PgR+ ≥20%), Ki67 (Ki67 high ≥14%), and HER2 (HER2+ defined as HER2 over-expressed or amplified). 26% received adjuvant chemotherapy, the remainder received tamoxifen 20 mg/daily for 5 years. Cox models for the locoregional recurrence (LRR) endpoint tested the association between treatment arms separately for patients with a low and high POLAR score using a pre-specified cut point. Cumulative incidences were computed, with distant metastasis and death without recurrence considered competing events. Results: 224 patients had tissue available and complete clinical data for analysis, 40 (18%) were node-positive. The distribution of clinicopathologic variables between the RT and no RT arms remained balanced. 43% were ER+/PgR+/Ki67 low/HER2-, 31% were ER+/HER2-/Ki67 high or PgR-, 5% were HER2+, and 13% were triple negative. The continuous standardized POLAR score was prognostic for LRR in the no RT arm after adjusting for relevant covariates (HR=1.78 [1.20-2.64], p=0.003). For patients with a POLAR-high score, the 10-year LRR rate was 31% [21%-42%] for patients not receiving RT and 8% [3%-15%] for patients receiving RT (HR 0.36 [0.19-0.69], p=0.0022). For

patients with a POLAR low score, the 10-year LRR rates were 20% [10%-33%] for patients not receiving RT and 6% [1%-18%] for patients receiving RT; HR=0.28 [0.08-0.98], p=0.046). In the subgroup of node-negative patients with ER+/HER2-negative tumors (N=137), there was a statistically significant RT benefit for patients with a POLAR high score (HR=0.31 [0.11-0.88], p=0.028) but not for patients with a POLAR low score (HR=0.5 [0.1-2.4], p=0.39). Conclusions: For patients with early-stage invasive breast cancer treated with breast-conserving surgery without RT, POLAR is prognostic for LRR and may refine the selection of “low risk” for omission of RT.

Background: Hormone-receptor (HR)+/HER2- breast cancer (BC) is a biologically heterogeneous disease. Homologous recombination deficiency (HRD) and BRCA mutations have been previously reported to be associated with worse outcomes in HR+/HER2- metastatic BC patients receiving CDK4/6 inhibitors and endocrine therapy. Here, we assess the relation between HRD and RB-loss signatures, intrinsic subtyping, the PAM50-based chemo-endocrine score, and response to chemotherapy-based therapy and endocrine treatment in HR+/HER2- early BC. Methods: GIADA is a multicentric neoadjuvant phase II trial that treated premenopausal patients with Luminal B (LumB)-like BC (HR-positive, HER2-negative, with Ki67>20% and/or histologic Grade 3) with a combination of chemotherapy, immunotherapy and endocrine treatment. Expression of 758 genes on baseline tumor samples from all 43 patients was quantified by nCounter platform. The LETLOB phase II trial randomized postmenopausal women with clinical stage II-IIIa HR+/HER2- BC to neoadjuvant letrozole + lapatinib or letrozole + placebo for 6 months (Guarneri, JCO 2014). Gene-expression data (Affymetrix platform) from pre-treatment frozen core-biopsies was available from 66 out of 92 pts enrolled. Intrinsic subtype was assigned using a research-based PAM50 subtype predictor. A published HRD signature (Peng, Nat Commun 2014) and a signature of RB loss (RBSig), previously reported to potentially predict resistance to CDK4/6 inhibitors in HR+/HER2- BC (Malorni, Oncotarget 2016) were computed. The PAM50 based chemo-endocrine score (CES) was calculated using published definition (Prat, CCR 2017). Higher values of CES indicate increased endocrine sensitivity, while lower values indicate chemosensitivity. Association between genomic

signatures was assessed through Pearson's correlation coefficient. Association of genomic signatures with pCR was assessed through logistic regression and association with PEPI scores was assessed through Kruskal-Wallis test. Results: HRD signature levels were significantly higher in non-luminal (Basal-like and HER2-enriched) tumors as compared to Luminal (A or B) tumors ($p > 0.001$ in the GIADA trial, $p = 0.021$ in the LETLOB trial). Moreover, higher levels of HRD signature were associated with higher levels of RB-loss signature (Pearson correlation 0.355, $p = 0.020$ in the GIADA trial; Pearson correlation 0.942, $p < 0.001$ in the LETLOB trial), higher levels of Basal-like signature (Pearson correlation 0.502, $p < 0.001$ in the GIADA trial; Pearson correlation 0.373, $p = 0.002$ in the LETLOB trial) and lower levels of CES (Pearson correlation -0.422, $p = 0.005$ in the GIADA trial; Pearson correlation -0.763, $p < 0.001$ in the LETLOB trial), indicative of higher chemosensitivity. In the GIADA trial, higher levels of HRD signature ($p = 0.018$) and RBloss signature ($p = 0.073$) and lower levels of CES ($p = 0.007$) were associated with higher pCR rates after chemo, endocrine and immunotherapy. In the LETLOB trial, lower levels of HRD signature ($p = 0.068$) and RBloss signature ($p = 0.042$) and higher levels of CES ($p = 0.050$) were associated with higher sensitivity to endocrine treatment (lower PEPI scores, 0 vs 1-3 vs 4 or more, after neoadjuvant letrozole). Conclusions: In HR+/HER2- early BC, HRD gene signatures, RB-loss gene signatures and non-luminal (especially Basal-like) intrinsic subtyping are associated with each other and associated with higher sensitivity to chemotherapy-based therapy and lower sensitivity to endocrine treatment. These observations might help correctly tailor systemic therapy, including biologic agents, in patients with HR+/HER2- early and advanced BC.

Background: Neoadjuvant chemotherapy (NAC) is standard of care for the majority of patients with clinical stage II-III triple negative breast cancer (TNBC) and is considered in high-risk patients with hormone receptor positive (HR+)/ human epidermal growth factor receptor 2 (HER2) negative (-) tumors, with expected pathological complete response (pCR) rates of 40-60% and 10-12%, respectively. In HER2- patients with residual disease (RD) after NAC, there is limited data on rates of gain of HER2 amplification. The biological and clinical significance of this phenomenon is unknown and determining the best adjuvant therapy for these patients

remains a challenge. We sought to determine the rate of HER2 gain in a cohort of consecutive patients with HER2- breast cancer (BC) treated with NAC.

Methods: From 01/2021 to 12/2021, we identified patients with HER2- breast cancer treated with NAC followed by surgery at our institution. Patients who received neoadjuvant endocrine therapy were excluded. The rates of pCR (ypT0/is ypN0) and HER2 status pre- and post-NAC were assessed. Estrogen receptor (ER), progesterone receptor (PR) and HER2 status on surgery specimens were internally determined for all patients using ASCO/CAP 2020 guidelines. ER-low was defined as ER expression by immunohistochemistry (IHC) 1-10%.

Results: We included 256 patients, 130 (51%) HR+/HER2- [13/130(10%) ER-low] and 126 (49%) TNBC. Median age was 48 years (range 25-82) and the majority presented with clinical T2 (57%) and N1 (59%). Of 130 patients with HR+/HER2-tumors, 120 (92%) received dose-dense (dd) doxorubicin/cyclophosphamide-paclitaxel (AC-T). Of 126 TNBC patients, 46 (37%) received ddAC followed by carboplatin in combination with paclitaxel +/- pembrolizumab. Centralized HER2 status assessment on the core biopsy was performed in 22% of samples. Overall, pCR was achieved in 40% of TNBC and 11% of HR+/HER2-. Among the 192 patients with RD, the rate of HER2 gain was 8/192 (4%), including 3% (2/76) of TNBC and 5% (6/116) of HR+/HER2- patients. 7 of the 8 patients (88%) converted from IHC 1+ or 2+ fluorescence in situ hybridization (FISH) not amplified on core biopsy to IHC 2+ FISH amplified on the surgical specimen. In only 1 case, the HER2 status converted from IHC2+ FISH not amplified to IHC3+. 3/8 patients had multifocal disease. All 6 patients with HR+/HER2- BC and HER2 gain had high (>90%) ER expression (Table 1). All but one patient with HER2 gain received adjuvant anti-HER2 therapy. After a median follow-up of 10 months, no recurrence events occurred in this group. 12 of the remaining 184 patients experienced a recurrence [11 distant recurrences (8 and 3, in the TNBC and HR+/HER2- groups, respectively), and there was 1 local event (localized chest wall recurrence) in the HR+/HER2- group].

Conclusions: At a single center, we found that in patients with HER2- BC treated with NAC, HER2 gain in patients with RD was uncommon and occurred more frequently in those with HR+ tumors. Analysis of a larger cohort is ongoing to corroborate these results. It remains to be determined if this phenomenon represents a true HER2 status conversion or tumor heterogeneity.

Background: The benefit of regional nodal irradiation (RNI) in patients with low burden metastatic axillary disease was established in MA.20 showing that patients randomized to receive adjuvant whole breast irradiation (WBI) plus RNI experienced a significantly better disease free survival (DFS) and distant disease free survival (DDFS) compared to those who received WBI alone and this advantage was maintained in the hormone receptor negative subgroup. Stromal tumor infiltrating lymphocytes (sTILs) have shown prognostic and predictive value in HER2 positive and triple negative breast cancers. To date, clinical importance of immune infiltrates as prognostic and predictive biomarkers in the context of benefit from RNI has not been shown. Methods: 1064 full-face hematoxylin and eosin (H&E) stained sections and formalin fixed paraffin embedded primary tumor blocks assembled into 16 tissue microarrays (TMAs) in quadruplicates linked with clinical data were accessible from the original 1832 patients in the MA.20 trial for this retrospective-prospective translational study conducted according to the REMARK guidelines. sTILs were assessed on scanned images of H&E sections according to the International Immuno-Oncology Working Group method, and on TMAs by CD8 immunohistochemistry (IHC) using a validated assay. Biomarkers were scored by pathologists blinded to the clinical data and analyzed as continuous and categorical variables using prespecified median cutpoints. The median follow-up was 9.5 years. Cox proportional regression modelling was used after adjusting for clinicopathological factors and treatments. Hazard ratios (HR) with 95% confidence intervals (CI) were reported for the primary endpoint of DFS and secondary endpoint of DDFS. Predictive value was assessed by the interaction test between the treatment arm and the biomarkers in the full cohort and an IHC defined non-luminal A subgroup. Results: 1035 cases were evaluable for sTILs on H&E sections. Of these 52.6% (n=544) cases with $\geq 10\%$ sTILs displayed a significant correlation with age < 50 years, grade III, tumor size >2cm, hormone receptor negative status, and non-luminal A subgroup ($p < 0.05$). Of the 857 evaluable cases on TMAs, CD8+sTILs (≥ 16) were observed in 49.8% (n=427) cases and showed a significant association with grade III, ER negativity and non-luminal A status ($p < 0.05$). For the full cohort, H&E sTILs assessed as a continuous parameter, were not prognostic for DFS (HR 0.993; 95% CI 0.984-1.003; $p=0.18$) but provided prognostic information for DDFS (HR 0.988; 95% CI 0.977-0.999; $p=0.04$) in multivariate analyses. H&E sTILs did not show predictive value as a continuous variable. Similarly, using the prespecified cutpoint ($\geq 10\%$), H&E sTILs were neither prognostic nor predictive. Increasing level of CD8+sTILs was associated with significantly improved DFS (HR 0.99; 95% CI 0.983-0.998; $p=0.02$) and DDFS (HR 0.98; 95% CI 0.97-0.99; $p=0.002$) in multivariate analyses. For the full cohort, CD8+sTILs as a continuous variable, showed a significant improvement in DDFS for patients randomized to WBI and RNI (HR 0.979; 95%CI 0.959-0.999; $p(\text{interaction}) = 0.04$) compared to WBI alone and a trend (HR 0.977; 95%CI 0.954-1.001; $p(\text{interaction}) = 0.06$) for better outcome was observed for the non-luminal A subgroup. CD8+sTILs at the prespecified cutpoint (≥ 16) were not prognostic or predictive. Conclusions: Pre-treatment tumoral infiltration with stromal lymphocytes provided positive prognostic information for DFS (CD8+sTILs) and DDFS (H&E sTILs and CD8+sTILs) when examined as a continuous variable but failed to do so at prespecified cutpoints. While CD8+sTILs as a continuous variable predicted benefit from RNI, significant prediction results were not seen for prespecified cutpoint or related biomarker H&E sTIL. These results require further validation.

Background: Hormone receptor (HR) low (1-10%) HER2-negative breast cancer (BC) is emerging as a distinct subtype with similarities in clinical outcomes to triple-negative BC. However, there is a lack of consensus on treatment recommendations for chemo-immunotherapy and endocrine therapy in this subset. Here, we present results from a US National Cancer Database (NCDB) analyses of patients with HER2-negative BC evaluating response to neoadjuvant chemotherapy (NAC) and patterns of care by HR expression.

Methods: Patients with stage I-III HER2-negative BC diagnosed in 2018 were identified in NCDB, a nationwide oncology outcomes database in the US. Quantitative HR expression was unavailable prior to 2018. Data were categorized into four groups by estrogen receptor (ER) and progesterone receptor (PR) expression: ER < 1% & PR < 1% (HR-Neg), ER 1-10% and/or PR 1-10% (HR-Low), ER > 11-30% and/or PR > 11-30% (HR-Int), ER > 30% and/or PR > 30% (HR-High). Those with undocumented HR status (3%) or without curative intent surgery (5%) were excluded. The primary outcome was pathologic complete response (pCR) by HR expression in those undergoing neoadjuvant chemotherapy. Key secondary objectives included

assessment of clinicopathologic characteristics and practice patterns. The categorical variables were compared between the four groups using a Chi-square test. Age was compared using a Kruskal-Wallis test.

Results: Out of 104,205 incident cases, 2541 (2.4%) were HR-Low and 1241 (1.2%) were HR-Int. Significant differences were found between HR groups with higher grade, clinical stage, and Ki-67 in HR-Low vs. HR-Int or HR-High groups (Table 1). Patients with HR-Low and HR-Int BC were more likely to receive chemotherapy than HR-High (74%, 70% vs. 20%; $p < 0.001$) and the use of adjuvant endocrine therapy correlated with HR expression. Only half of patients in the HR-Low group received any endocrine therapy compared to higher rates in the HR-Int and HR-High groups (52% vs. 74%, 92%; $p < 0.001$). pCR rates in those receiving neoadjuvant chemotherapy were significantly different by HR status, with higher pCR rates in HR-Low vs. HR-High groups ($p < 0.001$) (Table 2). NAC utilization significantly differed between groups. A higher proportion of patients with HR-Low BC received NAC than other HR-positive groups ($p < 0.001$). Additionally, there was an increased use of NAC in patients with HR-Low BC treated at academic vs. community cancer centers ($p < 0.001$).

Conclusions: This is one of the largest real-world analyses comparing key differences in biology and practice patterns of HR-Low, HER2-negative BC. Consistent with prior studies, we report HR-Low BC to be a rare and distinct subtype with higher pCR rates compared to HR-High BC. Practice patterns show wide variability in utilization of neoadjuvant chemotherapy and endocrine therapy for these patients. Future studies should address this disparity and enhance representation of patients with HR-Low BC in clinical trials to improve long-term outcomes.

Background Clonal Hematopoiesis (CH) is a well-established risk factor for adverse clinical outcomes including all-cause mortality, cardiovascular disease, and progression to hematologic malignancies. The presence of CH has been shown to adversely impact overall survival in non-hematologic cancers, however whether CH modulates response to specific therapies in breast cancer is not known. Here we investigate the impact of CH mutations on disease progression in patients with metastatic estrogen receptor (ER) positive breast cancer undergoing treatment with first line CDK4/6 inhibitors and endocrine therapy (CDK4/6i+ET). Methods We analyzed data from a well annotated cohort of patients with ER+ breast cancer who received endocrine therapy and CDK4/6 inhibitors. All patients underwent prospective tumor and matched WBC sequencing utilizing the MSK-IMPACT assay. CH variants were detected in blood samples utilizing the well-validated variant detection and filtration pipeline of MSK-IMPACT. CH mutations were defined as putative drivers (CH-PD) or non-putative drivers (CH) as previously described. To ensure the presence of CH at the time of therapy initiation, only patients who had CH sampling performed from 6 months before through 4 months after initiation of CDK4/6i+ET were included. We compared progression free survival (PFS) in patients with and without CH, as well as by CH-PD status and DNMT3A CH mutations. We investigated clinical covariates including type of endocrine therapy, receipt of prior neoadjuvant or adjuvant chemotherapy, and age at start of CDK4/6i+ET. Results The final cohort was comprised of 378 patients, of whom 135 (35.7%) had CH. The median time between sample collection and CDK4/6i+ET initiation was 0 (IQR -0.79 to 0.47 months). Patients with CH were older at time of therapy initiation (median 63.0 versus 54.7 years, $p < 0.001$). There were no significant differences between groups in terms of endocrine therapy (aromatase inhibitor or fulvestrant), prior chemotherapy, and time from CH sample collection to CDK4/6i+ET start. Univariate Cox-proportional hazard analysis did not reveal a difference between progression free survival and overall CH (HR 0.96, 95% CI 0.75 – 1.23, $p = 0.76$), CH-PD (HR 1.05, 0.77 – 1.43, $p = 0.77$), or DNMT3A mutations (HR 1.12, 0.80 – 1.60, $p = 0.52$) compared to patients without CH. Interestingly, age less than 60 years was found to be associated with PFS outcome (univariate HR 1.57, 1.22 – 2.01, $p = 0.0004$). Multivariate analysis adjusted for endocrine therapy partner and age at CDK4/6i+ET therapy did not reveal an association between outcome and overall CH (HR 1.07, 0.83 – 1.39, $p = 0.59$). In patients younger than age 60, presence of overall CH did not confer a significant PFS difference (HR 0.90, 0.63 – 1.29, $p = 0.57$). In the subset of patients older than 60 ($n = 168$) presence of CH conferred numerically, but not statistically, significant shorter PFS (HR 1.41 [0.96 – 2.09], $p = 0.08$). In this population, CH-PD conferred a shorter PFS (HR 1.75, 1.12 – 2.72, $p = 0.02$). Conclusion We found that CH, CH-PD and DNMT3A CH mutations did not affect PFS among metastatic ER+ breast cancer patients treated with first line CDK4/6 inhibitors. Younger age was associated with increased risk of progression, warranting further investigation. In the subset of patients with age older than 60, CH-PD conferred a shorter PFS. Further data, incorporating records of dose reductions, will be presented at the meeting.

Background: Immunotherapy has emerged as an essential treatment modality for enhancing survival in triple negative breast cancer (TNBC). Despite demonstrated improvements in pathologic complete response (pCR), both toxicity and adverse events from immuno-oncology (IO) drugs remain a significant limitation. Currently, a lack of tests to differentiate patients likely to respond to IO vs. poor responders precludes a tailored approach to immunotherapy. Here we describe an imaging biomarker that allows physicians to target breast cancer patients with the highest likelihood of response to immunotherapies. Methods: We identified a rapidly assessable, non-invasive biomarker of tumor response to immunotherapy. This biomarker uses

radiological imaging (DCE-MRIs) coupled with the biophysical simulation platform TumorScope® to predict a patient's likelihood of pCR following treatment with immunotherapy and backbone chemotherapy. While this biomarker does not depend on transcriptomic data, it was designed by matching biological function (transcriptomics) to tumor microenvironmental features (as observed in biophysical simulations) derived from the SimBioSys TumorBank®. With this simulation-derived biomarker in hand, we validated our methods in a small, independent cohort. We additionally applied the SimbIOScope IO-prediction analysis to assess a large immunotherapy-naïve cohort, in order to validate if an increase in pCR rates in the presence of immunotherapy correlated with the anticipated rate of response to immunotherapy. Results: In TNBC tumors prior to neoadjuvant therapy, we found that a high immune evasive capability was associated with low nutrient utilization. Tumor immune evasion (including the PD-1/PDL-1 axis) is strongly correlated with tumor hypoxia ($r = 0.45$, $p < 1 \times 10^{-6}$). Similarly, in HR+/HER2- tumors prior to neoadjuvant therapy, we found that immune evasion was negatively correlated with angiogenesis ($r = -0.40$, $p = 0.006$), suggesting that low tumor vascularization is associated with immune evasion capability. As these associations were identified from available transcriptomic data obtained from a single biopsy site within each patient's tumor, they were unable to account for tumor heterogeneity. We therefore sought to identify a spatially-resolved biomarker for immune evasive potential in TNBC and HR+/HER2- tumors. We used publicly available DCE-MRIs of patients treated with the immunotherapy drug pembrolizumab and paclitaxel from the ISPY2 trial ($n=63$) to train a model to predict pCR in IO-treated tumors. Critically, the resulting model's predictive power matched that obtained from transcriptomics data. SimbIOScope was then tested on IO-treated patients in a small, independent cohort and correctly predicted pCR in >91% ($n=12$). We further validated SimbIOScope by predicting the expected pCR rate in 292 patients from our virtual TumorBank in response to immunotherapy. Consistent with empirical increase (13.6% in TNBC, Keynote522) anticipated as seen from clinical trials, we found that SimbIOScope predicted a 14% increase in pCR rate in TNBC patients (and 9% increase in HR+ patients) with addition of immunotherapy versus chemotherapy backbone alone. Conclusions: The SimbIOScope platform offers physicians a rapid, non-invasive biomarker to differentiate patients likely to respond to immunotherapy from non-responders. This innovative technology thereby personalizes oncologic care and mitigates the potential for adverse effects by helping to optimize selection of patients best suited for immunotherapy.

Introduction: Genomic tests are routinely used by clinicians to guide treatment decisions in early-stage breast cancer (EBC). The 70-gene MammaPrint assay (MP) assesses the risk of distant recurrence in untreated patients with EBC and categorizes the tumors as High Risk (HR, MP index: -1 to ≤ 0) or Low Risk (LR, >0 to $+1$). The LR category is further divided into Low but non-UltraLow (LNUL; >0 to ≤ 0.355) and UltraLow Risk (UL; >0.355 to 1). Here, we report the risk of distant recurrence by MP and 10-year outcomes in patients with EBC diagnosed at Magee Women's Hospital of the University of Pittsburgh Medical Center.

Methods: In this retrospective analysis, 259 women diagnosed with EBC between 2005 and

2008, who received a MP result, were included. Patient clinical and tumor characteristics were collected. The median FU was 13.1 year among patients with clinical data. Treatment received, 10-year Distant Metastasis Free Interval (DMFI) and 10-year Breast Cancer Specific Survival (BCSS) are reported according to the MP groups. Differences in DMFI and BCSS between MP risk groups were assessed by log-rank. Patients were treated at the physician's discretion. Treatment was started prior to obtaining MammaPrint results.

Results: Among the 259 patients, 69% were post-menopausal women (mean [range] age: 58 [31-81] years) and diagnosed with hormone receptor-positive HER2-negative tumors (90%), grade 1 or 2 (64%), and without lymph node invasion (93%). In this cohort, 69% (n = 159) had a MP LR result and 31% (n = 100) had a MP HR result. Overall, 14% (n = 35) of patients had a MP UL risk of recurrence of whom 74% (n = 26 / 35) were post-menopausal women. Substantially more patients received chemotherapy in the HR group (57%, n = 57) compared with the LR group (15%, n = 24) (table). Considering that treatment was initiated before MammaPrint results were known, MP results might have allowed chemotherapy de-escalation in 15% (n = 24) of patients with a MP LR. Similarly, in the 39% (n = 39) of women with a MP HR treated with endocrine therapy only, knowledge of MP results could have provided important information to add chemotherapy to the treatment plan.. In the MP UL group, 74 % (n = 26) of patients were treated with endocrine therapy only compared with those who received chemotherapy (9%, n = 3) and no adjuvant treatment (9%, n = 3). The 10-year DMFI and 10-year BCSS were higher in the LR compared with the HR group (table). When further stratifying the MP LR group in LNUL and UL, the 10y DMFI was 0.97 (95% CI; 0.94 – 1.00) and 1.00 for the MP LNUL and UL groups, respectively. Within the first 10 years, 8 of the 10 distant recurrences observed were in the MP HR group, and 2 were in the MP LNUL group. Among the 18 recorded deaths, 5 were breast cancer-related, 4 in the MP HR and 1 in the MP LR (LNUL) groups.

Discussion: In this single-institution retrospective analysis, all patients showed excellent BCSS and DMFI outcomes confirming the ability of MP to correctly predict the good prognosis (LR) and poor prognosis (HR) in patients with EBC. In this analysis, as observed in other cohorts, women with a MP UL risk result had an excellent prognosis at 10 years while being treated mostly with endocrine therapy only. Taken together, with the low endocrine therapy adherence reported in the literature, these data suggest that patients with a MP UL result may be candidates for further treatment de-escalation to optimize the risk/benefit ratio of endocrine therapy in future studies.

Table. Clinical outcomes and treatment received in patients stratified by MammaPrint results

	MammaPrint			
	High Risk (n=100)	Low Risk (n=159)	Low Risk (n=159)	
			Low Non-UltraLow Risk (n=124)	UltraLow Risk (n=35)
Probability of (95%CI)				
10y-DMFI	0.90 (0.84 – 0.96) ^{a,b}	0.98 (0.96 – 1.00) ^a	0.97 (0.94 – 1.00) ^b	1.00 ^b
10y-BCSS	0.96 (0.91 – 1.00) ^{c,d}	0.99 (0.98 – 1.00) ^c	0.99 (0.97 – 1.00) ^d	1.00 ^d
Treatment received*, n (%)				
ET Only	39 (39.0)	123 (77.4)	97 (78.2)	26 (74.3)
CT +/- ET	57 (57.0)	24 (15.1)	21 (16.9)	3 (8.6)

* Patients were treated at the physician's discretion

a p = 0.011, MP LR vs MP HR.

b p = 0.032, MP UL vs LNUL vs HR.

c p = 0.061 MP LR vs MP HR.

d p = 0.170, MP UL vs LNUL vs HR.

Introduction: Microcalcifications are a common feature in mammographic detection of ductal carcinoma in situ (DCIS), and occur in >80% of cases. Known to be present as type I (calcium oxalate-CaO) and type II (carbonated calcium hydroxyapatite-CHAP) microcalcifications, their association with DCIS and their role in the progression of DCIS to invasive breast cancer (IBC) remains unexplored. In an effort to understand the factors involved in DCIS prognosis, it is hypothesized that changes in the chemical composition of calcifications, in tandem with molecular changes in the surrounding soft tissue, will define patients with DCIS who will progress to develop IBC from those who remain with a stable DCIS phenotype. To this end, a novel label-free approach of hyperspectral imaging using mid-infrared (mid-IR) and Raman spectroscopy was used to probe calcification chemistry and molecular composition of the surrounding ductal and stromal soft tissue. The main aim of the work is to identify biomarkers for DCIS prognosis, based on chemical and molecular compositional changes of calcifications and the surrounding soft tissue. It is anticipated that the spectral biomarkers will provide patients and clinicians an informed risk assessment whether to undertake treatment for DCIS or to be placed under active surveillance. **Methods:** Tissue samples from 422 patient have been obtained and include (i) 'pure DCIS' (DCIS without recurrence) (n=193), (ii) 'DCIS with invasive recurrence' (DCIS from patients who subsequently were known to develop invasive disease) (n=123), (iii) 'DCIS plus contemporaneous invasive cancer' (n=44) and 'benign' (n=62) samples. Serial tissue sections were measured using mid-IR and Raman hyperspectral imaging approaches targeting the same calcification and soft tissue regions from specific DCIS ducts. Hyperspectral imaging data was initially pre-processed to digitally remove paraffin and unintended spectral interferences. The pre-processed data was subjected to cluster analysis followed by unsupervised and supervised machine learning classification models to identify spectral features associated with DCIS and its progression to IBC. **Results:** Cluster analysis based segmentation of hyperspectral images revealed histopathological features including calcifications, epithelium, necrotic areas, connective tissue and stroma. Spectra were extracted from each of the histopathological features using image coordinates, and biomodelling analysis was performed. Initial analysis of 314 calcification images from 170 patients with (i) 'pure DCIS' (n=118) and (ii) 'DCIS with invasive recurrence' (n=52) showed an area under the receiver operating characteristic (AUROC) mean value of 85% in distinguishing pure DCIS from DCIS that later recurred as IBC. The calcification features appeared to indicate pathology specific changes in phosphate and carbonate content as well as changes in magnesium whitlockite content. Similar analysis of the surrounding soft tissue spectral features showed an AUROC mean value of 85% (necrotic regions surrounding calcifications) and 76% (epithelium) respectively. The epithelial features showed changes in protein secondary structure and content, which together with the calcification changes indicate structural remodelling in DCIS that progresses to IBC, from those that do not. **Perspectives:** In the ongoing analyses of imaging data from 422 patients, it is anticipated that molecular/structural features from calcification and soft tissue imaging data will provide important cues in understanding DCIS prognosis and could be a promising way forward in determining management of DCIS risk and treatment underpinned by the identification of specific discriminatory spectral markers. **Acknowledgments:** This work was supported by Cancer Research UK and by KWF Kankerbestrijding (ref. Background: The influence of the local immune infiltrate on tumor progression is dependent on tumor-intrinsic characteristics. Among highly aggressive subtypes, an immune infiltrate is associated with a favorable prognostic effect. The aim was to investigate whether the integration of histological grade and degree of tumor-infiltrating lymphocytes (TILs) permits improved treatment individualization for clinically high-risk tumors. Methods: The SweBCG91RT trial included 1178 patients with stage I-IIA breast cancer, randomized to breast-conserving surgery with or without adjuvant RT, and followed for a median time of 15.2 years. In total, 8% were treated with systemic therapy. Histological grade and TILs were evaluated on whole-tissue sections by board-certified pathologists. Grade III tumors were compared to grade I and II tumors. TILs were classified as high ($\geq 10\%$) or low ($< 10\%$). The primary endpoint was ipsilateral breast tumor recurrence (IBTR) within 10 years. Results: In total, 134 (57%) of the 235 grade III tumors had high TIL levels compared to grade I/II tumors where 142 (19.7%) out of 721 tumors exhibited high TIL levels. Grade III tumors with high TILs had a reduced risk of IBTR (HR 0.49, CI 95% 0.26-0.91, $p=0.025$) compared to grade III tumors with low TILs (HR 1.0). Among grade I/II tumors, high TILs was not prognostic (HR 1.02, CI 95% 0.62-1.68,

p=0.95) compared to grade I/II tumors with low TILs (HR 1.0). Grade III tumors with low TILs had a high risk of recurrence without RT (36.2%) and derived benefit from RT (HR 0.16, CI 95% 0.047-0.53, p=0.0029). In contrast, grade III tumors with high TILs had a lower risk of IBTR without RT (14.5%) and did not benefit significantly from RT (HR 0.71, CI 95% 0.26-1.90, p=0.50). Conclusion: Measurements of the local immune infiltrate may improve treatment individualization when integrated with tumor-intrinsic features of aggressivity, such as histological grade. High-risk tumors with an immune infiltrate may be candidates for RT de-escalation.

Background: Despite chemotherapeutic advances, surgery remains a putative treatment modality for breast cancer. The type of surgery chosen, and its ultimate clinical and cosmetic consequences, depends on a surgeon's ability to accurately assess a tumor's size, distribution, and position in the breast relative to anatomical landmarks. Moreover, in cases in which the tumor-to-breast volume ratio is substantial, neoadjuvant chemotherapy (NAC) offers the potential to shrink a tumor such that enhanced cosmesis or breast-conserving surgery becomes possible. Therefore, doctors must not only build an accurate picture of the current tumor shape, size and location, but anticipate how they might change over time and during treatment. SimBioSys' TumorSight (TSi) offers doctors the ability to simulate the way a patient's tumor might respond to various drug therapies, volumetrically and morphologically. These predictions are critical for surgical planning, in which a patient's eligibility for breast-conserving surgery depends on the spatial distribution of the tumor. Primarily, this means consideration of (1) tumor multicentricity, (2) the extirpative tumor-to-breast volume ratio, and (3) the distance from the

tumor to nipple. TSi provides physicians with estimates of each of these three key metrics, in 3D, over time, and as a function of regimen, to facilitate accurate evaluation, visualization and forecasting of NAC response with respect to surgical planning. Methods: TSi was used to create 3D models across multiple patient cohorts using DCE-MRI. These included segmentations for skin, chest wall, nipple, adipose tissue, glandular tissue, vasculature, and tumor. Volumetric and morphological changes in the tumor and adjacent tissues were simulated throughout a chemotherapy treatment regimen, as described previously. The resulting tumor distributions were analyzed and compared to distributions in post-treatment MRI segmentations. Metrics of interest in this study were the distance of closest approach between the tumor and nipple, tumor volume-to-breast volume ratio, tumor convex hull-to-breast volume ratio, and whether the tumor was monocentric. Results: In a set of N=292 patients, both the predicted tumor volume and tumor volume from a post-treatment MRI segmentation were computed. We took the difference in these volumes, normalized by the total breast volume (also computed from an MRI segmentation), to assess how well TSi predicts the final tumor volume-to-breast volume ratio after treatment. We found that the median difference in this metric was $3.26e-07$, and 5th and 95th percentiles were 0.0035 and 0.0023, respectively. Similar performance was seen when using the volume of a convex boundary enclosing the tumor and a 1 cm margin (to simulate operative conditions). In a set of N=164 patients, the accuracy of our prediction of whether the tumor will be monocentric after treatment was assessed. We found that our simulations were 78.7% accurate in predicting monocentricity. Finally, in a set of N=134 patients, TSi predicted a distribution of changes in the closest distance between the nipple and tumor, with a median of 1.06 cm and standard deviation of 1.64 cm. In all studies, there was no difference in median values seen between cancer subtypes. Conclusion: The ability to accurately measure, visualize, and predict post-NAC metrics such as tumor-to-nipple distance, monocentricity, and tumor-to-breast volume ratio is critical to surgical planning in breast cancer. To assist in this planning, TSi provides a surgeon and their patient with a realistic three-dimensional representation of tumor volume, shape, and location in the breast, and reliably predicts how these metrics change during treatment.

[Introduction] Invasive lobular carcinoma (ILC) has different pathological and clinical features from invasive ductal carcinoma (IDC). ILC has more likely to be hormone receptor (HR) positive, and several studies reported that the prognosis of ILC was better than IDC. However, ILC also has different prognosis according to the subtypes as IDC does, and better prognosis of ILC might depend on their high HR positivity. Additionally, there are many reports that chemotherapy (CT) does not improve the prognosis of ILC due to the high positivity of HR. Therefore, we compared the prognosis of ILC and IDC in the same subtypes and considered necessity of CT for luminal ILC. ILC usually constitutes small population of invasive breast cancer. Thus, we have planed the analysis by using the Breast Cancer Registry (BCR) run on the National Cancer Database (NCD) in Japan. [Methods] 318,338 breast cancer patients were registered in BCR between 2004 and 2012. We selected 250,736 patients who were diagnosed as ILC or IDC. Patients with distant metastasis, those who did not receive surgery, and those who received preoperative therapy, and those who had bilateral breast cancer were excluded, and it resulted in 207,428 patients. Of these cases, the cases with 10-year follow-up data were 136,654, and we examined 5,705 ILC and 130,949, IDC. Because it was presumed that there are differences in pathological and clinical characteristics between ILC and IDC, we have planned to make the matched cohorts by using exact matching for comparing their prognosis. To evaluate the prognosis of each subtype, we compared DFS and OS for IDC and ILC in each subtype. To evaluate the effect of CT in luminal ILC, we corrected the data of luminal ILC with pT2N0M0 or pT1-2N1M0 patients and compared DFS and OS between endocrine therapy (ET) only group and ET+CT group. DFS was defined as the time from surgery to local or distant recurrence or death from any cause. OS was defined as the time between the surgery and the death from any cause. Peason's Chi squared test was used to identify the characteristics. Survival curves were constructed by Kaplan-Meier method and were compared by log-rank

test. [Results] We made the matched cohort by using exact matching and we identified 5,633 ILC and 5,633 IDC for prognosis analysis. In overall subtypes, the 10-year DFS of ILC was poor than those of IDC (76.56% vs 79.14%, $p=0.04$). In the analysis by each subtype, there was no statistical difference in DFS for luminal HER2, HER2, and TN cohorts, however luminal ILC had statistically significant poor DFS than luminal IDC (78.04% vs 81.17%, $p< 0.01$). The analysis of 10-year OS showed similar results, and there were no differences in the OS of luminal HER2, HER2 and TN cohorts between ILC and IDC. However, ILC had worse OS than IDC in luminal cohort (85.95% vs 89.13%, $p< 0.01$). To evaluate the effect of CT in luminal ILC, we made the matched cohort and we identified 95 luminal IDC and 95 luminal ILC in pT2N0 cohort, and 83 luminal IDC and 83 luminal ILC in pT1-2N1 cohort for the analysis. In pT2N0 cohort, the 10-year DFS was 82.12% in ET+CT group and 87.35% in ET only group ($p=0.99$). The OS of the ET+CT and the ET only group was 93.48% and 94.04% ($p=0.88$). In pT1-2N1 cohort, the ET only group had 54.17% and the ET+CT group had 77.03% of DFS ($p=0.34$). The OS in the ET only group and the ET+CT group was 61.96% and 94.81% ($p=0.01$). [Discussion] Although luminal HER2, HER2 and TN cohorts had no differences in prognosis between ILC and IDC, luminal ILC had a poor prognosis than luminal IDC. Therefore, luminal ILC needs stronger approach to improve their prognosis. And it was suggested that chemotherapy is effective for recurrent high-risk luminal ILC such as those with positive lymph node metastasis. [Conclusion] ILC had worse prognosis than IDC in luminal cohort, however it was comparable in luminal HER2, HER2, TN cohorts. A new strategy of treatments for luminal ILC might be needed to improve their prognosis.

BACKGROUND Recent pooled analysis of four major clinical trials of neoadjuvant chemotherapy (NAC) indicated that tumors with low expression of HER2 (HER2-low) as defined by immunohistochemistry (IHC) could be a new subgroup of breast cancer, distinct from HER2-negative tumors. In estrogen receptor (ER)-positive/HER2-negative breast cancer, we previously reported that 9.5% ER expression by IHC was the most appropriate cutoff to predict survival outcomes. However, little is known about the effect of quantitative ER expression on NAC outcomes in patients with HER2-low breast cancer. The present study aimed to elucidate the role of quantitative ER expression as a predictive and prognostic biomarker in the newly established HER2-low subgroup. **MATERIALS AND METHODS** We retrospectively reviewed the charts of 2,016 patients with newly diagnosed ER- and/or progesterone receptor (PR)-positive breast cancer between January 1982 and January 2019 in an extensive clinical database at The University of Texas MD Anderson Cancer Center. Our analysis included

patients whose ER%, PR%, and HER2 IHC (0 to 2+) data were available. HER2-low was defined as IHC 1+ and 2+/situ hybridization (ISH)-negative. All patients had stage II or III disease at presentation and received NAC with anthracycline and a taxane-based combination regimen. Those with ER-positive tumors also received adjuvant endocrine therapy. The primary outcome measure was pathologic complete response (pCR) rate, compared between groups using logistic regression. Secondary outcomes were progression-free survival and overall survival after NAC completion, compared using Kaplan-Meier analysis and the log-rank test. The cutoff value for ER and PR positivity was 10% in the main analysis, identified by recursive partitioning and regression trees. RESULTS Among the 2,016 patients, 1134 (56%) had cStage II and 882 (44%) had cStage III disease. For IHC HER2 levels, 739 patients had 0 (37%), 926 had 1+ (46%), and 351 had 2+ (17%). For the primary outcome, 123 patients (6%) achieved pCR. The median follow-up period was 6.78 years. During the follow-up, 571 (28%) had distant metastasis. Mean ER expression (%) increased with HER2 IHC (HER2 IHC 0: 74.2%, 1+: 76.7%, 2+: 78.2%). In the multivariate logistic model, ER-negative ($p < 0.0001$), PR-negative ($p < 0.0001$), and high nuclear grade ($p < 0.05$) disease were associated with higher pCR rates. Although pCR rate did not differ among HER2 IHC groups (0 = 6.09%, 1+ = 6.26%, 2+ = 5.7%; $p = 0.93$), significantly higher pCR rates were observed in the HER2 IHC=0/1+ and 1% \leq ER< 10% group ($p = 0.0013$) than in the HER2 IHC=0/1+ and ER \geq 10%, and HER2 IHC=2+ and ER \geq 10% groups. Kaplan-Meier curves showed that patients in the ER \geq 10% group had marginally improved PFS ($p = 0.046$) and significantly longer OS ($p = 0.004$) regardless of HER2 IHC status. Multivariable analysis showed that HER IHC status did not affect survival outcomes. Exploratory analysis showed that the patients with 70% or less in ER expression and HER2 IHC 1+/2+ tumor had higher pCR rate (12.3%) compared to those with ER>70% (4.1%). CONCLUSIONS Patients with \geq 10% ER expression had better survival outcomes than those with ER< 10% regardless of HER2 expression level. The degree of HER2 expression in the HER2-low subgroup was not an independent predictive and prognostic factor for NAC response. The cutoff for ER expression for its predictive effect on pCR needs further validation in large external datasets.

Background

Brain metastases is one of breast cancer's leading causes of death, and the incidence is increasing with advances in diagnosis and treatment techniques. Nevertheless, these patients have fewer opportunities to participate in prospective randomized clinical trials because of the design challenges of increasing target population heterogeneity or differentiating the definition of endpoints and how the endpoints are evaluated. Real-world data has the potential that reaches the information at a blinded area of RCT approaches. In recent years, observational studies using real-world data have gotten attention for their capability to enhance an understanding of hard-to-reach RCT approaches. However, the yet incomplete gold standard of the study protocol and the unpredictable 'hidden labor' of secondary use of clinical data become barriers to clinical researchers. In the study, we demonstrate data attainability assessment focused on clinicians' clinical unmet needs in breast cancer brain metastases (BCBM) as a preliminary step of the observational study for screening study feasibility on a certain data source.

Methods

A breast cancer registry based on the clinical data warehouse (CDW) of Samsung Medical Center has been used as the data source (N=45,219, up to 31 Dec 2021). A total of 5 clinical questions (CQ) were presented as the result of the interview of two breast cancer experts about

BCBM for the study (Table 1). Additionally, we conducted an attainability assessment for the population size and core variables constrained by a clinical question and a survey of 7 breast cancer clinicians for evaluation of the recognized clinical significance and research methods' suitability for each CQ.

A working group was formed for data attainability tests with a person with experience in clinical research for at least several years across interdisciplinary areas, including clinical expertise, medical informatics, and epidemiology. For the first step, we declare the operational definition for the study population and core variables in which the research question is inherent conceptually. And appropriate data fields and value sets are figured out from the data set. Data attainability is examined via RWD extraction on the population size and availability of core variables.

Result

The collected five CQs were mostly about the relationship between brain metastases, systemic metastases, and systemic treatments. Other CQs were related to the relationship between brain metastases incidence and the type of neoadjuvant treatment or patients' described symptoms. Assessment of the importance of clinical questions aligned well, especially for the questions with higher scores. ($r = -0.98$)

For CQ E, filtered out not to fit the SMC BCR dataset at the early stage of the data attainability screening process due to lack of explicit data field or semantically related value sets for one of the core variables, 'neurological symptom.' For CQ A, B, and D, we could confirm enough population size and dataset for conducting the study, but additional logical reconstruction of data elements had needed. For example, we used the 'clinical subtype' variable, which is provided from SMC BCR, as pre-processed feature variable using an expert-knowledge-based algorithm. For CQ C, we were able to obtain pertinent data for the study only with direct data field match and explicit code set definition.

Conclusion

To effectively use CDW, the variables have to be interpreted and defined in a clinically meaningful way with the cooperation of clinicians and data science experts. For observational studies based on RWD, understanding the data source contents and clarifying the research question enough to translate to the data level is essential. The step-by-step protocol presented in the study could be applied to the other clinical researcher using RWD at preliminary feasibility screening.

Table 1. List of clinical questions from expert interviews

A	A study on whether there is a difference in survival prognosis when brain metastases occurs as 1st metastases and when brain metastases is accompanied by systemic metastases
B	A study on whether or not systemic treatment for brain metastases patients makes a difference in survival prognosis according to subtype
C	A study on whether the timing of systematic treatment initiation differs on survival prognosis when brain metastases is accompanied by systemic metastases
D	A study on whether there is a difference in the prognosis for the occurrence of brain metastases compared to patients who previously received trastuzumab alone for neoadjuvant and patients who received pertuzumab and trastuzumab for neoadjuvant
E	A study on whether any record about neurological symptom in EMR which described by patients can be translated as surrogate factors of brain metastases

Background: Epithelial membrane protein 1 (EMP1) belongs to PMP22 gene family and is reported to be expressed low in numerous gastrointestinal cancers. However, little is known about its role in breast cancer. EMP1 functions to promote cell proliferation. In this study, we hypothesized that low EMP1 expressing breast cancer is associated with high proliferative characteristics and poor survival. Material and Methods: The clinicopathological data and transcriptome data of breast cancer patients from two independent large publicly available databases, The Cancer Genome Atlas (TCGA, n = 1090) and The Molecular Taxonomy of Breast Cancer International Consortium (METABRIC, n = 1904), were utilized in the current study. Survival analyses; Overall survival (OS), Disease-specific survival (DSS) and Disease-free survival (DFS) were performed by comparing the high and low expression groups. CYT score, xCell, and other immunological factors were used to evaluate intratumoral immune cell composition. Also, gene set enrichment analysis (GSEA) was performed between EMP1 high and low expression groups. Results: We divided each cohort into EMP1 expression high and low groups by utilizing median cutoff. The expression levels of EMP1 were not associated with clinical stage in any subtypes. However, interestingly lower expression of EMP1 was significantly associated with more advanced grades in ER positive/HER2 negative (ER+/HER2-) subtype in both TCGA and METABRIC cohorts ($p < 0.001$ and $p < 0.001$, respectively). Also, low EMP1 expressing tumors demonstrated higher MKI67 expression levels in ER+/HER2- subtype consistently in both TCGA ($p < 0.001$) and METABRIC cohorts ($p < 0.001$). Furthermore, GSEA demonstrated that low EMP1 expressing tumors enriched the gene sets associated with cell proliferation such as MYC Targets, E2F signaling, and G2M Checkpoint signaling, compared

with low EMP1 expressing tumors in ER+/HER2- of both TCGA and METABRIC cohorts. On the contrary, high EMP1 expressing tumors enriched the immune related gene sets such as Coagulation, Inflammatory_Response, Complement, and IL-6_JAK_STAT3 Signaling in ER+/HER2- of both TCGA and METABRIC cohorts. To this end, we further hypothesized that high EMP1 tumors were associated with favorable tumor immune microenvironment (TIME) and analyzed TIME utilizing xCell. However, to our surprise high EMP1 expressing tumors were not associated with favorable TIME. Low EMP1 expressing tumors demonstrated worse DFS, DSS, and OS compared with high EMP1 expressing tumors in ER+/HER2- breast cancer patients ($p=0.013$, $p=0.003$, and $p=0.006$) which was not the case in the other subtypes in METABRIC cohort. Conclusion: Low EMP1 expressing tumors were associated with improved OS, DSS, DFS in ER-positive breast cancer patients. Also, low EMP1 expressing tumors were found to associate with advanced grades and enriched gene sets related to cell proliferation and cell cycle, which may explain the poor survival of patients with low EMP1 expressing ER+/HER2- breast cancer.

Background: Surgical oncologists currently rely on 2D image slices, such as those from mammograms, to assess the locations and extents of their patients' breast cancer tumors. In order to accurately evaluate the potential success of various surgical options, a surgeon must mentally translate these 2D images into more realistic, 3D image to visualize breast and tumor morphologies. For a patient without the same experience, it is even more difficult to imagine the true, 3D shape, size and location of their tumor and to participate fully in decision-making and surgical planning. Since the type of surgery chosen (nipple-sparing versus skin-sparing, mastectomy versus lumpectomy), and its ultimate clinical and cosmetic consequences,

depends on not only a surgeon's accurate pre-operative assessment, but also on the patient's understanding; a method of clear, precise, 3D visualization in the clinic would represent a significant advancement. Methods: Using DCE-MRI as input, we developed TumorSight (TSi) to provide surgical oncologists with an accurate, 3D representation of a patient's breast tissue and tumor, and to allow computation of useful metrics, such as the tumor-to-breast volume ratio and distance to surgically useful anatomical landmarks such as the nipple. TSi was used to create 3D models of breast cancer patient tumor using MRIs from the SimBioSys Virtual TumorBank which currently houses thousands of patients. Results: After creating the models, labels for tumor, as well as skin, chest wall, nipple, adipose tissue, glandular tissue, and vasculature were created. After tumor segmentation validation studies (of 49 patients) were completed, the median absolute volumetric error was 0.32 and the median maximum Hausdorff distance was 17.72mm. From these representations, we determine whether the tumor is monocentric, multifocal or diffuse, compute the tumor volume-to-breast volume ratio, and measure the distance of closest approach between the tumor and the nipple. In addition, by adding a margin to the tumor and computing the volume within a convex boundary containing the tumor+margin, TSi provides a pre-operative estimate of the extirpative volume and its fraction of the total breast volume. Conclusion: The ability to visualize, in 3D, a tumor's location and distribution in the breast, and to accurately measure important metrics such as tumor-to-nipple distance, multifocality, and tumor-to-breast volume, are critical to surgical planning in breast cancer. To assist in this planning, TSi provides a surgeon and their patient with a three-dimensional breast and tumor representation and reports measurements of key features of interest.

Background: The HER2DX assay is a genomic test in early-stage HER2-positive (HER2+) breast cancer that provides prognostic and predictive information. HER2DX is a supervised learning algorithm incorporating tumor size, nodal staging, and 4 gene expression signature scores (immune/IGG, tumor cell proliferation, luminal differentiation and the expression of the HER2 amplicon). Among them, the IGG signature is associated with both overall survival and probability of achieving a pathologic complete response (pCR). Here, we studied the association of percentage (%) of tumor infiltrating lymphocytes (TILs) with HER2DX scores, immune genes and other breast cancer-related genes. Methods: HER2DX and %TILs were evaluated in 670 formalin-fixed paraffin-embedded (FFPE) samples of HER2+ breast cancer, including in 3 clinical studies SHORTHOR (n=437), PAMELA (n=86), a cohort of patients treated with anti-HER2 therapy plus chemotherapy at Hospital Clínic of Barcelona (n=147). The %TILs were quantified by histological evaluation with hematoxylin eosin staining according to International TILs Working Group guidelines. The nCounter platform determined the expression of 192 genes and HER2DX scores. Pearson correlations (Cor) and Significance Analysis of Microarrays (SAM) with a false-discovery rate (FDR) < 5% assessed the association between %TILs and the expression of individual genes or HER2DX signature scores. Results: A moderate correlation was observed between %TILs and the immune IGG signature (Cor=0.56, p< 0.001). Of note, 171 (25.52%) cases had low %TILs (< 30%) and high IGG score, while 1 (0.15%) case had high %TILs (≥30%) and low IGG score. The %TILs were significantly associated with the expression of immune genes, ERBB2, IGG signature and HER2 amplicon score, and negatively associated with the expression of luminal genes (i.e., ESR1, PRG and BCL2). An unclear relationship between TILs and proliferation genes was observed. Finally, moderate correlations were observed between %TILs and HER2DX pCR score (Cor=0.48, p< 0.001) and between %TILs and HER2DX risk score (Cor=0.33, p< 0.001). Conclusions: Important differences exist between the %TILs and the HER2DX IGG signature in early-stage HER2+ breast cancer. The %TILs should not be used to predict the HER2DX scores. Biologically, a higher %TILs indirectly capture a higher ERBB2 expression and a lower expression of luminal genes, both associated with response to anti-HER2 treatment.

Persistence with adjuvant endocrine therapy in patients with early breast cancer at high risk of recurrence: a US-based real-world study

Presenting Author(s) and Co-Author(s):

Kristin M. Sheffield, *n/a, Sr. Director - Eli Lilly & Company*

Country: United Kingdom

Background: Previous studies have highlighted concerns regarding treatment persistence (TP) of patients with early breast cancer (EBC) taking adjuvant endocrine therapy (ET) but these data have not been analyzed based on patient's risk of recurrence. The aim of this study is to evaluate the TP of patients at high risk of recurrence based on clinicopathologic criteria used in the monarchE trial.

Methods: This observational retrospective cohort study used nationwide Flatiron Health electronic health record (EHR)-derived de-identified database of US patients diagnosed with EBC from Jan 2011 to Sept 2020. Overall, 4028 patients were selected based on the following criteria: adult female or male with diagnosis of HR+, HER2- EBC (stage IA-IIIC) with no evidence of distant metastasis who received surgical resection and adjuvant endocrine therapy. Patients were divided into 2 groups; GroupA: patients with clinicopathologic features suggestive of high risk of recurrence: ≥ 4 positive(+) axillary lymph nodes (ALN), OR 1-3+ ALN and either Grade3 disease, or tumor size ≥ 5 cm, or Ki-67 $\geq 20\%$. GroupB: patients with stage IA-IIIC disease who did not meet those high risk criteria. TP (time from start to discontinuation of adjuvant ET) was compared between the 2 groups. Patients who had a gap of >90 days after their last date of ET, as documented in the EHR, were considered to have discontinued ET. Patients whose last ET was ≤ 90 days from Sept 2020 were censored. Cumulative incidence functions of nonpersistence were estimated, treating recurrences or deaths occurring during ET as competing risks.

Results: While gender and race distributions were similar between groups, patients in GroupA (n=557) were younger and more likely to be premenopausal, have an ECOG PS score of 1 or 2+, and have received mastectomy, radiation and chemotherapy compared to GroupB (n=3471). Estimates of the cumulative incidence functions of nonpersistence were statistically different between the groups ($p < .001$). The Table shows the cumulative incidence (standard error) of nonpersistence at years 1-5 after initiating ET.

Conclusions: This study suggests that patients at high risk of recurrence have higher ET-TP than those at lower risk. The separation was most pronounced at 5 years. The steep increase

in 5-year nonpersistence in lower risk group could be due to a perception of less need to continue ET for longer periods of time in lower risk disease. The greater persistence in patients at high risk is noteworthy, but interventions to improve patient's TP are still warranted.

Cumulative incidence of nonpersistence after initiating ET

Risk Group	1 yr	2 yrs	3 yrs	4 yrs	5 yrs
GroupA	7.3% (1.1)	11.7% (1.4)	16.9% (1.8)	20.9% (2.0)	28.2% (2.5)
GroupB	9.6% (0.5)	14.6% (0.6)	19.3% (0.7)	24.6% (0.9)	43.6% (1.3)

Background Low-dose aspirin irreversibly inhibits the cyclooxygenase enzymes COX-1 and COX-2, which catalyze the formation of prostaglandins and thromboxanes, inhibiting platelet aggregation. Platelets are thought to play a role in tumorigenesis. As such, aspirin may have a beneficial effect on breast cancer prognosis, but results to date are conflicting. **Objectives** To evaluate the association between aspirin use and breast cancer recurrence up to 23 years after primary diagnosis. **Methods** We included all women diagnosed with non-metastatic breast cancer during 1996-2004 registered in the Danish Breast Cancer Group (DBCG) clinical database. We obtained information on aspirin prescriptions (≥ 2 prescriptions filled between

cancer diagnosis and the landmark) from the Danish National Prescription Registry. Information on early and late (>10 years after primary diagnosis) recurrence was obtained using the DBCG database (for recurrence within the first 10 years after diagnosis) and for late recurrence via a previously described and validated algorithm, drawing on data from the Danish National Patient Registry, the Danish Pathology Registry, the Danish Cancer Registry and a contralateral breast cancer database. We used Cox regression to compute crude and adjusted hazard ratios (HRs) with 95% confidence intervals (CI) employing landmark analyses starting follow-up at years 5, 10, 15, and 20 after primary diagnosis. We adjusted for potential confounders including calendar year of diagnosis, menopausal status, comorbidities, estrogen receptor status, clinical stage, grade, surgery type, chemo- and endocrine therapy, diagnostic codes for alcoholism and obesity, as well as co-medications (angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, statins, bisphosphonates, metformin, digoxin, hormone replacement therapy, non-steroidal anti-inflammatory drugs, and vitamin K antagonists). We followed patients until recurrence, death, second cancer, loss to follow-up, or 31 December 2018. Results Among 21,684 women with non-metastatic breast cancer, 4,902 experienced recurrence during 242,427 person-years of follow-up. Our landmark analyses showed a reduced hazard of recurrence in the 5-, 10-, and 15-year landmark cohorts (5-year landmark adjusted HR = 0.80, 95% CI = 0.68, 0.94; 10-year landmark adjusted HR = 0.84, 95% CI = 0.71, 1.00, 15-year landmark adjusted HR = 0.83, 95% CI = 0.61, 1.14). The 20-year landmark analysis revealed an adjusted HR of 1.09 (95% CI = 0.49, 2.46). Conclusions The potential anti-cancer effect of aspirin appears most pronounced in the first 15 years after breast cancer diagnosis. Funding Elisabeth Solmunde is funded by the Danish Cancer Society (R320-A18464-B5768) and the Independent Research Fund Denmark (1149-00013B). Dense breasts are associated with a higher risk of breast cancer diagnosis, which has impacted risk prediction tools and patient notification policies. However, given that mammography is less sensitive for women with dense breasts and these women may be subject to different confirmation testing pathways, the true association between breast density and cancer risk is unknown. We investigated the relationship between breast density and onset using a natural history model that accounts for differential sensitivity and rates of exams by breast density. Data consisted of Breast Cancer Surveillance Consortium mammogram and cancer outcomes among women aged 40-54 with a first digital mammogram between 2000-2018 (N=33,542). Of these, 15,092 had non-dense (almost entirely fatty or scattered fibroglandular densities) and 18,450 had dense (heterogeneously dense or extremely dense) breasts. We estimated the empirical sensitivity of mammograms in dense and non-dense breasts (fraction of diagnosed cancers that were screen detected) and examined rates of mammograms by density. We estimated the relative risk of breast cancer diagnosis five years after the first exam using Kaplan Meier methods and the relative risk of breast cancer onset from a natural history model, assuming density-specific sensitivity was equal to the empirical sensitivity. Empirical sensitivity was .88 in women with non-dense and .78 in women with dense breasts. Mammogram utilization was somewhat higher in women with dense breasts (HR for subsequent mammograms 1.10 (95% CI [1.07, 1.12])). The relative risk of diagnosis for dense versus non-dense breasts was 1.80 (95% CI [1.46,2.57]); based on the natural history model the relative risk of onset was 1.73 [1.43,2.25]. The estimated relative risk of onset ranged from 1.67 to 2.03 under assumptions that the relative sensitivity of the screening episode for dense versus non-dense breasts was 1.0 to 0.4. In conclusion, the association of risk of breast cancer onset with breast density is robust to assumptions about the relative sensitivity in dense and non-dense breasts.

Background: Introduction: Cancer is the second leading cause of death worldwide. Every year 10 million cancer deaths are reported, 70% of which occur in low- and middle-income countries (LMICs). Breast cancer in the world is the second in incidence and the second in mortality. In Costa Rica cancer incidence occupies first place in incidence and fourth place in deaths. The Costa Rican health system is a public and universal system called the Costa Rican Social Security Fund (CCSS) and information on cancer is collected by the National Tumor Registry (RNT) which is governed by the Ministry of Health. Objectives: We sought to develop the first population-based description of the characteristics of women diagnosed with breast cancer in Costa Rica. This analysis allows us to measure the burden of breast cancer in Costa Rica and will enable assessments of quality of prevention, treatment, and care. These data will also inform how the burden of breast cancer in Costa Rica compares to other nations. Methods: Data from all patients registered in the CCSS with breast cancer was collected between January 2008 and December 2012. We evaluated sociodemographic, clinical, and treatment related characteristics. In this analysis we performed using SPSS, STATA version 17, and infostat. Results: In the CCSS, we identified 4,775 women of which 3,836 were diagnosed and 391 did not have clinical records. A total of 3,160 women were analyzed in the study. The mean age of diagnosis was 59.1 years old, 32.5% diagnosed were older than 65 years. 50.6% of the tumors originated in the left breast and 46.9% in the right breast. 50.7% of the tumors were in the superior outer quadrant. For diagnosis, core needle biopsies were used in 46.5% of the cases. About 60% of cases were diagnosed in early stages (IA, IIA, IIB), and 1.7% of cases in metastatic stages. Less than 40% of cases have positive lymph nodes and 76% of cases were infiltrating ductal carcinoma. Moderately differentiated tumors (40.7%) prevailed over poorly or well differentiated tumors. The most frequently affected site by metastasis was bone (3.0%). Most tumors did not have vascular (63.0%) or lymphatic invasion (52.5%) 80% are Ki-67 negative. We measured treatment-related characteristics and found that the average waiting time between diagnosis and surgery was 72 days, 77.9% waited less than 90 days for their treatment and the rest waited >90 days. 88.7% received surgery as the first treatment, 54.4% received some type of adjuvant and the combination of treatments was used in 58.3% of the patients. 85.6% of the patients successfully completed their treatment. Discussion: This study is the first to describe the population with breast cancer in Costa Rica using data from the National Tumor Registry. Currently, only 3 of Latin American (LATAM) countries have high

quality cancer registries and 20 of LATAM nations have a national registry. Some of the findings coincide with what is described in the world literature. We also identified novel information such as the impact of insurance type, occupation, and age on breast cancer that will inform the CCSS how the existing protocols for the care of breast cancer in Costa Rica can be improved.

Title: HER2 + Breast Cancer in Afro-Caribbean Women in New York City Emanuela Cimpeanu¹, Eve Frangopoulos¹, Ana M Ventura¹, Edwin Chiu², Bo Lin³, Evelyn Taiwo^{2,4}
¹Department of Medicine, Division of Hematology and Oncology, State University of New York, Downstate Medical Center, Brooklyn, NY ² Department of Medicine, Division of Hematology and Oncology, Kings County Hospital Center, Brooklyn, NY ³ Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX ⁴ Department of Medicine, Division of Hematology and Oncology, Weill Cornell Medical College, New York, NY
Background: Human Epidermal Growth Factor receptor 2 (HER2) protein overexpression and/or amplification positive breast cancer accounts for 14% of breast cancer cases in the United States. The use of anti-HER2 targeted therapy in combination with chemotherapy has resulted in better response rates leading to better outcomes in patients with this breast cancer subtype. Few studies directly investigate breast cancer outcomes in Afro-Caribbean women in the U.S, and fewer studies have investigated HER2 positive (HER2+) disease in this patient group. We describe the clinicopathologic characteristics and outcomes of HER2+ breast cancer in this minority patient group. Methods: This is a retrospective study conducted at Kings County Hospital (KCH), a public hospital in Brooklyn, a New York City borough with the highest population of Afro-Caribbeans in the United States, outside of Miami, Florida. Data of patients diagnosed with breast cancer from 2015-2018 was collected from the hospital's tumor registry. Clinical and pathologic data was collected and analyzed with descriptive statistics and Chi-

square testing. Results: A total of 299 women with breast cancer were screened and 18% (54) had HER2+ disease. 63% (34) of these patients were post-menopausal, with median age 56. 78% self-identified as Afro-Caribbean. 19% (11) of patients reported first- or second-degree relatives with a breast cancer diagnosis, 22% (13) reported first-degree relative with non-breast malignancy. Half of the patients younger < 45 years age reported a positive family history of any type of cancer. 74% of patients presented with Nottingham Grade 3 disease, 31% with localized disease, without lymph node involvement, 52% with regional lymph node involvement, and 17% with distant metastasis. 63% of patients were estrogen receptor (ER) positive and 37% were ER negative. Post-menopausal women presented with higher rates of lymph node involvement at 70.4% vs. 50% in pre-menopausal women (p=0.17). 41% (22) of patients received neoadjuvant chemotherapy while 31% received adjuvant therapy with standard chemotherapy and anti-HER2 targeted treatment. Of the 22 patients who received neoadjuvant treatment, 14% had complete pathologic response, 68% had partial response, and 18% had disease progression. Treatment response to neoadjuvant therapy was independent of lymph node status (90.9% in local disease vs. 85.7% in lymph node involvement, p=0.66). The median progression free survival was 48 months, overall survival at 7 years was not reached, and mortality rate was 16.7%. Conclusions: In our analysis, Afro-Caribbean patients with HER2+ breast cancer presented with high grade tumor, high incidence of regional lymph node involvement, and ER positive tumors. Noteworthy was the presence of strong family history of cancers, suggestive of familial or inherited cancers. Pathologic complete response to neoadjuvant chemotherapy was remarkably less than anticipated, and further research is warranted to study tumor biology and responses to standard HER2 systemic therapies in these patients. Jesus Anampa Mesias, MD, MS, Associate Professor - Albert Einstein College of Medicine, Bronx, NY

Country: United States

Background: Breast cancer(BC) is a common female malignancy [1]. Triple-negative breast cancer (TNBC) is the least common (10-15% of cases)[2], but the most aggressive subtype. TNBC accounts for 5% of all-cancer-related deaths every year[3, 4].Hispanic women are 1.3 more likely to develop TNBC [3, 5]. Whether Hispanic and non-Hispanic patients suffering from TNBC show different survival. We aim: (1) to evaluate the differences in overall (OS) and breast cancer specific survival(BCSS) between Hispanic(H) and non-Hispanic black (NHB) women in non-metastatic TNBC, and (2) to assess the contribution of sociodemographic, clinical, and neighborhood factors to TNBC survival disparities. Methods: With the SEER database of the National Cancer Institute, we identified 4271 (39%) H and 6594 (61%) NHB patients who were diagnosed with non-metastatic TNBC between 2010 and 2016. Patients with tumor in situ were excluded from the analysis. Logistic regression was used to identify odd ratios for treatment modalities. Kaplan-Meier methods were used to estimate OS and BCSS. Competing risk analysis was used to asses the association between race/ethnicity and risk of breast cancer mortality adjusting for age, insurance, social, SDI, rurality, BC stage, tumor grade, surgery, chemotherapy, and radiation therapy. Results: The mean age at diagnosis for H vs. NHB was 53 and 56 years, respectively ($p < 0.001$). 54% of Hispanics were married vs. 35 % of NHB, $p < 0.001$. Tumor size > 5 cm was present in 14% NHB vs. 12% H patients, $p < 0.001$. Grade I tumors were only 1 % in both groups, grade II were 13% and grade III-IV were 82% also in both groups, $p > 0.99$. H (28% stage I, 50% stage II) had more advance disease as compared to NHB (30% stage I, 48% stage II) [$p < 0.001$]. Private insurance was more common in NHB than H (74% vs. 66%, $p < 0.001$). Rural residence was more common in NHB than H (8% vs. 3 %, $p < 0.001$). High level of SDI was more common in H as compared to NHB(43% vs. 36%, $p < 0.001$). Surgery was performed in 92% of NHB and 91% of H, $p = 0.03$. Radiation was given to 54% of NHB and 43% of H, $p < 0.001$, while chemotherapy was given to 79% of NHB and 79% of H patients, $p = 0.54$. After adjusting for clinicopathological features, the odds ratio (ORs) for receiving surgery, radiation, and chemotherapy for NHB as compared to H were 0.9 ($p = 0.32$), 1.57 ($p < 0.001$), and 0.89 ($p = 0.03$), respectively. The 5-year OS and BCSS rates were higher in H as compared to NHB(OS 76% vs. 72% , $p < 0.001$; BCSS 81% vs. 78%, $p < 0.001$). For stage I patients, neither 5-year OS (86% vs. 89%, $p = 0.054$) nor BCSS (91% vs. 93%, $p = 0.37$) was different between NHB and H patients. For stage II and III patients, the 5-year OS rates for Hispanics vs. NHB were (79% vs 74%, $p < 0.001$) and (51% vs 45%, $p < 0.004$), respectively. After adjusting for age, marital status, insurance, stage, grade, treatment, SDI, rurality; NHB have higher risk of BC death as compared to H patients (subdistribution Hazard Ratio (HR) = 1.39; 95% CI 1.2 – 1.56, $p < 0.001$). The association between race/ethnicity and risk of breast cancer death was not affected by age ($p = 0.44$) , insurance($p = 0.89$), SDI($p = 0.40$), or living in a

rural area($p=0.14$). The risk of BC death between NHB and H was even higher for patients who did not receive radiation (HR 1.5) than in those who received radiation (HR 1.2). The risk of BC death between NHB and H was also higher for patients who did not undergo surgery (HR 1.7) than in those who underwent surgery (HR 1.3). Conclusions: In patients with non-metastatic TNBC, H patients present with increased rates of high-grade and advanced stage tumors than NHB. NHB are 57% more likely to receive radiation and 11% less likely to receive chemotherapy than H women. NHB patients have a 39% higher risk of BC death as compared to H even after adjusting for clinicopathological, treatment and socioeconomic factors. Future studies need to assess potential etiologies for racial disparities in BC outcomes such as differences in tumor microenvironment, access to healthcare, tumor biology and treatment efficacy.

BACKGROUND: Japan is the globe's fastest ageing country: 32.0 % of the female population are 65 or older in 2021. The birth rate was 1.30 children per woman in 2021. Japan's population has been constantly shrinking since 2011 with aging. The number of breast cancer cases has increased rapidly in the course of low birth rate and aging population. Breast cancer has increased and accounted for the first place of all of cancers in Japanese women.

OBJECTIVES; Number of breast cancer has increased recently and accounted for the first place of all of female cancers in Japan. Detailed analytics of the increase and aging of breast cancer are not studied. We elucidate the transformation of Japanese breast cancer by ages at diagnosis over the past decade. **MATERIALS:** We used the registry data of Japanese Breast Cancer Society and Statistics Bureau of Japan in 2018. Female breast cancer new cases were 59,389 patients in 2008 and 93,858 patients in 2018, respectively. The total female population was 65.441 million in 2008 and 64.911 million in 2018, respectively. 65 years and older women accounted for 23.4% in 2008 and 31.0 % in 2018, respectively. **METHODS:** We compared incidences and incidence rates of breast cancer by ages in 2008 and 2018, respectively. We used the statistical method of Ameijeiras-Alonso et al for mode assessment. **RESULTS;** Total number of incidences and incidence rates of breast cancer in 2018 were higher than those in 2008 among all ages. Difference of number of incidences were maximum in age of 60-69 in both years. Difference of incidence rates in both years reached maximum in age of 75-79. Incidence rates in 2008 showed unimodal age distribution with the gentle peak. Incidence rates in 2018 showed bimodal age distribution with two peaks of 45-49 and 65-69. **CONCLUSIONS;** Incidences and incidence rates of breast cancer increased rapidly among all ages in this decade in Japan. The incidence rates increased most in ages of 75-79 and turned into bimodal age distribution in 2018.

Country: China (People's Republic)

Kamila Czene, *n/a, Professor - Karolinska Institutet*
Country: Sweden

Background: False-positive mammography recalls are common and associated with an increased risk of subsequent breast cancer. But the long-term risk and whether the risk restricts to the breast cancer detected on the false-positive recalled side remain unclear. Objective: To examine long-term risk of breast cancer after false-positive recalls by side of breasts, mode of detection and tumor characteristics. Design: Matched cohort. Setting: The mammography screening program in Stockholm, Sweden. Participants: We included 45,588 women who received false-positive recalls (1991-2017) and 455,880 matched women who were not recalled, and then followed them until March 31st, 2020. Measurement: Breast cancer incidence; mode of breast cancer detection; tumor characteristics; re-attendance at mammography screening. Results: With Kaplan-Meier curves, we showed that women with false-positive recalls were more likely than those without to have breast cancers, on not only the previously recalled (false-positive) side but also the unrecalled side, up to at least 20 years since the next scheduled screen. We further found that risks were particular higher for breast cancer diagnosed on the false-positive side within first four years of follow-up (hazard ratio [HR]: 2.40; 95% confidence interval [CI]: 2.17-2.65), by the use of stratified Cox model while allowing for time-varying effects. In addition, when stratifying by age at matched mammograms, we found the association was stronger among old women (60-74) than young women (40-59). This was consistent with the result that the risk of breast cancer was higher among women with low density than those with high density. Of note, within the first four years, women with false-positive recalls were at an increased risk of clinical detected cancers (cancer detected among women who did not attend last scheduled screen or were at an age out of screening age ranges) on the false-positive side compared with those who were not recalled. In addition, we found that women with false-positive recalls had statistically significantly lower re-attendance rates at every of next five scheduled screenings. Conclusion: Women with false-positive recalls are at an increased risk of breast cancer for at least two decades, while these women are less likely to adhere to subsequent mammography screens comparing to women who were not recalled. Thus, women with false-positive recalls, especially older women, should be encouraged to re-attend the mammography screening program.

Background: Early studies reported a 4-6-fold risk of breast cancer between women with extremely dense and fatty breasts. As most early studies were case-control studies, we took advantage of a population-based screening program to study density and breast cancer incidence in a cohort design. Methods: In the Capital Region, Denmark, woman aged 50-69 are invited to screening biennially. Women screened November 2012 - December 2017 were included, and classified by BI-RADS density code, version 4, at first screen after recruitment. Women were followed up for incident breast cancer, including ductal carcinoma in situ (DCIS), to 2020 in nationwide pathology data. Rate ratios (RR) and 95% confidence intervals (CI) were compared across density groups using Poisson-regression. Results: We included 189,609 women; 1,067,293 person-years; and 4110 incident breast cancers/DCIS. Thirty-three percent of women had BI-RADS density code 1; 38% code 2; 24% code 3; 4.7% code 4; and missing 0.3%. Using women with BI-RADS density code 1 as baseline; women with code 2 had RR 1.69 (95% CI 1.56-1.84); women with code 3, RR 2.06 (95% CI 1.89-2.25); and women with code 4, RR 2.37 (95% CI 1.05-2.74). Results differed between observations accumulated during screening and above screening age. Conclusions: This cohort study showed a 2.37-fold difference in breast cancer risk between women with highest and lowest breast density. Translated into absolute risk of breast cancer after age 50, this was a 6.2% risk for the one-third of women with lowest density, and 14.7% for the five percent of women highest density.

Population-based survival outcomes of pure vs mixed invasive lobular breast carcinoma in Ontario, Canada

Presenting Author(s) and Co-Author(s):

David Lim, MDCM MEd PhD FRCSC, *Breast Surgical Oncologist - Women's College Hospital*

Office Phone: (416) 323-6225

City: Toronto

State: Ontario

Steven Narod, MD, *Scientist - Women's College Research Institute*

Country: United States

Kelly Metcalfe, RN, PhD, *Professor - University of Toronto*

Country: United States

Purpose: We aim to determine incidence and survival rates of pure vs mixed invasive lobular breast carcinoma between 1990 and 2020 in the province of Ontario, Canada. We further evaluated patient and tumour factors that predict survival for invasive lobular carcinoma (ILC). **Methods:** Using population-based administrative healthcare datasets at Institute of Clinical Evaluative Sciences (ICES) Ontario, we calculated the crude 5-year incidence rates of pure ILC versus invasive ductal carcinoma (IDC) versus mixed ILC-IDC in the province of Ontario, Canada between 1990 and 2020. Kaplan-Meier survival curves were generated to determine the 5-, 10-, 15- and 20-year survival for ILC (and mixed ILC-IDC) as compared with IDC. Survival curves were compared using the log-rank test and stratified by stage. Using a multivariable Cox proportional hazards regression analysis, we identified patient (e.g. demographic, geographic, socioeconomic) and tumour (grade, stage, receptor subtype) factors that predicted survival for patients with ILC. Statistical analysis was performed using SAS® and P values < 0.05 were considered statistically significant. **Results:** We identified 18,551 (8%) pure ILC, 10,234 (4%) mixed ILC-IDC and 192,371 (81%) IDC cases. The crude incidence of pure ILC increased from 55.7 per 100,000 in 1990 to 80.2 per 100,000 in 2020. The crude incidence of mixed ILC-IDC peaked in the mid-2000s at 48.6 per 100,000 and subsequently declined to 32.1 per 100,000 in 2020. There was a significant difference in overall survival between the three breast cancer subtypes. Over a 30-year follow-up period (mean 9.3 +/- 7.3 years), overall survival of mixed ILC-IDC mirrors the survival of pure IDC, while women with pure ILC have inferior survival compared with IDC beginning after 10 years of follow-up (P < .001). The 20-year overall survival was 40% for ILC and 50% for IDC and mixed ILC-IDC. Older age > 55 years (vs. 50-54 years, P < .0001), lowest neighborhood income quintile (HR 1.1, P = .038), geographic location within Ontario (P < .01) and increasing Elixhauser Comorbidity Index score (P < .0001) predicted worse overall survival for ILC patients. Conversely, the increasing number of mammograms received in the five years prior to diagnosis predicted better overall survival (P < .0001). When stratified by cancer stage, the worse survival in ILC (compared with IDC and mixed ILC-IDC) was only observed for stage III patients (P = .01). Stage III and IV disease, grade 3 histology and ER/PR negativity predicted worse survival (P < .01). **Conclusion:** The crude incidence of ILC is increasing over time. Over a 30-year follow-up period (mean 9.3 +/- 7.3 years), ILC had worse overall survival compared with IDC and mixed ILC-IDC, particular

stage III patients. Patient demographic and tumour factors predict overall survival in ILC. While treatment paradigms for ILC mirror that for IDC, our data demonstrates worse overall survival for ILC and a need for more research and treatments focused on improving long-term survival for ILC patients.

Background: Individual environmental contaminants have been associated with breast cancer; however, evaluations of multiple exposures simultaneously are limited. The USPA has constructed an environmental quality index (EQI), which contains county-level environmental exposure data across five overarching environmental domains (air, water, land, sociodemographic, and built environment). Unfortunately, the links made between breast cancer and the EQI are lacking because these analyses used total breast cancer incidence quantities, masking potential associations between EQI domains and specific stages of disease. In this study, we investigated if multiple exposures in broad EQI domains was associated with incidence of breast cancer, stratified by stage.

Methods: The EQI data was linked to county-level age-standardized incidence rates (SIRs) obtained from the North Carolina Central Cancer Registry/NC CCR (2010-2014), a reporting system for all cancer cases diagnosed in residents of the state. Incidence rates and SIRs of total, in situ, localized, regional, and distant breast cancers were evaluated stratified by rural-urban status. Associations between county-level age-adjusted cancer incidence rates for each summary stage were assessed using general linear models (SAS 9.3), linear models with a continuous outcome with a p-value cutoff for statistical significance set at $p < 0.05$. We also evaluated incidence rates by summary stage comparing across rural versus urban counties using Mann-Whitney rank tests, since not all stages were normally distributed, confirmed by the

D'Agostino-Pearson normality test.

Results: In counties with poor environmental quality compared to those with good environmental quality, total breast cancer incidence was higher by 10.82 cases per 100,000 persons (95%CI: 2.04, 19.60, $p=0.016$). This association was most pronounced for localized breast cancer ($\beta=5.59$, 95%CI: 0.59, 10.58, $p=0.029$). Higher incidence of early-stage disease (carcinoma in situ $\beta=5.25$, 95%CI: 2.34, 8.16, $p=0.001$ and localized breast cancer $\beta=6.98$, 95%CI: 2.24, 11.73, $p=0.004$) and total breast cancer ($\beta=11.44$, 95%CI: 3.01, 19.87, $p=0.008$) occurred in counties with poor land quality, especially urban counties. Overall, NC counties averaged 21.6% percent African American (AA) which is higher than the US national average of 12.6% at the time of the U.S. 2010 Census. The percentage of AA in each county in bivariate analyses was associated with increased incidence of regional (incident cases 0.12 cases per % increase in AA population, 95% CI 0.01, 0.22, $p=0.022$) and distant breast cancers (incident cases 0.06 per % increase in AA population, 95% CI 0.02, 0.10, $p=0.003$) (Table 1). In addition, in stratified models, associations persisted and were strengthened in urban county models for regional breast cancer and in rural county models for distant breast cancer.

Conclusions: Environmental quality is variable across NC akin to variability across the US, as the interquartile range (25th-75th percentile) of total EQI in NC is -0.187 to 0.734 while the interquartile range is -0.606 to 0.706 for the US (USEPA), making NC EQI analyses generalizable to a number of states and counties across the U.S., although what drives poor environmental quality varied by region and by county. Our analyses indicate significant associations between EQI and breast cancer incidence, which differ by breast cancer stage and urbanicity, identifying a critical need to assess cumulative environmental exposures in the context of cancer stage. Funding: Duke Cancer Institute seed grant (GRD, KH) as part of the P30 Cancer Ctr grant; Duke Environmental Health Scholars Award and NIEHS T32-ESO21432-05 (LMG).

AN EVALUATION OF BREAST CANCER RECURRENCE DATA REPORTED TO THE NCI SEER PROGRAM

Presenting Author(s) and Co-Author(s):

Esmeralda Ramirez-Pena, n/a, *Cancer Prevention Fellow - National Cancer Institute*

Cell Phone: (832) 600-1132

City: Bethesda

State: Maryland

Country: United States

Serban Negoita, MD DrPH, *Chief of Data Quality, Analysis, & Interpretation Branch - National Cancer Institute/ Division of Cancer Control and Population Sciences*

Country: United States

Background: There are currently 18.1 million cancer survivors in the U.S. and the number is expected to increase to 22.5 million in the next ten years. The increasing number of survivors also means that the population at risk for cancer recurrence will increase. Recurrence significantly impacts patients' health outcomes because there are limited treatment options. Currently, there are limited population level recurrence data in cancer registries world-wide. Most recurrence estimates have been derived from randomized clinical trials (RCTs) where the patient population only represents 4% of all cancer patients. Since 2018 the National Cancer Institute's Surveillance, Epidemiology and End Results (SEER) program has been collecting abstract-based recurrence information. Our goal is to use the SEER recurrence data sources to develop a high-quality population-based recurrence database to disseminate to the public for future research. Measuring recurrence from population-based cohorts can enhance our understanding of what clinical, demographic, and geographic factors impact the risk of recurrence and can inform researchers on developing prevention strategies. Methods: In November 2021 we obtained a dataset that included recurrence information such as type of first recurrence (defined by the Standard for Oncology Registry Entry manual) and date of first recurrence. To evaluate the burden of breast cancer recurrence in the U.S. SEER population, we described the cohort of women diagnosed with breast cancer from 2010 to 2019. We then evaluated the patients with information on the status of recurrence including those that never experience recurrence and those that were never disease free (NDF). We measured frequencies of recurrence by multiple clinical variables such as age at diagnosis, race, stage at diagnosis, and tumor subtype. We followed patients from their date of diagnosis to the event defined by first recurrence, second primary, death, or last contact. We used the Kaplan-Meier method to estimate DFS. Results: The analytic dataset included 412,920 female breast cancer cases diagnosed between 2010 and 2019. Most women diagnosed with breast cancer were between 40 and 64 years old (53%, n=218,760), were White (78%, n= 320,555), were diagnosed with localized tumors (52%, n=213,824), were HER2 negative (HER2-) hormone receptor positive (HR+) (56%, n=230,874), and received treatment (95%, n=390,959). During the observation period, 67% (n = 278,098) of women did not have a recurrence, 3% (n=10,922) had a recurrence, and 16% (n=66,319) were NDF. After excluding patients with NDF status, we observed that the age group with the highest frequency of recurrence was 20-39 (9%). For reference, 4% of women in the 40 to 64 age group has a recurrence event during the observation period. Black women had higher recurrence (6%) compared to white women (3%). Triple negative breast cancers had the highest recurrence (9%) out of all subtypes. When we measured DFS, we observed significant differences by race, independent of tumor subtype. For

example, in patients with HER2+/HR+ tumors, the percentage of patients at 120 months who did not experience a DFS event were 73.6% (95% CI, 72.3% to 74.9%) in white women and 67.5% (95% CI, 63.9% to 70.8%) in black women. Discussion & Conclusion: We are reporting population-based recurrence estimates for breast cancer obtained through the SEER program. This is the largest breast recurrence database in North America. The size of the database allowed precise estimation of recurrence stratified by demographics, subtype, and extent of disease. We observe trends consistent with previous reports and have identified some novel findings that warrant further study. Our long-term goal is to assess how DFS estimates derived from a population-based cohort compares to previously published estimates which are largely derived from RCTs.

Background: Dietary patterns promoting chronic inflammation, including the empirical dietary inflammatory pattern (EDIP), have been shown to strongly influence risk of weight gain, type 2 diabetes, cardiovascular disease, and colorectal cancer. However, it is unclear if this dietary pattern is associated with other tumors in which the mechanisms are not totally understood such as breast cancer. Methods: We prospectively followed 76,295 women from the Nurses' Health Study (NHS, 1984-2016) and 91,078 women from the Nurses' Health Study II (NHSII, 1991-2017). Diet was assessed by food frequency questionnaires (FFQs) every 4 years. The

inflammatory potential of diet was evaluated using the previously established EDIP based on plasma C-reactive protein (CRP), interleukin-6 (IL-6), and tumor necrosis factor alpha receptor 2 (TNF- α R2). Higher scores indicate higher inflammatory potential of the diet. Results: During 4,153,676 person-years of follow-up, we documented 10,632 invasive breast cancer cases (6,807 NHS; 3,825 NHSII). In the pooled multivariable-adjusted analyses, women in the highest, compared with the lowest, EDIP quintile were at higher breast cancer risk (HRQ5vsQ1=1.12; 95% CI 1.05, 1.20; P-trend< 0.001). This association was attenuated after adjusting for weight change since age 18 y, although it remained significant (HRQ5vsQ1=1.07; 95% CI 1.00, 1.14; P-trend=0.01). In subtype analyses, we found evidence that the inflammatory potential of diet influenced breast cancer risk differentially by ER status (P-heterogeneity=0.038) and by molecular phenotype (P-heterogeneity=0.007), with the association between EDIP and breast cancer limited to ER-negative tumors (HRQ5vsQ1=1.31; 95% CI: 1.11, 1.55; P-trend=0.002; for ER-positive tumors, HR Q5vsQ1=1.03; 95% CI, 0.96, 1.12;P-trend=0.10) and basal-like tumors (HRQ5vsQ1=1.78; 95% CI: 1.19, 2.65; P-trend=0.004). Further adjustment for weight change since age 18 y did not materially alter the association for these subtypes. Conclusions: Dietary patterns with high potential to contribute to chronic systemic inflammation, based on higher EDIP scores, were associated with a modestly increased risk of breast cancer, which was more pronounced for ER-negative and basal-like breast tumors.

Background

Prior data has been conflicting about how age at diagnosis impacts patient outcomes and survival. Some studies suggest that younger age at diagnosis may negatively affect survival, independent of other disease characteristics. Accurate predictions of outcomes and patterns of relapse provide invaluable information to patients and help inform physician treatment recommendations, such as the role of extended adjuvant endocrine therapy.

Purpose

To determine the relapse free survival and overall survival data for all patients diagnosed with invasive breast cancer and treated at BC Cancer from 2005 to 2014.

Methods

Using the BC Cancer Breast Cancer Outcomes Unit (BCOU) database, we identified all patients referred with newly diagnosed invasive breast cancer at any stage between 2005 and 2014. For descriptive statistics, we analyzed clinical and pathological features at diagnosis and treatment specific variables compared across the following age cohorts: < 35, 35-39, 40-49, 50-59, 60-69, 70-79, and 80 years of age or more.

To model the non-linear relationship of age at diagnosis as a continuous variable with the risk of relapse and death, we used an additive Cox proportional hazards model adjusting for subtype, LVI status, use of RT, chemotherapy, hormone therapy, and nodal status. We employed the fitted model to extract estimates for specific values of age while fixing other covariates at different values to create high and low risk cohorts. For subtypes Luminal B, HER2 positive and triple negative breast cancer, high-risk subgroups were defined as node-positive plus treatment with chemotherapy. Low risk was defined as Luminal A and node-negative. The extracted estimates were used to investigate the patterns of relapse among different ages via the means of adjusted cumulative incidence curves and to report the 10 year adjusted relapse free survival and overall survival estimates.

Results

We identified 24,469 patients who met the inclusion criteria with a median follow-up of 11.5 years. Patients < 35 and between 35-39 years of age were more likely to be diagnosed with breast cancer that was ductal histology, grade 3, LVI positive, HER2 positive, triple negative, and more advanced TNM stage at diagnosis. These younger patients were also more likely to undergo mastectomy, neoadjuvant and adjuvant chemotherapy compared to older age cohorts. Additive Cox proportional hazards revealed a statistically significant and clinically meaningful reduction in 10-year relapse free survival amongst patients with early-stage disease aged 30 and 35 as well as those aged 80, compared to patients aged 50 when adjusted for stage and treatment exposure. This was consistent across all high- and low-risk subgroups (Table 1). 10-year overall survival was significantly and meaningfully reduced in patients aged 30 and 80 compared to age 50 only amongst the high-risk patient populations.

Conclusion

Both younger and elderly age at breast cancer diagnosis were independent risk factors for poorer prognosis. To our knowledge, this is the largest patient cohort detailing such outcomes differences. Furthermore, this represents a more contemporary clinical context, compared to earlier publications. This work will help clinicians more accurately estimate disease trajectory, and may influence treatments recommendations. Other parameters for the entire cohort will be presented, including a more detailed identification and assessment of patient risk categories and its impact on outcomes.

Table 1

Background Tamoxifen is used to improve oncologic outcomes in a hormone receptor-positive breast cancer. High-dose tamoxifen induced ocular toxicities, and regular dose of tamoxifen is known to increase the risk of cataracts in landmark studies. The current study's objective is to review the incidence of cataracts in ductal carcinoma in situ (DCIS) patients who received adjuvant tamoxifen treatment, which can exclude the effect of other treatment modalities such as chemotherapy and target therapy. Method Data were obtained from the National Health Insurance claims database of the Health Insurance Review and Assessment Service in South Korea. Patients diagnosed with DCIS were sorted and retrospectively reviewed for the incidence of cataracts. The primary study outcome was the incidence of cataracts according to tamoxifen, and the incidence of cataracts was defined by concomitant diagnostic and behavioral code based on International Code of Disease, 10th revision. Results A total of 12,032 patients diagnosed with DCIS and received breast surgery from 2009 to 2015 were cut down to 4,759 patients, excluding those who already had cataracts, malignancies, or had developed cataracts within a year of breast cancer surgery. There were 3,037 patients who received tamoxifen and 1,722 patients who did not, median age of 49 years old. The incidence of cataracts was similar according to the use of tamoxifen, 7.6% and 7.7% respectively. The risk of developing cataracts did not increase with or without tamoxifen, even in the group who received adjuvant tamoxifen for more than two years (HR 0.978, 95% CI 0.782-1.222, p=0.843). The findings were consistent after propensity score matching (HR 1.072, 95% CI 0.829-1.388, p=0.595). Conclusions In a nationwide cohort study, the risk of cataracts in DCIS patients is similar whether the tamoxifen is used or not.

Background: Statins and low-dose aspirin have been associated with a reduced breast cancer (BC) incidence, but results are inconsistent. Based on emerging evidence that parity, a protective factor for breast cancer, and these drugs modulate immunity, we hypothesized that the association between drug use and breast cancer risk may differ by parity. Objectives: To assess the associations of statin and low-dose aspirin use with BC incidence according to parity in French and Danish cohorts. Methods: We conducted two cohort studies, using data from the French E3N study and a Danish nationwide population-based cohort, respectively. From E3N, 51,482 women, mean age 65.5 years, were enrolled in 2005 and followed until 2014. Data on parity (here full-term pregnancies), drug use, and incident BC were acquired from questionnaires, a drug reimbursement database, pathology verified self-reports and the national cause-of-death registry, respectively. From nationwide health registries, we included all Danish women free of BC and aged 45 years in 2000-2005 (n=198,575), with follow-up to 2014. Use of the exposure drugs were defined as at least two reimbursements/filled prescriptions. In both cohorts, multivariable-adjusted Cox regression was used to compute hazard ratios (HR) for drug exposure, treated as time-varying lagged variables, and BC risk stratified by parity (0, 1, 2, 3+). Results: In E3N and Denmark, 1,878 and 5,436 incident BC cases occurred in a mean follow-up of 8.5 and 11.5 years, respectively. At the end of follow-up, 35% and 19% of E3N and 16% and 8% of the Danish cohort had been exposed to statins and low-dose aspirin, respectively. In E3N, effect modification was observed between parity and statins, but not low-dose aspirin. For statins, the HRs for use vs no use were 1.29 (0.97-1.72), 1.27 (0.99-1.65), 1.08 (0.91-1.27), and 0.76 (0.61-0.95) among women with 0, 1, 2, and 3+ full-term pregnancies, respectively (p-het=0.005). The corresponding estimates for low-dose aspirin were: 1.17 (0.80-1.71), 0.81 (0.54-1.20), 1.13 (0.90-1.43), and 1.22 (0.93-1.61; p-het=0.6). In contrast, the

Danish data did not suggest any effect modification. HRs for use vs no use of statins were 0.82 (0.60-1.13), 1.05 (0.80-1.37), 0.91 (0.75-1.10), and 1.09 (0.83-1.44) among women with parity of 0, 1, 2, and 3+, respectively (p -het=0.3). For low-dose aspirin HRs were: 1.09 (0.75-1.59), 0.79 (0.54-1.15), 1.04 (0.82-1.32), and 0.99 (0.71-1.40; p -het=0.8). Conclusions: We observed effect modification by parity for the association between statins and breast cancer risk in the French but not the Danish cohort. Whether the age difference between the cohorts explains the inconsistent results should be explored.

Background:

Adjuvant endocrine therapy (AET) approximately halves the risk of recurrence among the two-thirds of premenopausal breast cancer patients whose tumors overexpress the estrogen receptor (ER+). AET is recommended for a minimum five-year duration, but many premenopausal women discontinue AET prematurely. Adherence to AET is dynamic and influenced by many behavioral, societal, clinical, and genetic factors. Describing longitudinal patterns of AET adherence is an important first step towards identifying patients at highest risk of nonadherence—and therefore recurrence—who may benefit from adherence-enhancing interventions. We used group-based trajectory models to (1) describe AET adherence patterns, and (2) estimate associations between AET adherence and breast cancer recurrence in a Danish premenopausal, ER+ breast cancer cohort.

Methods:

Our cohort included 4,487 premenopausal women diagnosed with ER+, stage I–III primary breast cancer registered in the Danish Breast Cancer Group (DBCG) clinical database and treated with AET (2002–2011). We followed all patients from initiation of AET until recurrence,

mortality, 10 years of follow-up, another primary malignancy, or the end of available follow-up. We excluded individuals with less than 1.5 years of follow-up as breast cancer recurrences that occur in this time are unlikely to be related to AET. At semi-annual follow-up visits, women were registered as having received (or not) a six-month supply of AET. We created daily indicators to determine if a woman had at least 80% of days covered by an AET fill within each six-month period for the first 4.5 years following AET initiation, yielding 9 variables indicating time-varying adherence. We used these indicators to characterize adherence trajectory groups. We defined recurrence as local, regional or distant metastases or contralateral breast cancer registered in the DBCG using follow-up data through 2017. We fit Cox regression models, adjusted for age and clinical factors, to estimate the association between adherence trajectory groups and recurrence.

Results:

We identified distinct trajectory groups in the cohort (Table 1)—high adherence (69%), slow decline (23%), and quick decline (8%). Women with quick decline were more likely to have stage I disease, have no positive lymph nodes, to not be treated with chemotherapy, and to have lumpectomy instead of mastectomy when compared to women with high adherence. Compared with high adherence women, the estimated rate of breast cancer recurrence was higher among those with slow decline (HR=1.12, 95%CI=1.04–1.21) and those with quick decline (HR=1.38, 95%CI=1.22–1.56).

Conclusions:

Group-trajectory modeling facilitated empirical description of AET adherence patterns in a premenopausal breast cancer cohort. As expected, women who more rapidly became AET-nonadherent were at increased risk of breast cancer recurrence compared with those who remained adherent. Future analyses will explore the contribution of specific socioeconomic, genetic, and clinical factors to AET adherence patterns, which will inform the design of interventions to improve AET adherence and reduce recurrence risk in breast cancer patients.

Table 1. Trajectory group and the observed proportion of individuals adherent to their adjuvant endocrine therapy (AET) over 4.5 years of follow-up

Time since AET initiation	Proportion of individuals adherent to AET		
	High adherence (69%)	Slow decline (23%)	Quick decline (8%)
0.5 year	1	1	1
1 year	1	0.90	0.74
1.5 years	1	0.89	0.64
2 years	1	0.98	0.44
2.5 years	1	0.92	0.26
3 years	1	0.90	0.08
3.5 years	1	0.83	0.06
4 years	1	0.71	0.05
4.5 years	1	0.59	0.05

P4-03-19

Expected real-world impact of escalation and de-escalation of Her2-directed therapy in breast cancer patients receiving neoadjuvant therapy.

Presenting Author(s) and Co-Author(s):

Background: For patients with palpable, early stage, Her2+ breast cancer, neoadjuvant therapy (NAT) is the preferred approach to curative treatment. While Trastuzumab (T) is standardly included in NAT protocols globally, there is variable ability to escalate or potentially de-escalate therapy due to perceived cost/benefit of additional Her2 targeting therapies, such as Pertuzumab (P) in the early stage setting. The impact of neoadjuvant Pertuzumab (NeoP) does have potentially significant impact on the need for therapeutic interventions in the setting of recurrence. It is challenging to estimate the real world impact financially on escalated therapy in the neoadjuvant setting and likewise the long-term effects of cost of recurrent therapy. We wanted to assess and estimate the impact of NeoP addition to T in British Columbian patients with Her2+ early breast cancer, and estimate incremental impact on short and long-term costs to our cancer system. Methods: Utilizing quality assurance database prospectively updated at BC Cancer Vancouver, we extracted cases of patients with Her2+ breast cancer who received NAT between 2012 – 2021 to provide real world estimations of prevalence of cases and estimated annual costs. Descriptive statistics were utilized to calculate rate of pCR in patients receiving neoadjuvant her2 directed therapy. Expected rates of improvement in pCR with the addition of NeoP were extracted from meta-analyses of Her2 directed therapy in the neoadjuvant setting. The publicly available national pCODR Economic Guidance Reports were utilized to identify cost per cycle per patient of Pertuzumab, Trastuzumab, TDM-1 and chemotherapy in the Canadian healthcare system. The additional cost of NeoP per centre, per year, was compared to the current cost of non-Pertuzumab containing neoadjuvant regimen. Based on recurrence data collected from the database, the expected impact of NeoP on rate of recurrence and subsequent need for Her2 directed therapy in the metastatic setting was calculated. Results: 347 patients with HER2+ breast cancer received neoadjuvant T + chemotherapy at the BC Cancer Vancouver Centre between May 2012 and May 2022. 137 patients (39.5%) achieved pCR and 210 (60.5%) did not achieve pCR. Of those who did not achieve pCR, 12% recurred and 6% died, compared to only 5% and 1% respectively in the group that did achieve pCR. Based on a risk ratio of 1.57, we calculated the expected rate of pCR in our real world cohort would have increased from 39.5% to 62.3% with the availability of NeoP routinely. For each year of data in our cohort, an average of 40 patients with Her2 positive disease were treated with neoadjuvant therapy. Using modeling based on our real world

cohort we predicted an added cost of \$669,920 to provide neoadjuvant pertuzumab at one Canadian Cancer centre per year. Based on extraction of data from current state, where adjuvant TDM-1 is provided for 13 cycles in the setting of no PCR, the adjuvant TDM-1 costs were estimated to be \$1,729,151 without NeoP and \$1,067,377 with NeoP. The cost difference for addition of NeoP in the treatment of early Her2+ breast cancer at one Canadian Centre per year was calculated as \$8,146 increase in cost. In patients who had recurrence in our cohort we observed a shorter median survival than expected with most patients succumbing to their recurrence within a 2-3 year period. We expanded our modeling to assess the incremental impact on estimated cost of treatment for those who may recur. We estimated a cost saving of \$85,054 per centre, per year, related to decrease in risk of recurrence of Her2+ breast cancer in those who receive NeoP. Conclusion: While the additional cost per centre of adding NeoP was \$8,146, the subsequent decrease in expected rate of recurrence resulted in a cost savings of \$85,054.

Background: The frequency of early estrogen receptor (ER)-negative breast cancers (BC) decreases with increasing age at diagnosis (Partridge P, JCO 2016). Giving birth is generally considered a protective factor for the occurrence of BC in a woman's lifetime. However, for up to more than 20 years following childbirth, BC risk may be higher. This appears to be due to an increase in hormone receptor-positive BC, especially in women older at the time of 1st childbirth (Nichols HB, Ann Int Med 2019). This means that the ER-negative BC are relatively less frequent in these 2 decades after delivery. In this study, we aimed at retrospectively investigating the impact of parity and age at first full term pregnancy (FFTP) on the frequency of ER-negative BC according to the age at diagnosis in a large institutional cohort of patients diagnosed with BC.

Patients and Methods: We considered all patients diagnosed and/or treated with early BC in UZ Leuven between January 2000 and November 2020. ER-negativity was defined as < 1% positive cells. Age at diagnosis was subdivided in categories of 5 years. Parous women could be having a low (1 or 2 children) or high parity (> 2 children) and age of FFTP was arbitrarily divided into < or \geq 27 years of age. BMI was considered a possible confounder and was corrected for. A logistic regression model was used for data analysis with ER-negative status as binary outcome and FFTP class and multiparity as explanatory variables. To test whether the difference in ER-negative proportions between FFTP classes depends on multiparity, we modelled the interaction between multiparity and FFTP class.

Results: We included 9955 consecutive female patients after excluding missing values. 8358 out of 9955 women had at least 1 child (84%). In our study population, parity as such was not an independent variable for BC subtype. Women with a FFTP \geq 27y as compared to those with a FFTP < 27y were less likely to have an ER-negative BC. The p-value for the interaction term between high parity (>2 children) and FFTP class equals $p= 0.0044$. Hence, there is statistical evidence to suggest that the differences between FFTP categories with regards to ER-negative BC may depend on multiparity. Table 1 shows a lower incidence of ER-negative BC in the FFTP \geq 27y group compared to the FFTP < 27y group in case of high parity. Table 2 shows the absolute proportion. These results seem to be independent of BMI.

Conclusion: Women with a FFTP at 27 years of age or older and more than 2 children have proportionally less ER-negative type breast cancers as compared to women with a FFTP before 27 years of age. This difference between FFTP classes is not observed in absence of high parity.

Table 1: effect of FFTP class by multiparity

Comparison	Group	Odds Ratio (95% CI)	P-value
FFTP>=27y vs FFTP <27y	1-2 children	1.027 (0.892;1.182)	0.7089
FFTP>=27y vs FFTP <27y	>2 children	0.665 (0.510;0.866)	0.0025

OR: odds ratio, CI: confidence interval

OR>(<)1: higher (lower) probability of ER-negative BC for FFTP>27y compared to FFTP <27y

Table 2: proportion of ER-negative breast cancer subtype

Age at diagnose	All	Parous	Age FFTP	All	Para 1-2	Para > 2

Hormone-receptor-positive (HR+) breast cancer (BC) accounts for around 70% of all BCs[1]. Targeting the estrogen-receptor (ER) pathway has been the therapeutic focus; however, a substantial subset of HR+ BCs are resistant to hormonal blockade. Addition of Cyclin-dependent kinases 4 and 6 inhibitors (CDKis) to endocrine therapy has demonstrated to improve progression-free and overall survival in patients with metastatic ER+ BC. However, these trials enrolled mostly non-Hispanic White patients, with minimal inclusion of non-Hispanic Black and Hispanic patients. The goal of this study is to assess survival trends for different racial/ethnic groups in patients with HR+ HER2- BC before and after introduction of the CDKis as standard of care (year 2015). Methods: Using the SEER database of the National Cancer Institute, we identified patients with metastatic HR+ HER2- breast cancer. We obtained patients with ICD-0-3 codes 8500/3, 8501/3, 8502/3, 8503/3, 8507/3, 8520/3, 8521/3, 8522/3, 8523/3 and 8524/3. We divided them in two time-based cohorts: patients diagnosed in 2010-2013 and patient diagnosed in 2015-2018. SEER*STAT and Kaplan-Meir methods were used to estimate breast cancer specific survival at 6, 12, 24, 36 and 48 months for each group. Trends in survival were compared among Hispanic (H), Non-Hispanic White (NHW), and Non-Hispanic Black (NHB) patients. Results: We identified 10,019 patients that met our inclusion criteria, 4,667 (47%) diagnosed during 2010-2013 and 5,352 (53%) diagnosed during 2015-2018. For the patients diagnosed during 2010-2013, there were 4610 (99%) female and 57 (1%) were male. In the 2010-2013 group non-Hispanic white patients were 3,124 (67%) vs. 3,443 (64%) in 2015-2018, Non-Hispanic black patients were 639 (14%) vs. 736 (14%) and 521 (11%) vs. 645 (12%) were Hispanic of any race. For the 2010-2013 group, 3,463 (74%) had bone, 884 (19%) liver, 239 (5%) brain and 1,222 (26%) lung metastasis. There were 3,830 (83%) ER+/PR+ tumors, 777 (17%) ER+/PR- and 60 (1%) ER-/PR+. For the 2015-2018 group, there were 5266 (98%) female and 86 (2%) were male. 4011 (75%) had bone, 961 (18%) liver, 257 (4%) brain metastasis and 1469 (27%) lung metastasis. There were 4,424 (82%) ER+/PR+ tumors, 876(16%) ER+/PR- and 52 (1%) ER-/PR+. The 48-month BCSS rate for all patients improved from 2010-2013 to 2015-2018 (46.3% vs. 40.2 %), with an absolute improvement in 7.4%, 1.4%, 3.6% for NHW, NHB, and H patients, respectively. The 36-month BCSS rate for all patients improved from 2010-2013 to 2015-2018 (55.6% vs. 51.3%), with an absolute improvement in 4.9%, 2.6% for NHW, H patients, respectively, whereas NHB showed an absolute decrease of 4.5%. The 12-month BCSS rate for all patients improved from 2010-2013 to 2015-2018 (81.5% vs. 80.2%), with an absolute improvement in 2.4% and 0.8% for NHW, and H patients respectively. For NHB there was an absolute decrease in survival of 2.4%. Conclusions: Using population data, we report that the 48-month BCSS has improved from 2010-2013 to 2015-2018 by about 5.9%. However, the magnitude of the improvement was

different by racial/ethnic groups. The magnitude of improvement in BCSS is higher in NHW as compared to NHB and H patients. Our results suggest that despite recent advancements in the management of ER+/HER2- metastatic BC, racial disparities in outcomes still persist which could be explained by either intrinsic genetic differences in response to novel agents or lack of access to them in some ethnical/racial groups.

Background: The Advanced Breast Cancer (ABC) program at The University of Texas MD Anderson Cancer Center was created by metastatic breast cancer (MBC) patients for MBC patients. The ABC Program seeks to improve quantity and quality of life for patients living with MBC. MD Anderson actively treats 2,076 patients living with MBC. ABC program patient advocates voiced the need to increase MBC patients' access to internal medicine services coordinated with oncology care.

Significance: Previous literature suggests patients living with MBC have difficulty receiving oncology coordinated internal medicine services due to their terminal diagnosis and indefinite prescription of anti-cancer treatment. Comorbidities in this setting are known to be associated with inferior outcomes. ABC Program patient advocates reported various challenges seeking care from community based medical professionals including, timely awareness of their local provider on the status of their cancer. Other challenges included the lack of familiarity of some providers with novel MBC cancer treatment, side effects, and interactions of their cancer

treatment with non-cancer conditions and treatment. Therefore, with the increasing life expectancy of MBC patients, there is a growing realization of the importance of managing the medical comorbidities in coordination with the MBC patient's cancer treatment.

Purpose: To increase access and coordinate internal medicine services for MBC patients with medical comorbidities.

Interventions: In partnership with ABC Program patient advocates, the Linking Internal Medicine and Metastatic Breast cancer for Success (LIMBS) clinic was created in February 2021. The LIMBS clinic aimed to bridge the gap in lack of oncology coordinated internal medicine service for MBC patients.

Evaluation: Breast Medical Oncology providers requested LIMBS clinic consults for 108 patients for comorbidity management since the clinic inception. This is a 44% increase in internal medicine consultations prior to LIMBS clinic creation (60 vs 108). The LIMBS clinic consults resulted in 474 follow up visits. Compared to MBC patients at MD Anderson, LIMBS patients were more likely to be African American (20% vs 13%) and were more likely to be older (59 years vs 57 years). Gender, marital status, and clinical trial enrollment did not differ between LIMBS patients and MBC patients. LIMBS patients had significantly higher rates of hypertension (46% vs 19%), Type II DM (19% vs 6%), hyperlipidemia (13% vs 10%), and hypothyroidism (13% vs 6%) compared to MBC patients in general. LIMBS patients had lower rates of anxiety (8% vs 11%) and depression (2% vs 7%) when compared to the MBC patients in general. The top 10 comorbidities for all MBC patients versus LIMBS patients are listed in Table 1.

Discussion: It is feasible to build and integrate internal medicine with breast medical oncology services for patients with metastatic breast cancer. Future research should focus on exploring, describing, and meeting the internal medicine needs of MBC patients. Future initiatives are needed to bridge the gap in care for oncology coordinated internal medicine services between community and tertiary care centers.

Table 1. Top 10 Comorbidities of all MBC patients versus LIMBS clinic patients

Table 1.

Top 10 Comorbidities of all MBC patients versus LIMBS clinic patients

Diagnosis	% MBC Patients (n=2,076)	% LIMBS patients (n=108)
Hypertension	19.4	46.3
Menopausal climacteric status	13.9	6.5
Allergic rhinitis	13.6	0.1
Gastroesophageal reflux	11.8	12.0
Anxiety	10.9	8.3
Hyperlipidemia	10.4	13.9
Osteoarthritis	7.6	4.6
Major depression	7.3	1.9
Diabetes Mellitus, Type II	6.3	19.4
Hypothyroidism	6.0	13.0

Note. This table demonstrates the top 10 comorbidities for MBC population and the LIMBS population.

Background: Atherosclerotic cardiovascular disease (ASCVD) and breast cancer are two of the most diagnosed chronic diseases among women in the U.S. Although prevention of ASCVD with statins is widely practiced, breast cancer chemoprevention with selective estrogen receptor modulators (SERMs) or aromatase inhibitors (AIs) is underutilized in the primary care setting, despite significant evidence in randomized controlled trials demonstrating its clinical benefits. We compared the risk of ASCVD and breast cancer among predominantly Hispanic women undergoing screening mammography, as well as uptake of statins and SERMs/AIs for ASCVD and breast cancer risk reduction, respectively, among high-risk women.

Methods: We conducted a retrospective cohort study among 1,655 English or Spanish-speaking women, age 40-79 years, with no prior history of breast cancer, who underwent screening mammography from 2014 to 2016 at Columbia University Irving Medical Center in New York City. Participants completed a survey collecting data on sociodemographic and

breast cancer risk factors and had available data in the electronic health record (EHR) for calculating ASCVD risk, including systolic blood pressure, total and HDL cholesterol, history of diabetes, treatment for hypertension, and current smoking status. The main outcomes included 5-year and lifetime invasive breast cancer risk according to the Gail model, and 10-year and lifetime ASCVD risk score according to the 2013 American College of Cardiology (ACC)/American Heart Association (AHA) ASCVD risk calculator. High-risk was defined as a 5-year invasive breast cancer risk \geq 1.67% and 10-year ASCVD risk \geq 7.5%. Secondary outcomes included uptake of chemoprevention with SERMs or AIs and statins among women at high-risk for breast cancer and ASCVD, respectively, based upon medication lists in the EHR. We compared mean lifetime risk of breast cancer vs ASCVD for the entire cohort using a paired t-test, and the proportion of high-risk women taking statins vs chemoprevention using McNemar's test.

Results: Among 1,655 evaluable women, mean age was 58 years (SD=10.1 years), with 76% Hispanic, 6% non-Hispanic White, 3% non-Hispanic Black, 2% Asian, and 13% other. About half (48%) of women met high-risk criteria for ASCVD compared to 15% who met high-risk criteria for breast cancer. Among all women, mean lifetime ASCVD risk was higher than mean lifetime breast cancer risk (10.71% vs. 5.46%, $p < 0.001$). Among women at high risk for ASCVD or breast cancer, respectively, statin uptake was higher compared to SERM/AI uptake for breast cancer chemoprevention (84% vs. 7%, $p < 0.001$). Overall, fewer Hispanic compared to non-Hispanic women met high-risk criteria for ASCVD (47% vs. 51%, respectively) and breast cancer (9% vs. 34%, respectively).

Conclusions: In a population of predominantly Hispanic women undergoing screening mammography, we found that more women met high-risk criteria for ASCVD compared to breast cancer. Among women at high risk for ASCVD, statin uptake was about 12-fold higher compared to uptake of breast cancer chemoprevention among women at high risk for breast cancer. Given significant underutilization of breast cancer chemoprevention, placing this in the context of prevention of other chronic diseases, such as statins for ASCVD, may enhance uptake of SERMs or AIs in the primary care setting.

Characteristic	Hispanics (N=1263, 74%)	Non-Hispanics (N=392, 26%)	Total (N=1655)	P-value
High-risk for ASCVD, N (%)				0.0165
Yes	597 (47.3)	201 (51.3)	798 (48.2)	
No	666 (52.7)	191 (48.7)	857 (51.8)	
High-risk for Breast Cancer, N (%)				<.0001

State variation in racial and ethnic disparities in triple-negative breast cancer rates: NPCR-SEER incidence data, 2015-2019

Presenting Author(s) and Co-Author(s):

Hyuna Sung, Ph.D., *Principal Scientist - American Cancer Society*

Country: United States

Background: Triple-negative breast cancer (TNBC) (i.e., estrogen receptor-negative, progesterone receptor-negative, and human epidermal growth factor receptor type 2-negative) is an aggressive subtype of breast cancer, more frequently diagnosed among non-Hispanic Black women than other racial/ethnic groups in the United States. TNBC risk also varies by location, but limited data exist for state-level variation in the racial/ethnic disparities in TNBC risk. Methods: Data for TNBC diagnosed at all ages during 2015-2019 were obtained from the National Program of Cancer Registries and Surveillance, Epidemiology & End Results for racial/ethnic groups classified as non-Hispanic American Indian/Alaska Native (AIAN), non-Hispanic Asian or Pacific Islander (API), non-Hispanic Black (Black), Hispanic, or non-Hispanic White (White). State-specific incidence rates were available for 8, 23, and 36 states for AIAN, API, and Hispanic women, respectively, and 38 states and Washington, D.C. for Black women and 50 states and Washington, D.C. (hereafter referred to collectively as “states”) for White women. State-specific rates were compared within and between racial/ethnic groups using incidence rate ratios (IRR). Results: Nationally, the age-standardized incidence rate of TNBC was the highest among Black women (25.1 per 100,000), followed by White (12.9 per 100,000), AIAN (11.1 per 100,000), Hispanic (11.1 per 100,000), and API (9.0 per 100,000) women. The highest state-specific rates were found among Black women in Delaware, Missouri, and Louisiana (>30 per 100,000) and the lowest rates were among API women in Oregon and Pennsylvania (< 7 per 100,000). State variations within a population were relatively larger among AIAN (2.8-fold) and Hispanic (2.3-fold) women, and smaller among White women (1.65-fold). Compared with White women, Black women had a higher rate of TNBC in all 39/39 states with the greatest IRRs in Delaware (2.31, 95%CI=1.90-2.81), Missouri (2.28, 95%CI=2.08-2.50), and Louisiana (2.20, 95%CI=2.02-2.38) and the lowest IRRs in Minnesota (1.38, 95%CI=1.12-1.68) and Colorado (1.38, 95%CI=1.12-1.68). In contrast, API women had a lower rate than White women in 22/23 states, except for Nevada, with the lowest IRR in Oregon (0.50, 95%CI=0.34-0.70) and the highest IRR in New York (0.82, 95%CI=0.75-0.90). The rate among Hispanic compared with White women did not differ statistically significantly in 23/36 states but was lower in 12/36 states, with the lowest IRR in Ohio (0.57, 95%CI=0.43-0.74), and higher in Massachusetts (1.21, 95%CI=1.04-1.39). The rate among AIAN compared with White women did not differ in 5/8 states but was lower in Arizona (0.53, 95%CI=0.38-0.73) and North Carolina (0.68, 95%CI=0.46-0.96), and higher in Oklahoma (1.30, 95%CI=1.09-1.54). Conclusions: State variations in TNBC incidence rates both within and between populations are

substantial, signifying the important role of potentially modifiable risk factors in determining the risk of TNBC by state and race/ethnicity. This finding highlights the need for more research to identify factors contributing to these variations to develop more effective preventive measures. Meanwhile, to mitigate the impact of the disproportionate burden of TNBC across states and racial/ethnic groups, universal access to screening modalities and timely, guideline-concordant treatments is essential.

Patient-level predictors of skipping screening mammograms during the COVID-19 pandemic at a large tertiary care center in Texas

Country: United States

Background:

Following the declaration of the COVID-19 national emergency, screening mammograms (SM) abruptly dropped across the United States. Stay-at-home orders discourage cancer patients from seeking care, and cancer screenings and surgeries were postponed. Upon resumption of screening services, rates of screening were slow to recover. At Baylor St. Luke's CHI (BSL), one of the largest tertiary care centers providing comprehensive cancer screening in Houston, we investigated patient level predictors, including comorbidities and area deprivation index (ADI), and the risk of skipping SM in the first year of the COVID-19 Pandemic.

Methods:

We used the local PENRAD database to retrieve the monthly gross number of SM performed at all BSL sites from 02/2018 to 01/2021. We obtained patient level data through EPIC, including address and demographics, comorbid conditions e.g., diabetes, hypertension, obesity (BMI \geq 30), chronic kidney disease and cardiovascular diseases (CVD). We identified ADI associated with patient addresses. We included patient who received at least one SM between 02/2018 to 01/2020. We compared patients did not get a mammogram in the first year of the pandemic; 02/2020 to 01/2021, to those who maintained screening during the pandemic. We performed a logistic regression analysis to assess the influence of age, 0 to +3 comorbid conditions, and ADI in quartiles on the odds ratio of skipping SM in the first year of the pandemic. Statistical significance was set at $p < 0.05$. The study was IRB approved.

Results:

Out of the 4591 women that screened in 2018 and/or 2019, only 1628 came back for SM in 2020 (35.5%). Women who obtained SM during the pandemic vs those who did not were slightly older, mean age 58 vs 56 (P< 0.001), were less likely to be living in the most deprived neighborhood, Q4 of ADI, 23.8% vs. 25.6%, more likely to be obese 39% vs. 35% (P< 0.001), more likely to have diabetes 48% vs. 41% (P< 0.001), more likely to have CVD, 16% vs. 13% (P< 0.001), and more likely to have hypertension 80% vs. 71% (P< 0.001). On multivariate logistic regression, living in Q4 ADI was associated with 22% higher risk of skipping SM in 2020 (95% CI 1.02-1.42), having one vs. two vs. three comorbid conditions increased the likelihood of obtaining SM in 2020 by 25% (95% CI 0.62-0.91) vs. 30% vs (95% CI 0.58-0.85), 42% (95% CI 0.48-0.7) compared to no comorbid conditions.

Conclusion:

Women living in Q4 of the ADI (most deprived neighborhood) were more likely to miss 2020 screening when compared with the Q1 women (least deprived neighborhood). The more chronic diseases women had, the less likely they were to skip 2020 screening when compared with those that had no chronic disease. This could be because women with many health issues have to frequent health facilities at higher rates and thus less likely to miss mammograms.

Breast cancer has increased dramatically in young women < 50 years in the US over the past decade. DNA methylation is a type of epigenetic change that plays an important role in cancer etiology by silencing tumor suppressor genes or DNA repair-related genes through hypermethylation or activating oncogenes through hypomethylation. Previous genome-wide association studies have suggested DNA methylation in blood is a potential epigenetic markers of breast cancer risk. In this study, we applied targeted methyl-seq to examine the DNA methylation profile in regulatory sequences of 57 known DNA repair pathway genes, together with 123 other genes, located in immune-related loci and genome-wide association peaks for breast cancer. We used a nested case-control design within the Breast Cancer Prospective Family Study Cohort (FroF-SC) and examined DNA methylation profile in DNA from the blood of breast cancer cases (N=293) and age-matched controls (N=327). In the preliminary data analysis, we observed that the methylation levels in 5 genes were statistically significantly different between cases and controls using Wilcoxon Rank Sum Test (Table 1). Some candidate loci show methylation values spanning a wide range (Std Dev) in both cases and controls, suggesting the presence of genotype-dependent allele-specific methylation (ASM). We then conducted generalized estimating equations (GEE model) adjusting for age at blood draw and calculated the odds ratios (ORs) and 95%CI for the association between methylation levels in the 90th and 10th percentiles of differentially methylated genes (90% vs 10% methylation) and breast cancer risk. The ORs (95% CI) from the GEE models were 1.26 (0.97, 1.63, p=0.08) for CD6, 1.27 (0.85, 1.91, p=0.24) for SDCCAG3, 1.12 (0.85, 1.48, p=0.40) for DCLRE1B, 1.29 (0.88, 1.90, p=0.20) for IP09, and 1.63 (1.08, 2.45, p=0.02) for GNPDA1 (Table 2). The associations were not different by age group. Our preliminary results suggest that DNA methylation measured in blood may be a biomarker of breast cancer susceptibility.

Background: Women of racial/ethnic minorities more often receive a diagnosis of advanced breast cancer (BC) at a younger age, and have higher morbidity, risk of recurrence and mortality. In addition to clinicopathologic and biological differences, sociodemographic factors may influence overall survival (OS) in these patients. BC care in AYA is particularly challenging and requires a multidisciplinary approach. In this National Cancer Database (NCDB) analysis, we aim to investigate various socioeconomic variables and their impact on survival in AYA patients with invasive BC. Methods: Using de-identified data accessed from the NCDB, we conducted a retrospective cohort analysis. Patients diagnosed with invasive BC between 2004-2019 and belonging to the age group of 15-39 years, defined as AYA, were included in the study. We performed an exploratory analysis and divided patients based on race/ethnicity, primary payer (government, private or uninsured), community median income (\leq \$40K, \$40-50K, \$50-63K, \geq \$63K), residence area (metropolitan, rural or suburban) and high school degree achievement. Step-wise univariate regression models were used to analyse the impact of the relevant factors on overall survival. Survival estimates were calculated using the Kaplan Meier method. Results: We identified 18,018 AYA patients with invasive BC. Median age was 36 years, the median time from diagnosis to treatment was 25 days and the median follow-up was 82.9 months (range 0.1 - 207.1 months). The majority of patients were Caucasian (66%), followed by Black (14%), Hispanic (10%) and Asian (6%). 61% of Asian and 47% of Caucasians had an income of \geq \$63,000, whereas only 31% of Hispanic patients and 26% of Black patients were in this income bracket. While Black patients constituted the majority of the lower income community (median income \leq \$40K), Hispanics had the largest amount of patients without a high school degree (44%). Considering all patients, the 5-year OS was 92% (95% CI 0.91-0.92) for this study period. However, improved survival was observed in patients with

private insurance versus government insurance (93% vs 84%, $p < 0.0001$); patients with median income $\geq \$63,000$ compared to $< \$40,000$ (94% vs 88%, $p < 0.0001$); a lower percentage of no high school degree quartile $< 6.3\%$ in contrast to $\geq 17.6\%$ (95% vs 88%, $p < 0.0001$); and lastly, patients living in a metropolitan area as opposed to suburban area (92% vs 89%, $p < 0.0001$). Additional details are noted in Table 1. Conclusions: In our analysis we have found that AYA patients with invasive BC included in the NCDB have a variable OS that is impacted by demographic factors and socioeconomic status. Patients with private insurance, higher income, higher level of education and living in a metropolitan area had improved OS at 2 and 5 years. Understanding and narrowing the disparities in the care provided to AYA patients with invasive BC, particularly to those with sociodemographic disadvantages, could lead to improve outcomes.

Background: Disparities in breast cancer outcomes are well documented, with a burgeoning body of literature shedding light on the influence of multiple factors. Much of the literature comes from the US, with the current situation in Canada less well understood. Canada's universal health care system may mitigate some, but unlikely all differences. First generation immigrants comprise 21.9% of the Canadian population. Differences in breast cancer screening rates and stage at diagnosis have been demonstrated between immigrant and non-immigrant Canadian women. However, breast cancer outcomes in the Canadian immigrant population have not been well studied. Patient reported outcomes are one such set of outcomes and crucial in understanding the patient experience. The purpose of this study is to compare symptom burden and trajectories between immigrant and Canadian long-term resident women with breast cancer undergoing breast cancer surgery in Ontario. Methods: A population-level retrospective cohort-study using linked Ontario administrative databases was constructed. Women >18 years of age with newly diagnosed breast cancer between 2010-2016 undergoing surgery at a regional cancer center were included. Baseline variables including immigration status, age, stage, comorbidity and income quintile were collected. The proportion of patients reporting moderate/severe Edmonton Symptom Assessment System Scale (ESAS) scores for each of 9 individual symptom categories over time was collected. Multivariable logistic regression models using generalized estimating equations with exchangeable correlation structure to account for repeated measures were constructed to assess the probability of a moderate/severe score for each of the individual ESAS symptom categories. Results: The cohort included 14,056 women, of which 12,250 (87.2%) were categorized as long-term Canadian residents and 1,806 (12.8%) as immigrants. Immigrant women had a younger mean age of diagnosis (53 vs. 61 years), were more likely to reside in a lowest income quintile neighbourhood (22.2% vs 15.4%), were less likely to be on a primary care physician roster within the last 2 years (83.7% vs. 90.4%) and were less often diagnosed with Stage I/II disease (80.9% vs. 84.6%) (all $p < 0.0001$). The proportion of women reporting moderate/severe scores

was significantly higher amongst immigrant women for 7/9 symptom categories (anxiety, depression, drowsiness, nausea, pain, shortness of breath and well-being) with the largest difference observed for depression (13.1% vs 10.8%, $p < 0.0001$) and pain (14.8% vs. 12.0%, $p < 0.0001$). Comparing symptom trajectories, differences between groups were most pronounced within the first 12 months, though for depression and pain, statistically significant differences also existed at 36 months. On multivariable regression analysis, immigration status was persistently associated with higher proportion of moderate/severe score for pain only (OR 1.12, 95% CI 1.02-1.23). Immigration status was associated with a protective effect for anxiety (OR 0.86, 95% CI 0.78-0.94), drowsiness (OR 0.81, 95% CI 0.73-0.89) and tiredness (OR 0.86, 95% CI 0.79-0.94). Conclusions: To our knowledge, this is the first study comparing symptom burden amongst immigrant and non-immigrant Canadian women with breast cancer at a population-level. Immigrant women undergoing breast cancer surgery were found to have a higher burden of symptoms across most categories, and for depression and pain this difference was found to persist even at 3-years. However, the higher burden of symptoms in many categories seemed to be explained by factors such as younger age and more advanced disease. Adjusting for other factors, immigrant women with breast cancer reported more pain, indicating a need for better symptom management in this population.

Country: Netherlands

Introduction. The SARS-CoV-2 infection rate and the COVID-19 death rate were relatively high in the Netherlands during the first wave of the COVID-19 pandemic (2.7 and 7.2 times higher than in Norway, respectively). Moreover, social measures differed between the two countries. This study aimed to compare the effect of the pandemic on breast cancer incidence and stage between the Netherlands and Norway.

Methods. Women diagnosed with DCIS or invasive breast cancer between January 2017 and December 2021 were selected from the Netherlands Cancer Registry and from the Cancer Registry of Norway. The COVID-19 period was divided in three approximately equal periods: March-September 2020 (first wave), October 2020-April 2021 (second wave), May-December 2021 (post-second wave). Breast cancer incidence during the COVID-19 periods was compared with averaged data of the corresponding reference period: March-September 2017, 2018, 2019 (first wave_ref), October-April 2017, 2018, 2019 (second wave_ref), May-December 2017, 2018, 2019 (post-second wave_ref). Incidences were compared by age group, clinical tumor stage, and method of detection.

Results. The number of breast cancer diagnosis and the breast cancer incidence are shown in Table 1. Compared to the reference period, breast cancer incidence was lower during the first wave in the Netherlands and Norway (IRR: 0.72; 95%CI: 0.70-0.75; IRR: 0.83, 95%CI 0.78-0.88, respectively), and was higher post-second wave in Norway (IRR: 1.10, 95%CI: 1.04-1.16) (Table 1). During the first wave, breast cancer incidence was lower in all age groups in the Netherlands (age < 50 IRR: 0.85, 95%CI: 0.79-0.91; 50-69 IRR: 0.64, 95%CI: 0.61-0.67; 70-74 IRR: 0.61, 95%CI: 0.56-0.67; >74 IRR: 0.86, 95%CI: 0.80-0.93, respectively). During the first wave, incidence was lower in women aged 50-69 in Norway (i.e., women eligible for screening; IRR: 0.68, 95%CI: 0.62-0.74). Post-second wave incidence was higher in women aged 50-69 and >74 in Norway (IRR: 1.09, 95%CI: 1.01-1.17; IRR: 1.13, 95%CI: 1.00-1.28, respectively). In

the first wave the incidence of DCIS, stage I tumors, and screen-detected tumors was lower in the Netherlands (IRR: 0.55, 95%CI: 0.50-0.61; IRR: 0.62, 95%CI: 0.59-0.65, IRR: 0.36, 95%CI: 0.33-0.38, respectively) as well as Norway (IRR: 0.66, 95%CI: 0.54-0.79; IRR: 0.73, 95%CI: 0.66-0.81, IRR: 0.46; 95%CI: 0.40-0.52, respectively).

Conclusion. The current study showed that the incidence of early-stage tumors mainly decreased. Moreover, during the first wave of the pandemic breast cancer incidence decreased in all age groups in the Netherlands but only in women aged 50-69 in Norway. The relatively high infection and death rate in the Netherlands might have increased the fear of patients to visit the general practitioner (GP) and/or to overburden the healthcare system at the start-up of the pandemic. In addition, it might have reduced the capacity at the GP. As a result, appointments with the GP might have been postponed, resulting in a decrease in the number of breast cancer diagnoses in all age groups. A catch-up in breast cancer diagnoses was seen post-second wave in Norway, but not in the Netherlands. Incidence rates should therefore be monitored in the coming period.

Table 1 Number of breast cancer diagnoses (breast cancer incidence) during the COVID-19 pandemic and during the corresponding reference period (incidence is expressed per 100.000 women living in the Netherlands or Norway during the period of interest)

	Period A_ref March- Sept 2017/2019	Period A March- Sept 2020	Period B_ref October- April 2017/2019	Period B October 2020- April 2021	Period C_ref May-December 2017/2019	Period C May-December 2021
Netherlands	9,300 (132.8)	6,849 (96.0)	9,220 (131.7)	9,559 (133.6)	10,621 (151.7)	11,048 (154.0)
Norway	2,242 (107.9)	1,892 (89.4)	2,415 (116.2)	2,607 (122.7)	2,628 (126.5)	2,964 (139.1)

Background: Tucatinib is an oral HER2-targeted therapy that was approved by the FDA in April 2020 for use in combination with trastuzumab and capecitabine for treatment of patients with previously treated HER2+ metastatic breast cancer (MBC). In the randomized HER2CLIMB trial median (95% CI) overall survival (mOS) and progression-free survival (PFS) for patients receiving tucatinib with trastuzumab and capecitabine were 21.9 (18.3, 31.0) and 7.8 (7.5, 9.6) months, respectively. HER2CLIMB utilized a placebo + trastuzumab + capecitabine comparator arm and included patients with active and stable brain metastasis (BM).

Objectives: Describe patient characteristics, treatment patterns, and clinical outcomes for tucatinib-based treatment in the real-world setting.

Methods: This retrospective cohort study included patients treated for HER2+ MBC between

January 2017 and March 2022 in the nationwide de-identified electronic health record-derived Flatiron Health Metastatic Breast Cancer database who received tucatinib-based treatment outside of a clinical trial setting. Demographic and clinical characteristics of patients were described at baseline (MBC diagnosis) as well as at initiation of each oncologist-defined, rule-based line of therapy (LOT). Key outcomes included time to next treatment (TTNT), persistence, and mOS.

Results: Of 2,057 patients treated for HER2+ MBC in the study period who met the inclusion criteria, 154 received tucatinib-based treatment. Of these patients, 18 (12%), 44 (29%), 33 (21%) and 59 (38%) received tucatinib-based treatment in the first-line (1L), second-line (2L), third-line (3L), and fourth-line or further (4L+) respectively. Median age at MBC diagnosis was 54 years. Median follow-up from tucatinib-based treatment initiation was 8.6 months. Overall, 106 (69%) had BM prior to initiating tucatinib therapy (14 [78%], 37 [84%], 20 [61%], and 35 [59%] in 1L, 2L, 3L, and 4L+ respectively). Those with BM initiated tucatinib-based treatment after a median of 2 prior therapies, compared with 2.5 in the non-BM group. The most common metastatic treatment regimens prior to 2L tucatinib-based treatment were trastuzumab + pertuzumab-based, and the most common regimens immediately following 2L tucatinib-based treatment were trastuzumab-based and trastuzumab deruxtecan. The most common regimens immediately prior to and following 3L tucatinib-based treatment were T-DM1 and trastuzumab deruxtecan, respectively. The median (95% CI) TTNT was 8.4 (6.3, 11.3) months overall, and 12.8 (5.5, not reached [NR]) months, 9.8 (4.8, NR) months, and 9.5 (6.1, 15.3) months in 1L, 2L, and 3L, respectively, the median OS was not reached overall (Table 1). Of patients with sufficient follow-up since treatment initiation, 65% (62/96) remained on tucatinib-based treatment after 6 months and 40% (20/50) after 12 months.

Conclusion: The majority of patients receiving tucatinib-based treatment in clinical practice have BM at treatment initiation, constituting a larger proportion of the population than in HER2CLIMB (47.5% of patients). Tucatinib-based treatment use in the real-world setting is associated with a similar mOS and TTNT as in HER2CLIMB.

Median overall survival and time to next treatment in HER2CLIMB and this study

	HER2CLIMB (N=410)	Flatiron Health overall (N=154)
mOS, months (95% CI)	21.9 (18.3, 3.10)	NR (18.8, NR)
Survival probability		
6-month, % (95% CI)	-	84.0 (78.0, 90.4)
9-month, % (95% CI)	-	75.9 (68.8, 83.8)
12-month, % (95% CI)	75.5 (70.4, 79.9)	71.1 (63.1, 80.0)
TTNT, months (95% CI)*	7.8 (7.5, 9.6)	8.4 (6.3, 11.3)
Proportion not on new therapy		
6-month, % (95% CI)	62.9 (56.9, 68.4)	60.2 (52.4, 69.0)
9-month, % (95% CI)	-	47.6 (39.5, 57.2)
12-month, % (95% CI)	33.1 (26.6, 39.7)	38.0 (29.8, 48.5)

*Time to next treatment was used as a proxy for progression-free survival in the HER2CLIMB clinical trial population.

CI, confidence interval; mOS, median overall survival; NR, not reached; TTNT, time to next treatment.

Objective: Benign breast disease (BBD), especially benign proliferative breast disease (BPBD), is related to increased breast cancer risk. However, few studies have examined whether conventional breast cancer risk factors influence risk of breast cancer among women with BBD. The aim of this study was to evaluate the associations of lifestyle factors with risk of breast cancer among women biopsied for BBD within a multi-center, hospital-based, case-control study in China, in order to provide scientific basis of health guidance for BBD patients and lay the foundation for primary prevention of breast cancer.

Methods: A multi-center, hospital-based, case-control study was conducted. Patients with BPBD (n=608) and patients with non-proliferative breast disease (NPBD) (n=366) were collected from 23 hospitals in 11 provinces during April 2012 to April 2013. A face-to-face survey, baseline data and fasting blood was collected with all study subjects. Serum adiponectin levels were assayed using ELISA. After 10 years, the cumulative incidence rate of breast cancer in the two groups was counted through follow-up. Logistic regression analysis was used to obtain the association between specific factors and risk of breast cancer.

Results: After 10 years' follow-up, 388 BPBD and 240 NPBD cases were included in the final analysis (Table 1), of which 16 (4.12%) and 3 (1.25%) developed breast cancer, respectively. The cumulative incidence of breast cancer between the two groups was significant difference (P=0.041). Compared with women in the NPBD group, BPBD group were more likely to be central obesity (with higher waist-to-hip ratio (WHR)) (OR 24.98, 95% CI 1.845-336.203, P=0.015) and less likely to have physical activity (OR 0.626, 95% CI 0.416-0.943, P=0.025) and less often to eat carrots (OR 0.616, 95% CI 0.398-0.953, P=0.030) (Table 2). Subgroup analyze indicated that, physical activity, eat carrots and ham sausage, body weight, BMI, waist circumference and WHR were statistical differences in premenopausal BPBD patients, while only physical activity (OR 0.423, 95% CI 0.269-0.665 P < 0.001) was the independent risk factors. Meanwhile, among the factors of Tea consumption, Glycemia, Body weight, BMI, Waist

circumference, WHR and HMW/total adiponectin ratio in postmenopausal group, only HMW/total adiponectin ratio (OR 0.041, 95% CI 0.002-0.820 P=0.037) was statistically significant factor. These stratified multivariate logistic regression analysis results are shown in Table 3.

Conclusion: In patients with BBD, physical activity may be the protect factor for breast cancer carcinogenesis in premenopausal women while lower HMW/total adiponectin ratio is a risk factor for postmenopausal women, which can provide direction for primary prevention of breast cancer.

Table 1. Pathological types of all subjects.

Pathology	N(%)	Pathology	N(%)
Benign non-proliferative breast disease	240	Benign proliferative breast disease	388
Simple fibroadinoma	167(69.58)	Complex fibroadenoma	109(28.09)
Inflammation	18(7.50)	Hyperplasia	177(45.62)
Duct ectasia	13(5.42)	Multiple papilloma	79(20.36)
Cysts	9(3.75)	Apocrine metaplasia	7(1.80)

Country: United States

Background The androgen receptor (AR) is expressed in 12-41% of the TNBC, contributes with differentiation, proliferation, apoptosis, and angiogenesis; its expression is associated with better recurrence free survival (RFS) and overall survival (OS). **Objective** The aim is to determine the association between AR and pathologic complete response (PCR), recurrence free survival (RFS) in TNBC patients treated with neoadjuvant chemotherapy (neoCT). **Patients and methods** Cross-sectional, retrospective cohort trial. Adult women with stage II-III TNBC, treated with neoCT from 2014 to 2021 were included. Incomplete medical record, AR not-determined, secondary malignant neoplasm were excluded. AR was determined with the VENTANA assay system, > 1% were considered as positive. Statistical analyses included frequencies and range, comparison was done with X2, cox regression model was made for the prognostic association with a two-sided significance level of 0.05 95% CI. RFS were evaluated with Kaplan Meier method and log-rank test. **Results** 309 patients were analyzed; AR prevalence was 14.6%. Median age was 49 years (21-87), tumor size was 6.3 cm (0.1-22), ductal histology (95.1%) and nuclear-grade 3 (79%), these findings were not different between the AR+ vs AR-. Median Ki67 was 52% within AR+ vs 65% AR- (p=0.05). All patients were treated with neoCT, 14.9% had disease progression, PCR rates were similar among two groups (48.5% vs 42.2%) p=0.78. At a mean follow up of 19 months, 7 recurrences presented in AR+ (15.5%) vs 67 in the AR- (25.4%) p=NS. Median RFS was 54.9 (IC 95% 45.2-64.6) and 65.5 months (IC 95% 60.4-70.7), p=0.3. We analyze the prognostic factors, for RFS we found statistically significant the locally advanced stage OR 5.6 (1.4-22.9), residual cancer burden (RCB) OR 2.8 (2.1-3.9), N stage OR 1.4 (1.1-1.8) and progression during neoCT OR 2.8 (1.5-5.1); and for OS the RCB OR 2.8 (1.9-4.1) and progression during neoCT OR 3.1 (1.5-6.9). **Conclusions** In this trial the AR expression did not show significant association neither with PCR and RFS; main reasons are the low prevalence of AR expression, high rate of disease progression and high residual cancer burden after neoCT. We found association with other known factors (RCB, N stage, progression during neoCT and locally advanced stage), which are more important factors that determine the bad prognosis of TNBC.

A Population-based Analysis of Prophylactic G-CSF Biosimilar and Originator Administration over time among Patients Diagnosed with Breast Cancer Pawloski PA1, McDermott CL2, Vazquez Benitez G1, DeFor T1, Mendelsohn A3, Marshall J3, Moyneur E4, Lockhart CM2; on behalf of the G-CSF Comparative Effectiveness Research Team. 1HealthPartners Institute, Bloomington MN USA 2Biologics and Biosimilars Collective Intelligence Consortium, Alexandria VA USA 3Harvard Pilgrim Healthcare Institute, Boston MA USA 4StatLog, Montreal QC Canada Objectives: To characterize G-CSF product use, including product switching, among patients diagnosed with breast cancer in the Biologics and Biosimilars Collective Intelligence Consortium's (BBCIC) Distributed Research Network (DRN). Methods: A retrospective analysis of electronically extracted insurance claims from 2015-2019 at 4 Research Partner Sites was conducted. Patients aged ≥ 20 years with a diagnosis of breast cancer who received chemotherapy associated with a risk of febrile neutropenia (FN) risk per National Comprehensive Cancer Network guidelines and any prophylactic granulocyte-colony stimulating factor (G-CSF), defined as before day 2 of the first cycle of chemotherapy were included. Results: A total of 11,788 patients were included; 89 (0.8%) were male sex per insurance records. The age distribution was 5,743 (49%) 50-64 years; 4,296 (36%) 20-49 years, and 1749 (15%) 65+ years. Chemotherapy regimens included cyclophosphamide/doxorubicin (n=7,377), carboplatin/docetaxel/trastuzumab/pertuzumab (n=1,862), cyclophosphamide/docetaxel (n=1,383), carboplatin/docetaxel/trastuzumab (n=430),

cyclophosphamide/docetaxel/doxorubicin (n=147), and docetaxel/trastuzumab/pertuzumab (n=128). Overall, 218 patients (1.8%) developed FN during the first chemotherapy cycle. G-CSF utilization was pegfilgrastim 10,895 (92%), pegfilgrastim-cbqv 315 (3%), pegfilgrastim-jmdb 225 (2%), filgrastim 156 (1%), filgrastim-sndz 118 (1%), tbo-filgrastim 46 (< 1%), a combination of pegfilgrastim+filgrastim 26 (< 1%), and a combination of filgrastim+biosimilar 7 (< 1%) received. A total of 10,953 (93%) patients received high-risk chemotherapy and G-CSF utilization was 10,162 (93%) pegfilgrastim, 288 (3%) pegfilgrastim-cbqv, 200 (2%) pegfilgrastim-jmdb, 132 (1%) filgrastim, 101 (< 1%) filgrastim-sndz, 40 (< 1%) tbo-filgrastim, and 30 (< 1%) combination of products. Eight hundred fifteen (7%) patients received intermediate-risk chemotherapy and G-CSF utilization was, 716 (88%) pegfilgrastim, 27 (3%) pegfilgrastim-cbqv, 25 (3%) pegfilgrastim-jmdb, 23 (3%) filgrastim, 16 (2%) filgrastim-sndz, 5 (< 1%) tbo-filgrastim, and 3 (< 1%) combination. Twenty patients received low risk chemotherapy and of those 17 (85%) received pegfilgrastim. In 2019, the first full year of pegfilgrastim biosimilar availability, pegfilgrastim use was 76% pegfilgrastim, 13% pegfilgrastim-cbqv, and 9% pegfilgrastim-jmdb. Most patients who received a second cycle of chemotherapy received the same G-CSF product in the second cycle, specifically 67% received filgrastim, 71% tbo-filgrastim, 73% filgrastim-sndz, 96% pegfilgrastim, 84% pegfilgrastim-cbqv, and 81% pegfilgrastim-jmdb. Conclusions: The most common chemotherapy agents included cyclophosphamide, carboplatin, doxorubicin, docetaxel, or pertuzumab. Pegfilgrastim biosimilar uptake occurred following market availability. Within each G-CSF product, most patients received the same product during the second cycle of chemotherapy rather than switching products.

Country: United States

Background Historically, standard-of-care treatments for human epidermal growth factor receptor 2-positive (HER2+) metastatic breast cancer (mBC) have been pertuzumab and trastuzumab combined with a chemotherapeutic agent in first line (1L), and trastuzumab emtansine (T-DM1) in the second line (2L). However, two new treatments have recently been approved for patients who previously received HER2-targeted therapy; fam-trastuzumab deruxtecan-nxki [Enhertu®] and tucatinib [Tukysa] (in triplet combination) in 2019 and 2020, respectively. The goal of this study was to characterize treatment patterns of patients with HER2+ mBC from receipt of first line therapy and subsequent treatments received in real world community oncology practices. Methods Adults diagnosed with HER2+ mBC from January 2013 – January 2021 were selected from the Flatiron Health electronic health record–derived database; a US-wide database curated from community clinics that comprises de-identified patient-level structured and unstructured data. Patients were followed from index date (start of 1L therapy) to death or last activity date. Descriptive statistics reported baseline patient characteristics and treatment patterns. Time to treatment discontinuation (TTD), real-world progression-free survival (rwPFS), and real-world overall survival (rwOS) were estimated using the Kaplan-Meier method. Results A total of 2,074 mBC HER2+ patients with at least 1 line of therapy were included during the study time period. Median follow-up time was 26.0 months (Interquartile range [IQR]: 12.6-44.7). Patients were mostly white (62.7%), median age 61 years (IQR:24-84), 43.0% were stage IV at initial breast cancer diagnosis, and 62.8% had positive hormone receptor (HR) status. Of the 2,074 patients in our study population, 1,159 (55.8%) received 2L therapy, and 584 (28.2%) received a 3L therapy. In terms of 1L therapy, 1,607 (77.5%) received a trastuzumab-based (T-based) regimen, 205 (9.9%) received chemotherapy only, and 153 (7.4%) received a T-DM1 based therapy. The most common regimens across 1L included pertuzumab+trastuzumab+taxane (THP) (38.9%), THP + a platinum agent (7.5%), and T-DM1 (6.1%). From start of 1L, overall median TTD was 10.8 months (95% confidence interval [CI]: 10.1-11.5), median rwPFS was 11.5 months (95% CI: 10.8-12.3), and median rwOS was

40.3 months (95% CI: 37.8-43.4). Among the 1,607 patients who received any T-based regimen in 1L, 496 (30.9%) received T-DM1, 175 (10.9%) received a T-based regimen again, 78 (4.9%) received any other HER2-based regimen, 59 (3.7%) received hormonal therapy alone and 33 (2.1%) received chemotherapy. The most common regimens across 2L (n=1,159) were T-DM1 monotherapy (35.7%), THP (11.2%), and T-DM1+hormone therapy (8.0%). From start of 2L, overall median TTD was 8.3 months (95% CI: 7.6-9.0), median rwPFS was 7.4 months (95% CI: 6.8-8.1), and median rwOS was 27 months (95% CI: 25.9-30.0). Conclusions Variability, which may impact outcomes, is observed in treatment approaches for HER2+ mBC. Additionally, more than half the patients on 1L treatment progressed within a year of initiating treatment, highlighting a remaining need for effective therapies that limit progression and maintain clinical benefit in 1L.

Purpose: The SARS-CoV-2 pandemic was declared a global public health emergency. Determinants of mortality in the general population are now clear, but specific data on patients with breast cancer (BC) remain limited, particularly in developing nations. Materials and methods: We conducted a longitudinal, multicenter cohort study in patients with BC and confirmed SARS-CoV-2 infection. The primary end point was the proportion of patients on treatment for severe SARS-CoV-2 infection (defined as need for hospitalization) or early death (within 30 days of diagnosis). Data were evaluated sequentially in the following way: i) univariate Fisher's exact test; ii) multivariable logistic regression analysis; and iii) multivariable logistic regression. In items i and ii only those with $P < 0.1$ are considered significant and in stage iii only those with $p < 0.05$ were the final significant variables. We divided patients' data into three major variable domains: a) signs and symptoms; b) comorbidities; and c) tumor and treatment characteristics; in item ii each variable domain was tested separately, finally, in item iii the significant variables of all domains were tested together and we called it the integrative step. Results: From April 2020 to June 2021, 413 patients with BC and COVID-19 were retrospectively registered, of which 288 (70%) had an identified molecular subtype and 273 (66%) had stage information. Most patients were on active systemic therapy or radiotherapy (73.2%), most of them in the curative setting (69.5%). The overall rate of severe SARS-CoV-2 was 19.7% (95% CI, 15.3-25.1). In the integrative multivariate analysis, factors associated with severe infection were metastatic setting, chronic pain, acute dyspnea, and cardiovascular comorbidities. Recursive partitioning modeling used acute dyspnea, metastatic setting, and

cardiovascular comorbidities to predict non-progression to severe infection, yielding a negative predictive value of 84.9% (95% CI, 78.9%-88.3%). Conclusion: The rate of severe COVID-19 in patients with BC is influenced by prognostic factors that partially overlap with those reported in the general population. High-risk patients should be considered candidates to active preventive measures to reduce the risk of infection, close monitoring in the case of exposure or SARS-CoV-2 -related symptoms and prophylactic treatment once infected.

Li Zhu, n/a, *Professor - Department of Breast and Thyroid Surgery, Shanghai General Hospital, Shanghai JiaoTong University School of Medicine*
Country: United States

Background: To explore the characteristics of molecular subtype in male breast cancer.

Methods: A retrospective study was conducted to investigate the characteristics and prognosis of patients with male breast cancer using the data recorded in the Surveillance, Epidemiology, and End Results (SEER) database from 2010-2014. Results: A total of 1597 cases were enrolled, including 1373 cases with HR+/HER2- (86%), 182 cases with HR+/HER+ (11.4%), 13 cases with HR-/HER2+ (0.8%) and 29 cases with Triple Negative (1.8%), respectively. There were significant differences in distributions in age, race, grade, tumor size and AJCC stage between the molecular subtypes. The molecular subtypes differed significantly in 5 years overall survival and 5 years cause specific survival, establishing the following sequence with HER2-/HR+ > HER2+/HR+ > HER2+/HR- > Triple negative. According to Cox regression, age>65y, ER negative, PR negative, TN subtype, advanced AJCC stage, larger tumor size, stage T3 and M1 were independent prognostic factors for poorer survival. Conclusion: The prognosis of male breast cancer varied by molecular subtypes. Age, ER and PR, status, stage as well as tumor size were independent prognostic factors.

Introduction

Breast cancer (BC) is a heterogeneous disease composed of multiple histologic subtypes. Invasive ductal carcinoma is the most common subtype, accounting for 75% of all BC cases and is followed by lobular carcinoma which represents another 15%. Other rare histologic subtypes make up the remaining 10%. To date, limited evidence exists regarding about the frequency, clinicopathologic characteristics, and prognoses of these uncommon variants in Mexico.

Methods

A single center retrospective cohort including women diagnosed with invasive BC between January 1990 and December 2019 was conducted. Only patients with rare histologic subtypes, excluding not otherwise specified ductal and lobular carcinoma, were included. The main objective of this study was to describe the frequency, clinicopathological characteristics, and outcomes of these histologic subtypes. Descriptive statistics including means, medians, and standard deviations, were used to analyze clinicopathological characteristics. Recurrence-free

survival (RFS) and overall survival (OS) were calculated using the Kaplan-Meier method and compared by the log-rank test. A p value of < 0.05 was considered statistically significant.

Results

Out of 1744 women diagnosed with invasive BC, 106 patients (6.1%) had a rare histologic subtype. Among the most frequent subtypes, 39 (36.8%) were mucinous, 12 (11.3%) metaplastic, 11 (10.4%) tubulolobular, 11 (10.4%) papillary, 10 (9.4%) tubular, and 8 (7.5%) medullary carcinomas. In the less common histologic subtypes (referred as “others”), 7 (6.6%) were apocrine, 4 (3.8%) neuroendocrine, 1 (0.9%) micropapillary, 1 (0.9%) signet cell, 1 (0.9%) acinic cell, and 1 (0.9%) histiocytoid carcinoma.

In the overall population, the median age at diagnosis was 58 years, 76.4% were postmenopausal at diagnosis, 29.2% had a family history of BC, and 7.5% had personal history of BC. Seventy percent of the patients were overweight or obese at time of diagnosis and 82.1% had diabetes mellitus type 2 diagnosis. An important proportion of women were diagnosed by self-detected tumors (61.3%), as opposed to less than a quarter (24.5%) detected by screening mammography. The median time of diagnosis interval was 3 months, 71.7% were diagnosed with early (I – IIA), 22.6% with locally advanced (IIB – IIIC) and 5.7% with metastatic (IV) disease. Most tumors (58.3%) expressed hormone receptors (HR), 7.2% were HER2 enriched, 8.3% expressed both HR and HER2, whereas 26% were triple negative. Clinicopathological characteristics according to the most frequent histologic subtypes are listed in Table 1.

With a median follow-up of 108 months, 12 recurrences were identified (5 mucinous, 3 metaplastic, 2 tubulolobular and 2 apocrine), 41% were local and 59% were distant recurrences. Globally, 15-year RFS and OS were 83% and 61%, respectively. Differences in RFS and OS were not statistically different according to histologic subtypes. The 15-year RFS and OS was 83% and 80% for mucinous, 100% and 78% for tubular, 100% and 58% for medullary, 65% and 52% for metaplastic, 77% and 86% for tubulolobular, and 100% and 49% for papillary carcinoma, respectively.

Conclusions

To our knowledge, this is the first study describing the frequency, clinicopathological characteristics, and outcomes of rare histologic BC subtypes in a large Mexican cohort. Our results show that these subtypes represent 6% of all invasive BC cases, that they are commonly diagnosed at an early stage, and present long RFS and OS.

Table 1

	Mucinous n = 39	Metaplastic n = 12	Papillary n = 11	Tubulolobular n = 11	Tubular n = 10	Medullary n = 8	Others n = 15
Median age at diagnosis (y)	57	67	66	57	61	59	55
Menopausal status							
- Premenopausal (%)	10 (25.6)	3 (25)	1 (9.1)	5 (45.5)	2 (20)	0	4 (26.7)
- Postmenopausal (%)	29 (74.4)	9 (75)	10 (90.9)	6 (54.5)	8 (80)	8 (100)	11 (73.3)
Clinical stage							
- Early (I – IIA) (%)	28 (71.8)	6 (50)	11 (100)	10 (90.1)	9 (90)	5 (62.5)	7 (46.7)
- Locally advanced (IIB – IIIC) (%)	9 (23.1)	6 (50)	0	1 (9.1)	0	3 (37.5)	5 (33.3)
- Metastatic (IV) (%)	2 (5.1)	0	0	0	1 (10)	0	3 (20)
Immunohistochemical subtypes							
- Hormone receptor positive (%)	25 (71.4)	1 (8.3)	10 (90.9)	9 (81.8)	6 (75)	3 (50)	2 (15.3)
- Triple positive (%)	4 (11.4)	0	0	2 (18.2)	1 (12.5)	0	1 (7.6)
- HER-2 enriched (%)	3 (8.5)	1 (8.3)	0	0	0	0	3 (23)
- Triple negative (%)	3 (8.5)	10 (83.3)	1 (9.1)	0	1 (12.5)	3 (50)	7 (53.8)

Obesity is a major health problem and is closely related to the incidence and progression of breast cancer (BC). Likewise, mammogram breast density (MBD) is a risk factor for breast cancer. This study aims to analyze the potential association between BMI (Body Mass Index) and MBD with different molecular subtypes of BC. The interaction with cholesterol, vitamin D, insulin levels, and lifestyle, will also be evaluated. Materials and methods: This is a transversal, descriptive, multicenter study involving women with a recent diagnosis of early BC for one-year duration (November 2019 to October 2020). BMI was classified as obesity (BMI ≥ 30 kg/m²), overweight (≥ 25 kg/m²), and normal weight (18-25 Kg/m²). American college of radiology was

used to classify MBD into 4 categories: A, B, C, and D. Data of weight, height, MBD, molecular subtype (according to 13th St Gallen International Breast Cancer Panel), cholesterol, insulin, vitamin-D, hypertension, diabetes, exercise, and lifestyle were collected at the moment of diagnosis. Results: 162 women with a recent diagnosis of early BC have been successively evaluated in 3 Spanish hospitals. The median age was 52 years, and 49.1% were postmenopausal. Molecular subtypes were: 43% luminal-A, 25% luminal-B, 17% HER2+, and 15% triple-negative. 7% of patients were MBD type A, 17% type B, 55% type C, and 21% type D. 52% were normal weight, 32% overweight, and 16% obese. 48% of women had normal cholesterol levels and 60% normal vitamin D. There was not association between BMI and molecular subtype, however considering menopausal status, BMI was significantly higher in postmenopausal patients with Luminal A subtype ($p= 0.011$) and HER2+ subtype ($p= 0.027$). There was no association between MBD and molecular subtype. However, there were significant differences between BMI and MBD ($p< 0.001$) with lower BMI in patients who had MBD type C or D. Patients with higher BMI had lower HDL-Cholesterol ($p< 0.001$) and higher levels of insulin ($p< 0.001$). Conclusion: This study showed a higher BMI in Luminal A and HER2 positive postmenopausal BC patients. Higher BMI was shown in patients with low MBD independently of menopausal status. More studies are needed to understand the role of obesity and molecular subtype of breast cancer.

Background and aim: HR+/HER2- is the most common molecular subtype of breast cancer (BC), also associated with improved survival compared with other subtypes in the metastatic setting. This study evaluated the patient and treatment characteristics of women with luminal subtype (HR+/HER2-) advanced (locally or metastatic) BC to identify patients' general characteristics and outcomes in a real-world setting in Turkey.

Methods: This study was designed as a retrospective, multicentered, non-interventional, and observational study to describe the patient demographics, clinical and disease characteristics, and treatment patterns of locally advanced and metastatic HR+/HER2- BC patients in routine practice between January 1, 2019, and December 31, 2020, in Turkey.

Results: After screening 823 patients, 758 women (median age 56 years) were included in the analyses. The median (Q1-Q3) follow-up duration was 12.0 (6.0-17.7), 12.2 (6.1-17.4), 19.3 (14.0-25.3) months for the 1st, 2nd, 3rd lines of treatment; 22% of the women were premenopausal. Metastatic disease was present in 57% at diagnosis, most commonly in bones (71%), distant lymph nodes (24%), and lungs (19%). The most common pathology was invasive ductal carcinoma (67%), followed by lobular carcinoma (6.5%). The CDK4/6 inhibitors (CDK4/6i) plus endocrine therapy (ET) administration rates before and after May 2020, the date of reimbursement in Turkey, were 14% vs. 71% in the 1st line, 14% vs. 61% in the 2nd line, and 15% vs. 56% in the 3rd line. Meanwhile, ET as monotherapy rates decreased from 37% to 8%, 43% to 11%, and 29% to 5%, whereas chemotherapy rates decreased from 49% to 21%, 44% to 28%, and 57% to 39% in 1st to 3rd lines of treatment, respectively. The median progression-free survival (PFS) increased from 10 months before May 2020 to 17.5+ months after May 2020 for 1st line treatment. Dose reduction during CDK4/6i+ET was 5.3%, 9.4%, and 6.6% in the treatment lines, and the most frequent toxicity leading to dose reduction was neutropenia. The best response rate assessments for CDK4/6i+ET showed an objective response rate (ORR) of 62.7%, 57.5%, and 63.9% and a disease control rate (DCR) of 71.3%; 63.2%, and 65.6% in the 1st, 2nd and 3rd lines of treatment (Table 1). Moreover, overall ORR independent of treatment lines for CDK4/6i+ET was found as 61.1%.

Conclusion: This study provided the most recent data from a large sample of HR+/HER2- metastatic breast cancer patients in Turkey. The results presented showed the current treatment preferences and the treatment efficiencies in a real-world scenario. In addition, the epidemiological characteristics identified will serve as a basis for detecting the changes in the patient characteristics over time and determining the best candidates for specific treatments. Missing data in patient files due to retrospective design of the study and limited experience with CDK4/6i and poly adenosine diphosphate ribose polymerase (PARP) inhibitors in Turkey (due to registration and reimbursement status) could be considered limitations of the current study.

OBJECTIVE: To evaluate the prevalence of sensitivity changes in patients during the cycle of chemotherapy with taxanes and the impacts on quality of life. **DESIGN:** A prospective, observational, Approved study was conducted at the Oncomastology outpatient clinic of Hospital São Paulo- Unifesp, in the period from November 2018 to February 2022, where 102 women with breast cancer were selected and 79 patients who underwent chemotherapy with paclitaxel were included. **METHODS:** Collection of demographic and clinical information. Used stesiometer that assessed sensitivity in dermatos and myotomes in the following body regions: arms, hands, legs and feet. **FACT/GOG-Ntx Questionnaire** analyzed the quality of life and chemotherapy-induced peripheral neuropathy of the patients before starting chemotherapy. All participants were informed and signed an informed consent form. **RESULTS:** The mean age was 49 years, mean BMI was 27.95Kg/m², NICC (Invasive Carcinoma not special) represented 89.9% of the sample, 88.6% had Neoadjuvant Chemotherapy, regarding the size of the tumor 45.6% presented from 2 to 5 cm, of the pre existing diseases Diabetes mellitus 15.2% and Systemic Arterial Hypertension 30.4%. The initial moment in relation to sensitivity alterations, of the arm regions presented (right C6 (HC 1.05-1.23) left C6 (HC 1.05- 1.23), and legs (right L5 (HC 1.14 -1.55) left L5 (HC1.22 - 1.52) and right S1 (HC 1.21-1.47) left S1 (HC 1.21-1.48). The conversion of the Estesiometer colors into numbers followed as follows, Green (1.0): normal sensitivity, Blue (2.0): decreased sensitivity. The **FACT/Taxane (TOI)** quality of life Questionnaire (30 items) its scores 0-120,(average 91.44 points) demonstrates in its response impairment in more than 80 % in the quality of life in the domains. **Physical Well-Being-PWB** (0-28 points) (mean 20.28/HC 18.88-21.66), **Functional Well-Being-FWB** (0-28 points) (mean16.00/HC14.22-17.22) and in the specific questions about chemotherapy-induced peripheral neuropathy (CPIN), **TaxS** (0-64 points) (mean 55.16/HC 52.74-57.26) reduced

scores. CONCLUSION: It is concluded that mean age, overweight, tumors between 02 and 05 cm were the most prevalent among patients diagnosed with breast cancer. At the beginning of chemotherapy containing paclitaxel, sensitivity changes were not present characterizing arthralgia, myalgia and the hand-foot syndrome (CPIN). The quality of life evaluated by FACIT/Taxane, showed a reduction of 80% in the scores of the domains Physical Well-Being-PWB, Functional Well-Being-FWB and general quality of life, that is, the quality of life of patients from the time of diagnosis is already very compromised.

Key words: Breast neoplasm, adjuvant drug treatment, chemotherapy, quality of life.

Number of Opinion: 2.351.174 DATA OF THE OPINION, CEP Number: 0934/2017 of the ethics in research committee. Registered in Clinical Trials on 12/12/2017, protocol number -NCT 03373032.

Table 1 Results of the sensitivity of dermatos and myths (monofilaments) undergoing chemotherapy cycles with paclitaxel (eyes closed)

Results of the sensitivity of dermatos and myths (monofilaments) undergoing chemotherapy cycles with paclitaxel (eyes closed)				
N= 79	Mean	Std.Deviation	HC (95%)	
Sensitivity C6 Right	1,14	0,38	1,05	1,23
Sensitivity C7 Right	1,15	0,43	1,06	1,27
Sensitivity C8 Right	1,19	0,43	1,08	1,28
Sensitivity T1 Right	1,16	0,44	1,06	1,24
Sensitivity L5 Right	1,38	0,85	1,14	1,55
Sensitivity S1 Right	1,38	0,58	1,21	1,47
Sensitivity Foot Right	1,65	0,68	1,49	1,8
Sensitivity C6 Left	1	0,38	1,05	1,23

Background: Early-onset breast cancer is typically defined as a diagnosis of disease before age 40-45. Prior studies have shown interesting associations between race and obesity on the incidence and prognosis of breast cancer. Data from the SEER program at the National Cancer Institute has shown increased mortality amongst African American women (0.2%) compared to Non-Hispanic White (NHW) women (0.1%) who were diagnosed with breast cancer at age 45 years or younger. This is despite a similar risk of diagnosis between racial groups of this age range (1.27%, 1.27%). Other large studies have shown that African American patients tended to present with more advanced disease had worse clinical outcomes. Our study sought to determine the impact of race and obesity on the diagnosis and prognosis of early onset breast cancer amongst the patient population at Georgetown University Hospital (GUH). Methods: We compiled a database of all new patients, 652 in total, seen at Lombardi Cancer Center at Medstar GUH from 10/2020- 6/2022. We reviewed patient charts in the EMR and documented age at diagnosis, race, ethnicity, stage at diagnosis, and BMI. The BMI was categorized by underweight (BMI < 18.5), healthy weight (BMI 18.5-24.9), overweight (BMI 25-25.9), obese (BMI 30-34.9), and morbidly obese (BMI ≥ 35). Stage at diagnosis was determined by comparing the pathology report with the NCCN guidelines version 4.2022. We identified 136 patients who were diagnosed at GUH at age 45 years old or younger and compared our findings to SEER data from 2017-2019. Results: Out of 136 patients who met our age criteria, 131 had racial data available: 29 AA (0.22), 68 NHW (0.52), 4 Hispanic (0.03), 30 Other (0.23). Out of the 34 patients with advanced disease (stage 3 and 4) 16 were NHW (0.47), 4 were AA (0.12), 2 were Hispanic (0.06) and 12 were Other (0.35). 131 patients had BMI data available: 5 underweight (0.04), 56 healthy weight (0.43), 41 overweight (0.31), 21 obese (0.16), and 8 morbidly obese (0.06). 18 patients with advanced disease were overweight or obese, out of which 11 were NHW (0.61), 3 were AA (0.16), 3 were Other (0.16), and 1 was Hispanic (0.06). Conclusion: In contrast with the SEER data, our study found that the patient population at GUH had a much higher proportion of Non-Hispanic White (NHW) patients who were diagnosed with advanced disease compared to African American (AA) patients. It also found a higher proportion of NHW patients amongst those who were diagnosed with advanced stage disease and were overweight or obese compared to AA patients. This data suggests that in our patient population, Non-Hispanic White women who were overweight or obese at the time of diagnosis of early onset breast cancer (≤ 45 years old) were more likely to be diagnosed with advanced stage disease than women in other demographic groups. It is possible that this discrepancy is related to racial variations in receptor status. Further investigation is required to correlate these associations in clinical practice with other known demographic variables and disease-specific

risk factors in order to better understand how they impact the diagnosis and prognosis of early-onset breast cancer.

Background: Breast cancer is the most common cancer in women, and metastatic disease accounts for most breast cancer related deaths. Identifying risk factors for the onset and progression of metastatic breast cancer (MBC) can help us understand how to address and improve morbidity and mortality due to MBC. Large national databases, such the Surveillance, Epidemiology, and End Results (SEER) Program are limited in their ability to capture granular details from patients' cancer histories. The Dallas Metastatic Breast Cancer Study (DMBCS) is a clinical database established at a single academic medical system to track patient demographics, associated pathology, treatments, and other variables to improve outcomes for patients with MBC. Methods: The DMBCS database was generated from a registry of breast cancer patients submitted to the National Cancer Institute from 2010 to 2021. Patients were initially excluded if they were identified as non-metastatic from this list. Chart review was then done to identify MBC patients from this subsequent group. Demographics, clinical history, pathologic features, lines of treatment, and subsequent recurrences were collected for all patients. Clinical data was stored in REDCap, a secure data collection platform for entering and managing data. Results: 230 cases were included in this preliminary data set. Of the 230 cases, 185 cases were metastatic at time of diagnosis while 45 cases were metastatic recurrences of breast cancer. At diagnosis, 14.8% were less than 40 years of age, 17.3% were

40-49, 35.7% were 50-59, 18.7% were 60-69, and 13.5% were greater than 70 years of age. In terms of ethnicity, 63.5% were White, 27.4% were Black, and 21.7% identified as Hispanic. At time of diagnosis, 30.9% of patients had a BMI classified as overweight and 40.4% were considered obese. Medical comorbidities included hypertension in 43% of cases, diabetes (18.3%), hyperlipidemia (27.4%), and autoimmune disease (13.0%). Clinical subtype analysis revealed 57.8% of patients were hormone receptor positive, 24.8% HER2 positive, and 17.4% triple negative, at diagnosis. 14.8% of cases were diagnosed as inflammatory breast cancer. The most common site of metastasis at presentation was bone with 69.1% of cases, followed by lung (33.9%), liver (30.0%), and brain (15.2%). Over 90% of patients were treated with at least one antineoplastic regimen and 39.6% underwent at least 4 therapies. Calculated 1-year survival after diagnosis was 85.7%. Conclusions: The introduction of the DMBCS will allow continued investigation into clinical drivers of MBC. In this first cohort of patients, we characterized key, yet often underreported, variables and outcomes. Potential applications of this database include investigating the association between obesity and overall survival in patients with MBC, understanding how socioeconomic disparities affects outcomes of patients with MBC, and exploring correlations between autoimmune disease and the progression of MBC.

Male breast cancer is a rare disease accounting for less than 1% of all breast cancer diagnosis. Male breast cancers occur later in life and are more estrogen receptor-positive compared to female breast cancers. Breast cancer in men is often diagnosed later and survival rates are lower than in female cases. The aim of this retrospective study is to analyze the epidemiological, clinical and therapeutic data of all male breast cancer cases over the span of 11 years to at Methodist Dallas Medical Center between 2010 – 2021. During this time period, there was a total of 1,784 cases of breast cancer diagnosed. There were 8 cases male breast cancers, accounting for 0.45% of all breast cancer cases. The average age of diagnosis was 69.5 years old. The most common type of male breast cancer was invasive ductal carcinoma with 7 cases (87.7%). The remaining 1 case (12.5%) were ductal carcinoma in situ (DCIS). 100% of our male breast cancer cases were estrogen receptor and progesterone receptor positive. No male breast cancer case had Her2/Neu receptor over-expression. Of all male breast cancer cases, 75% had a family history of cancer suggesting that genetic factors play a significant role in the development of breast cancer in men. At time of diagnosis, 4 cases (50 %) were staged at cT4 and the remainder of cases were between cT0 - cT2. 37.5% of all cases had sentinel lymph node involvement at time of diagnosis. From the time period of 2010 – 2014 there were no incidences of male breast cancer; however, from 2015 – 2021 there were 8 total cases. There were 2 cases (25%) of death.

Number of Male Breast Cancer Cases by Year

Number of male breast cancer cases diagnosed by year at Methodist Dallas Medical Center

Epidemiological and Clinical Data of Male Breast Cancer Cases

	Total Number of Cases	Percentage
Male Breast Cancer	8	0.45%
Female Breast Cancer	1,776	99.55%

+

Introduction Chemotherapy-induced peripheral neuropathy (CIPN) is a serious clinical problem that can be caused by some cytotoxic agents used in breast cancer (BC) treatment, most commonly seen following taxane-based therapy[1,2]. Several strategies have been studied for CIPN prevention and treatment, but, still, there is no standard recommendation, options are limited and results unsatisfactory [1]. Cryotherapy is a technique that consists of reducing the blood flow in a certain area of the body by cold temperatures, in order to limit the cytotoxic reach. A few studies have been conducted to analyze the safety and efficacy of this strategy in CIPN prevention and treatment, and results are controversial [3,4,5]. More data is needed to clarify cryotherapy role in this clinical context. Methods This is a retrospective analysis of 40 BC patients treated at a single Brazilian institution between December 2019 and June 2022, aiming at efficacy and safety of cryotherapy in the prevention and treatment of CIPN. Cryotherapy was administered by the Hilotherm Clinic Chemo HT02 device (Hilotherm GmbH - Oberwil bei Zug, Switzerland [6]). The procedure consisted of patients using glove and sock-like devices on hands and feet throughout the chemotherapy infusion. The devices were pre-cooled to 10oC and then put on patients 30 minutes before starting, till one hour after the end of chemotherapy infusion. A questionnaire, as proposed by Leonard et al [7], was administered to patients every cycle to assess the development and severity of CIPN symptoms. Statistical analyses were performed by using a Cox regression model. Results Of the 40 patients analysed, 33 (83.5%) underwent a taxane-based regimen. The median number of cryotherapy sessions was three (ranging from 1 to 12), and, when excluded patients who underwent only one session of

cryotherapy, the median was 4 (range 2 to 12). 75% of the 40 patients underwent cryotherapy in all chemotherapy sessions, or were still receiving chemo with cryotherapy by the time of our analysis. 80% of those who left treatment did so after the first session (HR 40.44 (CI95: 8.34 – 196.1; p< 0.0001). CIPN was stable or better than the baseline status for 26 (87%) of the 30 patients that underwent more than 1 session of cryotherapy; only 1 (25%) of the four patients who developed CIPN worse than the baseline status had grade 2 symptoms. Conclusion Cryotherapy is a safe and tolerable strategy that can be used during chemotherapy for breast cancer. Our data suggests that this is an efficient approach to prevent and treat CIPN, but the retrospective nature of the study and the small sample size must be considered when interpreting the results. Finally, strategies must be developed to further improve adherence and tolerability, and prospective randomized trials are needed to confirm the efficacy of cryotherapy in this context. 1. Purpose Bone metastases (BM) from breast cancer cause significant complications including pain, hypercalcemia, spinal cord compression, and pathologic fractures, collectively referred to as skeletal related events (SREs). Of all SREs, bone pain impacts the quality of life (QOL) most significantly. Cancer- induced bone pain (CIBP) is difficult to treat with limited treatment options and requires a multimodal approach. Management of CIBP is primarily by opioids which have notable side effects like sedation, constipation, and concern for addiction. In addition, pre-clinical evidence suggests that opioids accelerate bone loss and increase risk of fractures. There is an unmet need for novel analgesic therapy interventions to optimize QOL for patients with BM from metastatic breast cancer. Preclinical studies have shown that the endogenous cannabinoid (CB) system is involved in pain modulation, bone regulation, immunity, and restraint of cancer pathogenesis. CB2 receptor activation has been shown to inhibit proinflammatory cytokines/chemokines in pre-clinical models. Treatment with selective CB2 agonist in mice with BM led to significant antinociception, decreased cancer-induced bone degradation, and reduced side effects of morphine. In addition to alleviating pain, CB2 agonists were shown to enhance bone growth/strength in these mice. Based on this pre-clinical data, we hypothesized that the addition of a CB2 agonist will improve pain symptoms and decrease opioid requirement in patients with bone metastases from breast cancer. We proceeded to conduct a pilot study by repurposing a clinically approved CB2/CB1 agonist, dronabinol. Methods We conducted a prospective, single site study among patients with BM from breast cancer at our center (NCT03661892). Patients had to have been on opioids for CIBP for at

least 4 weeks and not using marijuana or CBD products. Patients were treated with 10mg dronabinol BID for 8 weeks. Our primary objective was to determine the proportion who decrease their opioid use by $\geq 20\%$. The null hypothesis value was 5% of women would have a 20% decrease. With 14 participants, we could detect an increase from 5% to 29% ($n=4$) with 80% statistical power using a one-sided alpha level of 0.05. Participants completed Brief Pain Inventory and the European Organization for Research and Treatment of Cancer quality of life questionnaires pre and post treatment. Results Twenty participants consented with 14 patients completing the study and evaluable for primary analysis. No patients received any palliative radiation therapy or other therapies for bone pain within 3 months prior to enrollment to this study. Four patients decreased their opioid use by $\geq 20\%$ meeting the primary objective. Patients reported significant improvement in pain severity, interference scores, quality of life and insomnia based on the questionnaires. There were no grade 4 side effects and only 1 patient had grade 3 adverse event (dizziness) related to study drug. Of the 14 patients who completed the study, 9 desired to continue dronabinol therapy after completion. Conclusion Our pilot study shows that the addition of dronabinol resulted in decreased opioid requirements for CIBP in patients with metastatic breast cancer. Patient-reported outcomes also demonstrated improved pain and QOL with the addition of dronabinol. While we did not see any significant AEs tolerability may be of concern due to CB1 psychoactive effects. Our results are promising and warrant further investigation into evaluating CB2 agonists for improved pain control from CIBP and to decrease opioid use.

Background: Cancer patients and survivors experience distress related to physical, psychological, social and financial concerns. Individuals diagnosed with triple negative breast cancer (TNBC) may be at increased risk of distress due to the aggressive nature of the illness and high rates of recurrence. The aim of the present study was to describe how TNBC patients characterize cancer-related distress and concerns and identify factors associated with distress. Methods: Cancer Support Community's Cancer Experience Registry® (CER) is an online research initiative examining the physical, emotional, practical, and financial impact of cancer. The CER measures cancer-related distress using CancerSupportSource™ (CSS), a 25-item validated distress screening tool in which participants rate their level of concern (0=Not at all; 4=Very seriously) across five key domains: (1) emotional well-being (EWB; 8 items, $\alpha=.91$); (2) symptom burden and impact (SYM; 8 items, $\alpha=.90$); (3) body image and healthy lifestyle (BHL; 4 items, $\alpha=.80$); (4) healthcare team communication (HCC; 2 items, $\alpha=.74$); (5) relationships and intimacy (REL; 2 items, $\alpha=.71$). CSS subscale scores were calculated as the average item rating. For item analysis, the proportion indicating moderate to very serious concern was reported. From January 2015 to August 2021, a total of 195 US residents with a history of TNBC took part in the CER and completed CSS. Multiple linear regression analysis was used to estimate the relationships between CSS subscales and socio-demographic variables (age,

low-income status, employment status) and clinical history (time since diagnosis, advanced or metastatic disease, and currently receiving treatment). Results: The sample was 82% Non-Hispanic White, 7% Non-Hispanic Black, 5% Hispanic, and 7% Non-Hispanic other/multiracial. 17% reported annual household income <\$40K. 44% was employed full-time, 12% part-time, 18% retired, and 24% unemployed due to disability or other reason. Mean age was 53 (SD=10) years; 11% were < 40 years. 14% of participants were < 1 year of cancer diagnosis, 27% 1 to < 2 years, 34% 2 to < 5 years, and 25% ≥5 years. 41% were currently receiving treatment, and 27% were diagnosed with advanced or metastatic disease. The mean distress subscale score was highest for concerns about BHL (1.61), followed by EWB (1.29), SYM (1.27), REL (1.04), and HCC (0.83). With regard to concerns about BHL, over half were moderately to very seriously concerned with eating and nutrition (55%) and exercise (55%). Regarding EWB, the items of greatest distress were worrying about the future (53%) and worrying about family (39%). For SYM, over half (53%) were concerned about thinking clearly, and 49% were concerned about fatigue. Participants reported moderate to very serious concern about intimacy, sexual function, and/or fertility (36%) and relationships (22%). Regarding HCC, 24% reported concern related to treatment decisions, while 22% reported concern about communicating with their doctor. In multivariate analysis, time since diagnosis was inversely associated with concerns about EWB ($B=-0.03$, $p=.030$), such that distress was higher closer to diagnosis. TNBC patients with advanced or metastatic disease status had significantly higher distress related to SYM ($B=0.40$, $p=.009$) and HCC ($B=0.61$, $p=.001$). Younger age was associated with concerns about BHL ($B=-0.02$, $p=.011$) and REL ($B=-0.02$, $p=.006$). Finally, unemployment was associated with higher distress related to EWB ($B=0.57$, $p=.001$), SYM ($B=0.63$, $p<.001$), BHL ($B=0.42$, $p=0.03$), and REL ($B=0.70$, $p<.001$). Conclusions: In this sample, average levels indicated slight distress across multiple domains. Many TNBC patients reported concerns that were physical and future-oriented, highlighting critical areas of unmet need. Factors of less time since cancer diagnosis, advanced/metastatic disease, younger age, and unemployment were predictors of higher levels of distress.

Introduction: Breast cancer surgery is a life altering event which can have profound consequences on a woman's physical, mental and emotional health. Breast Surgery creates cosmetic changes which can harm a woman's emotional well-being and quality of life. Breast reconstruction following mastectomy has been found to improve many quality of life measures and has been well studied. This has been less well studied in breast conserving surgery. The addition of oncoplastic breast surgical techniques and involvement of a plastic surgeon for immediate reconstruction following partial mastectomy can improve the cosmetic outcome for patients, reduce symptoms of breast hypertrophy and improve quality of life. To assess this, we applied the Breast Q scale before and after surgery and found a significant improvement in multiple quality of life indices. Methods: Between January 2020 through May 2022, 136 women undergoing breast conservation were given the Breast Q Version 2.0 Breast conserving therapy module (pre-and postoperative scales) written questionnaire before and again between 3 and 6 months after surgery. The Breast Q survey is a standard tool used by surgeons to assess a variety of quality of life factors following breast surgery. The patients were prospectively studied but not randomized in any specific way. The surgical technique used for the procedure was determined by a discussion between the patient and her breast surgeon. Results were divided into groups based on type of surgery and differences between groups with respect to the Breast-Q questions were analyzed with the student T test for p values. Results: Patients were divided into three categories; simple closure, the control group (20% n=26), oncoplastic closure with internal tissue rearrangement greater than 10 cm² (60% n=79) and patients who had involvement of a plastic surgeon for therapeutic mammoplasty and contralateral symmetry procedure (25% n=31). Significant improvement (p<.05) over the control arm and patients undergoing standard oncoplastic closures without a plastic surgeon was noted in several areas. These include an increase in confidence in a social setting, acceptance of her body, overall attractiveness, overall emotional health, sexual confidence and comfort wearing clothing and/or bra. Relative to the control group, the addition of oncoplastic closure also showed significant improvement in scores over patients without these techniques although the magnitude was smaller than with the use of a plastic surgeon. Conclusion: In breast conserving surgery, the addition of oncoplastic closure and especially the involvement of a plastic surgeon for therapeutic mammoplasty is highly effective at limiting some aspects of the deficits in quality of life and, surprisingly, significantly improved this from baseline in many patients. Where appropriate, these techniques should be employed to enhance individual patients quality of life..

Background: Financial toxicity (FT) is a multi-faceted construct, encompassing material hardship, psychological responses, and coping behaviors. FT adversely impacts patient-reported outcomes by decreasing mental health, affecting health-related quality of life (HRQOL), and deteriorating healthcare adherence. Few studies have assessed the relationship between financial toxicity, distress, coping, self-efficacy, and HRQOL within the context of cancer care disruptions resulting from the pandemic. Methods: In the COVID-19 Breast Cancer Care Survey, 46 women with primary breast cancer were cross-sectionally evaluated for financial hardship (FACIT-COST), distress (Perceived Stress Scale), coping behaviors (Brief COPE), self-efficacy (Cancer Behavior Inventory–Brief) and HRQOL using the Functional

Assessment of Cancer Therapy General (FACT-G) measure. Cancer care disruptions were measured with a series of questions investigating the impact of COVID-19 guidelines on access to healthcare services, treatment, and transition to telemedicine. Given the role of informal caregivers for patients' outcomes, social isolation was additionally included (PROMIS Social Isolation Scale). Descriptive statistics were computed, and bivariate correlations examined. Then, a subsequent regression model investigated predictors of FT in the present sample. Statistical analyses were performed using SAS 9.4 and significance level was set at $p < 0.05$. Results: Overall, participants were adult (Mean = 46.3 ± 10.9) women diagnosed with early-stage breast cancer (75.61% Stage I/II). Approximately half of the participants were in active treatment (51.2%) and received multiple types of treatment (85.4% surgery; 61% chemotherapy, and 36.5% radiation). Although all participants were insured at time of the study, the mean score of FT was 22.75 (SD=4.10, range: 0-44). Correlation analyses indicated that cancer care disruptions ($r = -0.57, p < .001$), health-related quality of life ($r = -0.51, p = 0.0007$), coping behaviors ($r = -0.33, p = 0.037$), well-being ($r = 0.56, p = 0.0001$), social isolation ($r = -0.40, p = 0.0096$), and psychological distress ($r = -0.42, p = 0.0064$) were significantly correlated with FT. That is, women who reported greater disrupted cancer care delivery, greater difficulties managing the illness, reduced physical and mental health, and those experiencing more social isolation reported worse financial toxicity. Results of the final regression model showed that women who experienced greater COVID-19-related cancer care disruptions ($\beta = -2.82, p = 0.0013$) and isolation ($\beta = -0.44, p = 0.0196$) from supportive networks were more likely to indicate elevated FT scores. Conclusions: A multidisciplinary and patient-centered FT management approach can be implemented to extend current financial navigation models to address psychosocial and behavioral factors exacerbated by altered care delivery protocols.

Background: Roughly 20% of people diagnosed with breast cancer (BC) will be considered HER2+. HER2+ BC patients are among those at highest risk for developing brain metastases, with up to 50% developing brain metastases. Brain metastases are associated with faster disease progression, shorter survival, and myriad increased impairments. Despite the significant burden faced by HER2+ BC patients living with brain metastases (BMBC), there is little empirical research available regarding the unique experiences of this population. The goals of this exploratory study were to examine the feasibility of recruiting HER2+ BMBC patients to complete an online survey, and to describe their health-related quality of life (HRQOL) and experiences with work impairment. Methods: 62 women with HER2+ metastatic BC were recruited via advocacy partners, Living Beyond Breast Cancer and Metastatic Breast Cancer Alliance, and completed an online survey in January 2022. Participants reported sociodemographics, clinical history, current caregiving support received, physical health (Patient-Reported Outcomes Measurement Information System (PROMIS) Global Physical Health 2av1.2), HRQOL (PROMIS-29v2.0 and PROMIS Cognitive Function Short Form 8a) and work impairment (Work Productivity and Activity Impairment Questionnaire–Specific Health Problem (WPAI-SHPv2.0)). Descriptive statistics were calculated for study variables; PROMIS measures were converted to T scores (M=50, SD=10), enabling comparisons to established population benchmarks. Results presented in this study are restricted to the 30 HER2+ participants living with BMBC. Results: Participants were 47% White, 23% Hispanic, 23% Asian, 3% Black/African American, 3% American Indian/Alaska Native; mean age=43y (range: 33-72); 83% held a Bachelor degree or higher; 70% were married or partnered; mean years since BMBC diagnosis=2.7 (range: < 1-20); mean years between diagnosis and onset of metastatic disease=1.8 (range: 0-11). 67% of participants reported receiving constant care from a caregiver; the remaining participants reported receiving an average of 10.2 hours/week of care. 50% of participants reported physical health corresponding to poor levels (>2 SD on

PROMIS). The majority of participants reported HRQOL impairments corresponding to moderate to severe levels (>1SD on PROMIS): Anxiety (84%); Physical Function (80%); Pain Interference (77%); Depression (70%); Fatigue (70%); Sleep Disturbance (67%); Cognitive Function (63%); and Ability to Participate in Social Roles and Activities (53%). Mean symptom burden T-scores (range: 60.4-67.7) and mean functional impairment T-scores (range: 36.0-39.9) were poorer relative to several reference groups (i.e., other women with HER2+ MBC, overall BC population benchmarks, general US population benchmarks). At the time of the survey, 73% of participants were not employed due to disability. Among those employed (n=7); 100% reported that BMBC negatively affected their employment in the past week: mean percent of scheduled work hours missed=37% (range: 14-74%); mean percent of reduced productivity while working=39% (range: 0-80%); and mean overall work impairment=60% (range: 39-95%). Conclusions: HER2+ BMBC patients experience substantial emotional, physical, social, and cognitive quality of life impairments, high work absenteeism, reduced productivity, and overall work impairment, suggesting significant unmet needs for this population. Efforts to recruit HER2+ BMBC patients were successful, suggesting high feasibility of future work with a more robust sample. Despite the small sample size, our descriptive results provide a key foundation for future research with HER2+ BMBC patients to formally test hypotheses and evaluate predictor variables impacting patient HRQOL and work impairment.

The Psycho-Social Factors Impacting Black Women Breast Cancer Survivors

Presenting Author(s) and Co-Author(s):

Virginia Leach, B.A., *Manager of Research & Writing - Tigerlily Foundation*

Country: United States

Background: Breast Cancer (BC) mortality rates disproportionately affect African American (AA) women over any other racial or ethnic group in the United States. However, questions about how AA women who survive the disease navigate psychosocial factors such as body image, self-esteem, stigma and shame, thoughts and fears surrounding fertility, and romantic relationships remain unanswered. This study's primary research question is, "How do AA women BC survivors create a new normal post-breast cancer while figuring out their own identity?" Methods: This qualitative study aims to address the psychosocial factors experienced by 20 AA women BC survivors in the U.S. The 20 women were recruited to participate in the IRB-approved study (University of Illinois at Urbana-Champaign) through the Tigerlily Foundation, a non-profit breast cancer advocacy organization. The total duration of the study lasted a maximum of 1 hour and 45 minutes with participants answering one pre-interview questionnaire for demographic purposes and one interview with a member of the research team. Results: Preliminary results from the data conclude that AA women BC survivors, and potentially all cancer survivors, mirror individuals in the postpartum phase. Being postpartum is not inherently harmful; however, if one begins to experience symptoms of depression, loss of appetite, irritability, and insomnia for an extended period, there is a high possibility they are experiencing Postpartum Depression (PPD). BC survivors experience numerous changes that can drastically impact their quality of life. AA women BC survivors struggle immensely with body image and self-confidence issues after experiencing breast cancer, various surgeries, and treatments. Conclusion: If BC survivors, particularly AA women BC survivors experiencing systemic and institutional racism, are treated with the same care postpartum individuals are given, there can be a shift in how oncologists work with BC survivors. Creating more personalized survivorship care plans between patients, oncologists, and hospital-based social workers can improve psychosocial factors experienced by AA women BC survivors.

Background: Challenges for breast reconstruction (BR) after delayed CPM relate to previous ipsilateral reconstructive procedures, adjuvant therapies and co-morbidities. The same type of BR for both sides may be impossible and use of an abdominal flap-based reconstruction for the therapeutic side precludes a similar technique for the contralateral side; an implant-based reconstruction may be difficult to size match with autologous tissue reconstruction. Alternative sites for tissue harvest are the latissimus dorsi and gluteal artery perforator flaps but these can be associated with significant donor site morbidity and poorer breast symmetry. Types of reconstruction and complications were evaluated in the context of BR and delayed CPM. Methods: A retrospective analysis examined breast cancer patients undergoing CPM either as an immediate or delayed procedure with or without breast reconstruction (BR) between January 2009 and December 2019. Clinical information was extracted from a prospectively maintained database with collection of data on demographics, timing and type of surgery, previous adjuvant treatments and complications. Patients undergoing delayed CPM were categorized into 4 groups based on BR or no BR and its timing in relation to both CPM and therapeutic mastectomy. Complications were listed according to the Clavien-Dindo system (scale of 1 – 5) with major adverse events being wound infection requiring intravenous antibiotics or drainage and explantation. Despite small numbers, complications were compared for therapeutic and prophylactic mastectomy together with the type and timing of reconstruction. Results: A total of 39 CPM patients were analyzed with 12 (31%) undergoing immediate BR at the time of cognate mastectomy, 22 (56%) choosing bilateral BR simultaneously with delayed CPM, 3(8%) opted for bilateral delayed BR following delayed CPM whilst 2 (5%) had no reconstruction. The mean patient age was 52 years (24–73) and the average interval between initial and delayed mastectomy was 2.67 years (0–22). The majority of reconstructions (28/39) were implant-based (72%) rather than exclusively autologous reconstruction and most patients had a similar type of BR for contralateral and ipsilateral sides. More than half of patients received neoadjuvant therapy and 85% had post-mastectomy radiotherapy prior to CPM. Major complications occurred in 8 patients (67%) with unilateral BR compared with 5 patients (23%) with bilateral immediate BR and 3 patients (100%) undergoing bilateral delayed BR. Small numbers and confounding factors preclude any robust statistical analysis but no statistically significant differences between the immediate and delayed BR groups were found on Fisher's exact test. Complication rates appeared higher when immediate BR was performed after delayed CPM

compared with therapeutic mastectomy. Conclusion: Potential complications and limitations of BR in the context of delayed CPM should be discussed with patients and used to inform decision-making processes for timing of CPM and associated reconstruction. There are no clear differences in rates of complications depending on laterality, type or timing of reconstruction. This study provides reassurance that reconstruction can be successfully performed either at the same time as delayed CPM (with or without BR on therapeutic side) or as a delayed procedure.

Background Breast cancer diagnosis in Nigeria is perceived by most as a death sentence and women who have been diagnosed have to battle with different choices at any given time, whether to fight so as to survive, what if they fight and lose, or maybe it is better not to fight at all judging from different cases discussed during our monthly cancer patient support group meetings. Making informed choices with limited resources is the bane of many breast cancer patients who feel guilty spending so much on their medical care while their family suffers financial neglect. This is because health insurance covers barely 10% of the country's population and most families pay out of pocket. Some women on the other hand completely ignore their treatment and channel these resources towards education and general welfare of other members of their families. Aim To determine the extent to which financial choices made by women who are diagnosed and are undergoing treatment of breast cancer in Nigeria affects their treatment journey. Method A qualitative research approach was used and structural interview was used to collect data. Female breast cancer patient who are undergoing treatment and those who are through with their treatment {chemotherapy , surgery, and radiotherapy} and are currently on periodic check up with their oncologists participated in the study. Grounded theory was used in data analyses. Results Most of the patients interviewed had at one time or the other suspended their treatments in order to take care of pressing family issues and these had caused delays in proceeding with their treatment with its attendant consequences. In early triple-negative breast cancer (eTNBC), platinum-based chemotherapy has been shown to improve pathological complete response, but recommendations to include platinum chemotherapy are not consistent in international guidelines. We performed a systematic review of published randomized control trials to assess to assess survival outcomes and quality of life for people with early TNBC. The results presented in this abstract have not yet been peer-reviewed by Cochrane. If the final version of the review meets the necessary standards, the review is expected to be published in the Cochrane Database of Systematic Reviews. Methods: Randomized controlled trials examining neoadjuvant or adjuvant platinum chemotherapy for eTNBC were included. We searched for published and unpublished data using standard Cochrane search strategies. The primary outcomes assessed were disease free survival (DFS) and overall survival (OS). Secondary outcomes included rate of pathological complete response (pCR), dose intensity and completion of regimens, grade III or IV toxicity related to chemotherapy, and quality of life. Prespecified subgroups included BRCA mutation status, HRD status, lymph node status, frequency of chemotherapy, type of platinum agent used, and the presence or absence of anthracycline chemotherapy. Results: From 3972 records, 19 published studies were eligible. Twenty six ongoing studies were identified. Risk of bias was judged low for most trials. There were 14 neoadjuvant chemotherapy trials, 4 adjuvant

chemotherapy trials, and one trial of neoadjuvant and adjuvant therapy. Most trials used carboplatin (16 trials) followed by cisplatin (2), and lobaplatin (1). Eight trials had an anthracycline free intervention arm, 5 of which had a carboplatin-taxane intervention compared to an anthracycline-taxane control. All studies reporting DFS and OS used carboplatin. Twelve of 19 studies with a total of 3347 participants reported DFS data. Inclusion of platinum chemotherapy improved DFS in neoadjuvant and adjuvant setting (HR 0.63, 95% confidence interval (CI) 0.53-0.75; HR 0.69, 95% CI 0.54-0.88 respectively). Eleven studies collected OS data, with a total of 3229 participants and 460 deaths reported. Inclusion of platinum chemotherapy in the regimen improved OS (neoadjuvant: HR 0.69, 95% CI 0.69, 0.55-0.86; adjuvant: 0.70, 95% CI 0.50 to 0.96). Median follow up for survival outcomes ranged from 36 – 97.6 months. Our analysis confirmed platinum chemotherapy increased pCR rates (RR 1.46 [1.33-1.61], $p < 0.00001$). Subgroup analysis revealed that survival outcome benefits were seen regardless of BRCA mutation status, HRD status, lymph node status, or whether the intervention arm contained anthracycline chemotherapy or not. Platinum chemotherapy was associated with reduced dose intensity, with participants more likely to require chemotherapy delays (RR 2.23 [1.70-2.94], 4 studies), dose reductions (RR 1.77 [1.56-2.02], 6 studies) and early cessation of treatment (RR 1.20 [1.04-1.38], 16 studies). Increased hematological toxicity occurred in the platinum group who were more likely to experience grade III/IV neutropenia (RR 1.55 [1.45-1.66]), anemia (RR 10.12 [6.61-15.50]) and thrombocytopenia (RR 7.59 [5.10-11.29]). There was no increase in febrile neutropenia (RR 1.16 [0.89-1.49]). Treatment-related death was very rare (7 events in 3094 patients) and similar across treatment groups (RR 0.58 [0.14-2.33]). Five studies collected quality of life data but did not report it. Conclusion: Platinum-based chemotherapy using carboplatin in the adjuvant or neoadjuvant setting improves long-term outcomes in eTNBC, regardless of the examined subgroups. This was at the cost of more frequent chemotherapy delays and dose reductions, and greater haematological toxicity. Benefit from platinum was seen both when platinum agents were added to anthracycline containing regimens, as well as in anthracycline-free regimens.

Introduction Neoadjuvant systemic therapy (NST) is increasingly applied in breast cancer to increase breast-conserving surgery (BCS) rates and to improve oncological outcomes. Ductal carcinoma in situ (DCIS) can be present adjacent to invasive breast cancer (IBC), especially in HER2-positive IBC. DCIS was previously considered to be insensitive to NST. Consequently, mastectomy rates are higher in IBC with adjacent DCIS. Recent studies have shown that DCIS can be sensitive to NST, however, only small populations were investigated. Therefore, the aim of this study was to determine the rate of complete response of adjacent DCIS in HER2-positive IBC and to assess the potential influence of clinicopathological variables in a nationwide cohort.

Methods All women diagnosed with HER2-positive IBC, treated with NST and surgery between January 2010 and December 2019, were selected from the Netherlands Cancer Registry (NCR). Of these patients, all pre-NST biopsy and postoperative specimen pathology reports were obtained from PALGA, the Dutch Pathology Registry, and assessed for presence of DCIS. Response of DCIS was defined as absence of DCIS in postoperative pathology when a DCIS component was present in the pre-NST biopsy. Clinicopathological factors associated with DCIS response were assessed using logistic regression analyses. **Results** In total, 5834 patients were included, of whom 1443 (24.7%) had a DCIS component in the pre-NST biopsy. Mastectomy rates were higher in IBC with adjacent DCIS compared to IBC without adjacent DCIS in the pre-NST biopsy (53.6% versus 41.0%, $p < 0.001$). Of these 1443 patients, 743 (51.5%) showed complete response of the DCIS component. Complete response of DCIS occurred more frequently in patients who also had a complete response of IBC (63.4% versus 33.8%, $p < 0.001$). Multivariable logistic regression analysis showed ER negative IBC (OR 1.79; 95% CI 1.33-2.42) and treatment with HER2-targeted therapy (OR 5.97; 95% CI 1.82-19.55) to be independently associated with complete response of DCIS. **Conclusion** More than half of HER2-positive IBC patients with adjacent DCIS in the pre-NST biopsy showed a complete response of the DCIS component to NST. Complete response of DCIS should be considered, especially in ER-negative HER2-positive IBC and in case of complete response of IBC. Future studies should investigate the evaluation of DCIS response by imaging and the possibility of increasing breast-conserving surgery rates.

Introduction

Breast cancer (BC) is the most frequent neoplasm in Colombia, with mortality rate increasing in past decade. The expected 5-year overall survival (OS) is < 80%, being the Latin American country with the worst prognosis. 2 factors related to this are higher frequency of advanced stages and higher frequency of aggressive tumor subtypes.

Neoadjuvant chemotherapy (NACT), and ypCR, have demonstrated impact on the risk of relapse and death.

This trial describes the characteristics, treatment patterns, clinical outcomes, and ypCR after NACT in a cohort of Colombian BC patients.

Methods

We included BC adult patients treated with NACT in 3 institutions in Colombia. Clinical, sociodemographic, and outcome variables were retrieved retrospectively from clinical charts. Univariate, bivariate and time-to-event analyses were performed. A partition survival tree was performed to explore interactions between variables. Statistical analyses were done in R software.

The protocol was approved by the IRC and EC of Fundación Cardioinfantil and Hospital Militar Central.

Results

We included 312 patients treated between 2013 and 2019. 50.9% were ER and/or PgR positive, 28.5% HER2 positive and 20.5% triple negative breast cancer (TNBC). 75.9% of the patients had a LABC. TNBC patients were younger (median age 46 years), premenopausal (58%), had higher Ki67 index (Ki67 \geq 20%= 91%), and a higher tumor grade (Grade 3= 56.7%). Most of the patients (91.7%), received Doxorubicin + Cyclophosphamide, and Taxanes (97.8%), 76.6% of TNBC patients received Carboplatin. Breast conserving surgery was performed in 53.7% of the patients, and only 38.9% received immediate breast reconstruction. 88.5% of the patients were treated with adjuvant radiotherapy.

The ypCR rate was 34.6% and was achieved more frequently in HER2 positive subtype. The ypCR rates in TNBC were higher in patients treated with carboplatin (55% vs 20%, $p=0.02$). Other factors related to ypCR were high Ki67 ($p= 0.0005$) and higher tumor grade ($p= 0.0034$). Most of the relapses were distant (14.1%), with only 1.9% of local relapse rate. Table No 1 summarizes clinical outcomes.

With a median follow up of 4.9 years, the 5 year OS was 88.2%. Clinical stage at diagnosis ($p= 0.01$); node involvement ($p= 0.0014$); ER ($p= 0.0032$); PgR ($p= 0.0069$); HER2 ($p= 0.0334$); phenotype ($p=0.0145$); type of surgery ($p< 0.0001$); ypCR ($p=0.003$); and relapse ($p= < 0.00001$) were related with OS. We did not found differences in the 5 year OS between stage II and III patients (87.8% vs 88%). The 5 year OS did not differ between ypCR and ypCR-IS (94.2% vs 93%).

The relapse rate was 3.7% in ypCR vs 22.1% in non ypCR patients ($p< 0.00001$). The 5 year OS rate was 94.3% for ypCR and 85% for non ypCR patients ($p= 0.0059$). When analyzed by phenotype, ypCR was only related to risk of death among TNBC ($p= 0.011$).

We perform a partition survival tree, identifying 6 subgroups with different OS behaviors: TNBC and non TNBC; low proliferative and high proliferative; early stage and locally advanced stage.

Discussion

We found an increased number of LABC. The ypCR rate was higher than described elsewhere, explained by higher proportion of TNBC and HER2 enriched tumors and differences in treatment selection in subgroups. In the TNBC subgroup the use of carboplatin was associated with higher ypCR.

ypCR was related with risk of death and relapse, but with statistical significance for OS only in the TNBC population.

This study offers a baseline characteristic of NACT BC cohort, that will allow us to design and implement strategies to improve outcomes in early and LABC.

Table No 1: Treatment outcomes by phenotype.

Variable	Luminal A (n= 59) (% 95% CI)	Luminal B HER2 negative (n= 100) (% 95% CI)	Luminal B HER2 positive (n= 67) (% 95% CI)	HER2 enrich (n= 22) (% 95% CI)	TNBC (n= 64) (% 95% CI)	All (n= 312) (% 95% CI)
ypCR	6 (10.2%) (3.8 – 20.8)	19 (19%) (11.8 – 28.1)	37 (55.2%) (42.7 – 67.4)	16 (72.7%) (49.8 – 89.2)	30 (46.9%) (34.3 – 59.7)	108 (34.6%) (29.3 – 40.2)

Country: United States

Background: HER2-positive invasive lobular carcinoma (ILC) of the breast is a rare entity. Treatment decisions for HER2-positive lobular breast cancer are often extrapolated from the HER2-positive ductal subtype of breast cancer but the clinical outcomes and prognostic factors are not well defined. Methodology: Women with a diagnosis of stage I to III HER2-positive ILC or invasive ductal carcinoma (IDC) of the breast between 2010 and 2018 were identified from the National Cancer Database. Baseline characteristics were compared between ILC and IDC using Chi-square test for categorical variables and the Mann-Whitney U test for continuous variables. Five-year overall survival (OS) was estimated by the Kaplan Meir method. Multivariate cox proportional hazards regression model including age, race, ethnicity, Charleston Deyo score, grade, TNM stage, and treatment modalities such as type of surgery, chemotherapy, and radiation was used to identify factors associated with OS in HER2-positive ILC. In a subset of patients receiving neoadjuvant chemotherapy, the odds of achieving a complete pathological response were compared between women with ILC and IDC in a multivariate logistic regression model adjusting for age, race, ethnicity, Charleston Deyo score, grade, and clinical stage. Results: A total of 4,197 women with HER2-positive ILC and 116,984 women with HER2-positive IDC were included in the final analysis. The median age at diagnosis was 63 years for women with HER2-positive ILC and 56 years for women with HER2-positive IDC ($p < 0.001$). The five-year OS among women with HER2-positive ILC was 93.1%, 90.8%, and 78.8% in TNM stages I, II, and III respectively. In multivariate analysis, a significant difference in overall survival was not observed between women with HER2 positive ILC and IDC (Hazard Ratio [HR]: 1.0, 95% Confidence Interval [CI]: 0.9 - 1.1, $p = 0.55$). Among women receiving neoadjuvant chemotherapy, a complete pathological response was observed in 31.7% of women with HER2-positive ILC and 42.7% of HER2-positive IDC. In multivariate analysis, there was no difference in odds of achieving a complete pathological response to neoadjuvant chemotherapy between HER2-positive ILC and IDC (Odds Ratio [OR]: 0.8, 95%CI: 0.7 - 1.0, $p = 0.12$). Higher odds of complete pathological response in HER2-positive ILC were observed for women with estrogen-receptor negative (OR: 2.0, 95% CI: 1.1- 3.8), $p = 0.02$) and progesterone-receptor negative (OR 2.4, 95%CI: 1.5- 3.7), $p < 0.001$) tumors. The

five-year OS for women with a complete pathological response, partial response, and no response after neoadjuvant chemotherapy in HER2-positive ILC were 89.6%, 84.9%, and 77.3% respectively (p=0.01). Conclusion: This study demonstrates that HER2-positive ILC has comparable clinical outcomes to HER2-positive IDC and response to neoadjuvant chemotherapy correlates with OS in HER2-positive ILC. These findings lend support to the current practice of treating HER2-positive ILC and IDC in a similar manner.

Background: - Low levels of HER2 expression among women with HER2-negative breast cancer is an emerging target. In addition, prior studies have suggested that low levels of HER2 expression might confer resistance to chemotherapy among women with triple-negative breast cancer (TNBC). In this study, we assess the response to neoadjuvant chemotherapy among women with TNBC with varying degrees of HER2 expression. Methodology: - Utilizing the National Cancer Database, we identified adult women treated with neoadjuvant chemotherapy for a diagnosis of clinical TNM stage I to III triple-negative invasive ductal carcinoma of the breast between the years 2010 and 2018. Baseline characteristics were compared between HER2 immunohistochemistry (IHC) scores of 0, 1+, and 2+ (Women with HER2 2+ expression had to be negative for amplification in the HER2 gene by FISH) using Chi-square for categorical variables. The odds of achieving a complete pathological response were compared among women with different HER2 expression statuses in a multivariate logistic regression model adjusting for age, race, ethnicity, grade of the tumor, and clinical TNM stage at diagnosis. A multivariate cox proportional hazards regression model was used to identify the prognostic effect of HER2 expression on overall survival (OS) adjusting for age at diagnosis, race, ethnicity, grade of tumor, and clinical TNM stage at diagnosis. Results: - A total of 11,038 women with HER2 IHC score of 0, 8,718 women with a score of 1+ and 2,700 women with a score of 2+ were included in the final analysis. The median age at diagnosis was 52 for women with a HER2 IHC score of 0, 53 for women with a HER2 IHC score of 1+ and 54 for women with an IHC score of 2+/FISH negative. The rates of complete pathological response among women with HER2 IHC scores of 0, 1+, and 2+ were 39.5%, 38.1%, and 36.1% respectively. In multivariate analysis, a significant difference in the odds of achieving complete pathological response was not observed for women with HER2 1+ (OR: 1.1, 95% CI: 0.95-1.20, p = 0.3) or HER2 2+ (OR: 0.9, 95% CI: 0.7-1.0, p = 0.1) tumors compared to women with HER2 IHC score of 0. In multivariate Cox regression analysis, women with TNBC with HER2 IHC score 2+ were found to have a better OS (Hazard Ratio [HR]: 0.88, 95% CI: 0.80-0.97, p = 0.01) compared to women with HER2 IHC score of 0 whereas a significant difference in OS was not observed between women with HER2 IHC scores of 0 and 1+ (HR: 0.95, 95% CI: 0.89-1.01, p = 0.1). Conclusion: - This study demonstrates that HER2 expression status does not influence the rates of complete pathological response to neoadjuvant chemotherapy in women with TNBC.

However, women with HER2 IHC score of 2+ were found to have a favorable prognosis, which needs to be evaluated further in future studies.

Background: Neoadjuvant chemotherapy (NACT) is the standard early-stage triple-negative breast cancer (TNBC) treatment. Achieving pathological complete response (pCR) is considered an essential prognostic factor with favorable long-term outcomes. Younger patients have with poorer prognosis in breast cancer. To date, few studies are comparing the prognosis of AYA and older women (≥ 40) with breast cancer subtypes, specifically Triple-negative breast cancer (TNBC), as AYAs had higher proportions of this subtype. Method: Retrospective review was performed on female patients who received NACT at a King Hussien Cancer Center from January 2014 to June 2020. Data were collected from patients' electronic medical records. TNBC was histopathologically confirmed. Logistic regression analysis of predictors of pathologic complete response (pCR). Survival curves were estimated with the Kaplan-Meier method. Multivariate analysis for EFS was performed using Cox's proportional hazards regression model, covariates included age at diagnosis (AYA vs. ≥ 40), tumor size, nodal status LVI and pCR Result: We analyzed 211 women with stage I-III TNBC, including 62 (29.4%) women aged 18 to 39 years (AYA) and 149 (70.6%) ≥ 40 years. 138 (68.3%) were node positive, and 71 (34.8%) were T3/4 disease. Median follow-up was 28.1 months, median number of ER visit during NAC is 1 (0-11) , 23 (10.9 %) patients had admission during neoadjuvant chemotherapy, most commonly due to febrile neutropenia 13 (56.9%). 37 (17.5%) patients did not complete NAC, due to disease progression in 22 (10.4%), and toxicity in 15

(7.1%) patients. 195 (92.4%) patients had surgery, including 75 (35.5%) had breast-conserving surgery (BCS). 166 (76.3%) patients had objective response, and 64 (30.3%) had pCR. 170 (80.6%) received adjuvant radiotherapy, and 38 (18%) received adjuvant capecitabine. No significant differences between the AYA and the ≥ 40 group in terms of clinicopathological, toxicity, pCR rate, and the rate of BCS. In univariate analysis, the LVI, nodal status, pCR, and age group were significant predictors of DFS. In multivariate analysis, only PCR and age are the only independent predictor of DFS. The median DFS was worse in the AYA population 47.8 (31.21-64.39) months vs. NR in ≥ 40 (p-value 0.013). In patients who achieved pCR, the estimated 5-years DFS for the AYA group was 56.1% versus 86.8% for the ≥ 40 group, (p-value 0.71). In patients with residual disease, PFS for AYA was 34.2 (95%CI 11.5-57) months vs. 59.5 months in the ≥ 40 group, (p 0.009). Conclusion: Although there is no difference in pCR between the AYA age group patient treated with NACT for TNBC and the older age group, the DFS is significantly worse in the AYA than the ≥ 40 age group in patients with residual disease. As well, DFS is numerically worse in the AYA age vs. the ≥ 40 age group in patients who achieved pCR.

BACKGROUND: Pathologic complete response (pCR) or microinvasive residual breast cancer (ypTmic) following neoadjuvant chemotherapy (NAC) is critical for good long-term outcomes in triple negative breast cancer (TNBC) patients (pts) but is achieved only in 40-50% of pts. Its combination with pembrolizumab, the new standard of care in TNBC, increases the pCR rate to 65% but is associated with significant immune-related and permanent toxicities. Higher intratumoral levels of CD8+ cytotoxic T-lymphocytes (CTLs) and low levels of regulatory T-cells (Treg) and myeloid derived suppressor cells (MDSC) predict improved relapse-free survival (RFS), overall survival (OS) and higher probability of pCR, a surrogate marker for RFS. Locally produced chemokines CCL5, CXCL9, CXCL10 and CXCL11 are critical for local infiltration with CTLs, while CCL22 is responsible for Treg attraction, with high CXCL9 expression being associated with a 3-fold higher rate of achieving pCR in response to NAC. Our preclinical data show that Chemokine-modulatory (CKM) regimen, combining rintatolimod (TLR3 agonist), interferon (IFN)- α 2b and celecoxib (COX-2 inhibitor), selectively induces CTL-attractants but decreases MDSC- and Treg-attractants in the tumor microenvironment (TME). We hypothesized that the combination of CKM with paclitaxel will promote selective CTL infiltration into TNBC, and along with doxorubicin/cyclophosphamide (AC), will result in higher rate of pCR, translating into improved RFS and OS. **METHODS:** In the phase I study NCT04081389, 9 pts with stage I-III TNBC were enrolled with median age of 47 (37-55) years. All patients were treated with paclitaxel 80 mg/m² IV weekly for 12 weeks, and for first 3 weeks days 1-3 also

received CKM regimen consisting of rintatolimod 200 mg IV and celecoxib 200 mg oral twice daily. IFN- α 2b was administered in an accelerated titration design at doses 0 or 5 million units (MU)/m² [Dose Level (DL) 1,2 respectively] in first 2 pts (no intra-patient dose escalation), then 10 MU/m² [DL 3] in 4 patients and then 20 MU/ m² [DL 4] in 3 patients. Pre- and 3 week-on treatment biopsies were performed at DL 3 and DL 4 (5 patients). This was followed by standard dose-dense AC and surgery. Dose-limiting toxicity (DLT) was defined as grade 3 or higher toxicity within the first 3 weeks of treatment. The primary endpoint was safety and tolerability, to determine the recommended phase II dose (RP2D) of CKM for extended efficacy study. The secondary endpoints included the efficacy (pCR), along with RFS and OS. Tumor and blood biomarkers were analyzed in exploratory studies. RESULTS: Treatment was well-tolerated with mostly grade 1 or 2 treatment-related adverse events (TRAEs) and no DLTs. Grade 3 TRAE were neutropenia (3/9), attributed to CKM (1/9) or paclitaxel (3/9), pneumonia (1/9) and anemia (1/9) attributed to AC. Two additional severe adverse events (pneumonia and squamous cell carcinoma of skin in situ) were observed, unrelated to study treatment. Paclitaxel- or AC-related toxicities were not higher than expected. There was no evidence of delayed or immune-related toxicities 90 days post-treatment. 5/9 (56%) pts attained pCR, and 1 additional pt had ypTmic at the time of surgery. There were no patients with progressive disease. All patients were able to get planned surgery with no additional delays observed. There was consistent (p=0.07) selective increase in CD8 α (CTL marker) in on-treatment tumor biopsies with concomitant decrease in CD8 α in the blood (p=0.04). CONCLUSIONS: The treatment was well-tolerated and no DLTs were observed and we determined RP2D for future studies. We observed promising clinical activity with pCR + ypTmic rate of 66%, comparable to pembrolizumab combination with NAC. A larger phase II study is being designed to confirm the observed efficacy and to determine if CKM regimen would be a safer short-term alternative to pembrolizumab or if CKM can overcome the resistance to the standard pembrolizumab/NAC therapy.

Background In HER2-positive breast cancer, pathologic complete response (pCR) has been known to be a surrogate marker for favorable prognosis after neoadjuvant chemotherapy. We aimed to identify the clinico-pathologic factors related to pCR in patients with HER2-positive breast cancer treated with neoadjuvant dual HER2-targeted therapy. **Methods** Two-hundred ninety-five patients with HER2-positive breast cancer who received neoadjuvant chemotherapy with docetaxel, carboplatin, trastuzumab, and pertuzumab (TCHP) were included in this retrospective analysis. We assessed the association between age, clinical T, N stage, pathologic factors such as histologic grade, hormone receptor (HR), tumor-infiltrating lymphocytes, the membranous expression of HER2 protein evaluated by immunohistochemistry (IHC) and pCR. The fluorescent in situ hybridization (FISH) was performed in a tumor with HER2 score of 2+. **Results** Of the 295 patients, 195 (66.1%) achieved pCR (ypT0/is and ypN0). Besides, 240 (81.4%) patients were HER2 score of 3+, and 55 (18.6%) patients were HER2 score of 2+. The pCR was frequently observed in patients with HER2 score of 3+ (64 of 176 [73.3%]) than in those with HER2 score of 2+ (19 of 55 [34.5%]), regardless of HR status. After adjusting other clinicopathologic factors, the high HER2 protein expression was only an independent factor for pCR (adjusted OR 3.85, 95% CI, 1.66-8.91, p=0.002). **Conclusions** Our results suggest that high expression of HER2 protein assessed by IHC is important in predicting neoadjuvant TCHP response in HER2-positive breast cancer.

Background: The pathologic complete response (pCR) rate in inflammatory breast cancer (IBC) patients is worse than in non-IBC patients; new drug combinations are warranted to improve pCR rates across all IBC molecular subtypes. Based on our preclinical data, we added neratinib to standard neoadjuvant chemotherapy in both HER2+ (synergy) and HER2-/hormone receptor (HR)+ (high frequency of ERBB2 mut) untreated IBC, as a single-center, non-randomized phase I/II trial. Patients and Method: This study enrolled three cohorts: Cohort I phase Ib (C1P1B), Cohort I Phase II (C1P2) and Cohort II (C2). In C1P1B to determine the recommended phase 2 dose (RP2D), we enrolled patients with HER2+ metastatic or locally advanced breast cancer. Patients received paclitaxel/trastuzumab/pertuzumab (THP) + neratinib x 4 cycles (up to 8 cycles per physician's discretion). For C1P2 and C2, we enrolled Stage III – IV primary IBC patients. In C1P2, patients with HER2+ IBC received neratinib (RP2D) combined with THP x 4 cycles followed by doxorubicin/cyclophosphamide (AC) x 4 cycles. Per stage I design, 11 patients were enrolled with plan to enroll 20 more patients in Stage II if at least 6 had a pCR. In C2, patients with HER2-/HR+ IBC received neratinib 200 mg/day combined with paclitaxel x 4 cycles followed by AC x 4 cycles. Stage I design planned for enrollment of 16 patients with enrollment of 15 more patients on stage II, if at least 2 Stage I patients had pCR. In all three cohorts, patients initiated prophylactic anti-diarrheal medication (loperamide & budesonide) with the first dose of neratinib. Results: From 2018 to 2022, thirty-

four patients were enrolled and treated (n=4 C1P1B, n=14 C1P2, n=16 C2). In C1P1B, observed DLTs (dose limiting toxicities) were Grade (Gr) 2 Diarrhea, n=2 (50%); Gr3 diarrhea, n=2 (50%); 2 patients had a serious adverse event (SAE); 3 patients (55%) had Gr2 nausea. The RP2D was established at 80 mg/day (dose level 0). For patients in C1P2, the most frequently occurring adverse events (AEs) included Gr2 Alopecia, n=14 (100%); Gr2&3 Diarrhea, n=14 (100%); Gr2/3 Nausea, n=12 (86%); Gr2/3 Anemia, n=7 (50%); Gr2/3 Fatigue, n=8 (57%); Gr2/3 Hypokalemia, n=6 (57%); and Gr2/3 Neutrophil count decreased, n= 7 (50%). 6 patients had an SAE. Of the first 11 patients, 5 (46%) had pCR, 1 (9%) RCB-1, 1 (9%) RCB-II and 1 (9%) RCB-III. Three patients stopped study treatment for toxicity (27%), were non-evaluable and replaced. Of these, one had RCB-III (33.3%), one progression of disease (PD) (33.3%), and one came off study for toxicity (33.3%). Rather than replacing additional non-evaluable patients, the study was closed to new patient accrual. In C2, the most frequently occurring AEs were Gr2 diarrhea, n=7(44%); Gr3 diarrhea, n=8 (50%); Gr2 alopecia, n=14 (88%); Gr2/3 Anemia, n=10 (63%); Gr2/3 Nausea, n=7 (44%); Gr2/3 Neutropenia, n= 7 (44%). 3 patients had an SAE. Of 16 patients in this cohort, 1 had pCR (6%), 5 RCB-II (31%), 4 RCB-III (25%), 3 came off study for toxicity (19%) and 3 had PD (19%). C2 also closed to new patient accrual given the high toxicity profile. Conclusion: The addition of neratinib did not improve the pCR rate in HER2+ or HER2-/HR+ subtypes of IBC, and increased toxicities were observed. The trial closed to new patient entry March 2022. However, some patients achieved significant response. Biomarker analysis is ongoing. Evaluable participants will continue long-term follow-up per protocol. Acknowledgments: This study is supported by PUMA Biotechnology.

Background: Breast cancer is the second most commonly diagnosed cancer in North American women. The administration of neoadjuvant chemotherapy (NAC) is the mainstay of treatment

for individuals with high risk disease in an effort to reduce the extent of surgery, evaluate the role of additional adjuvant therapies (based on pathologic response to NAC), and improve disease-free and overall survival (OS). Anthracyclines have been shown to increase response rates leading to a greater likelihood of pathologic complete response compared to non-anthracycline regimens. However, for some individuals anthracyclines are omitted from the NAC regimen due to toxicities including greater immunosuppression, cardiac toxicity and risk of acute leukemia. We established a population-based cohort of individuals treated with NAC for breast cancer. We report the outcomes of women selected for treatment with non-anthracycline NAC compared to those treated with anthracyclines. Methods: This is a retrospective population-based cohort study using linked health administrative data held at the Institute for Clinical Evaluative Sciences (ICES) in Ontario, Canada. We identified adult women diagnosed with stage I-III breast cancer (ICD-10 C50^A) between 2012 and 2020 who received NAC. Administration of at least 50% of the planned chemotherapy regimen was required. We excluded patients with bilateral breast cancer, previous malignancy and male sex. NAC regimens were classified as anthracycline and non-anthracycline-containing regimens. To address confounding between those receiving anthracycline and other regimens, we built a propensity score model including patient and disease characteristics. The association with OS was calculated using Cox proportional hazards models, and breast cancer-specific survival (BCSS) was calculated using cause-specific Cox proportional hazards models. Models were adjusted for the propensity score, radiation treatment as a time-varying covariate, age, socioeconomic status, breast cancer stage and receptor sub-type, as well as Charlson comorbidity index. Results: A total of 4,180 women were identified with a median follow up of 62 months (IQR 44 – 85). Of these, 279 (6.7%) were treated with non-anthracycline regimens compared to 3,901 treated with anthracycline. Patients who received non-anthracyclines were older (median 62 years vs. 50 years; $p < 0.001$), and less likely to have stage III disease (33.0% vs. 48.7%; $p < 0.001$), and harbor triple-negative breast cancer (TNBC) (14.0% vs. 24.4%; $p < 0.001$). They were more likely to have no recorded comorbidities (89.2% vs. 96.5%; $p < 0.001$), undergo mastectomy (82.1% vs. 71.9%; $p < 0.001$), and sentinel lymph node biopsy (44.4% vs. 32.3%; $p < 0.001$). After propensity score and multivariable adjustment, women selected for treatment with non-anthracycline regimens had similar OS (HR 0.85, 95% CI 0.60-1.21) and BCSS (cause-specific HR 0.76, 95% CI 0.46-1.25) compared to those treated with anthracyclines. When stratified by stage, women treated with non-anthracycline regimens did not have significantly higher incidences of breast cancer death or death from any cause (stages I, II, and III Gray's Test p -value all > 0.1). The mean OS was 7.2 years for women who received non-anthracycline regimens (95% CI 7.0 – 7.4) compared to 7.9 years for those who received anthracycline (95% CI 7.9 – 8.0) (log-rank $p = 0.100$). Conclusions: Women with stage I-III breast cancer treated with non-anthracycline NAC regimens are a highly selected population. These patients were older and healthier, with earlier stage disease and more favorable subtype (i.e. non-TNBC) when compared to those treated with anthracycline NAC. Our results demonstrate that women were well selected to omit anthracyclines and did not have worse survival outcomes. Further research is needed to better understand in whom anthracycline can be safely omitted.

Pathologic Complete Response in Triple Negative Breast Cancer of Black vs White Patients in the Post-Keynote 522 Era Melanie Sheen MD, Victoria Chung DO, Ruby Maini MD, Michael Duggan BS, Julia Levy BS Background Triple-negative breast cancer (TNBC) is an aggressive form of breast cancer that lacks estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER-2) gene amplification. Women with TNBC have worse survival outcomes and increased rates of relapse and distant metastasis as compared to women with non-TNBC. Treatment of TNBC has recently been focused on neoadjuvant chemotherapy (NACT) with a goal of achieving a pathologic complete response (pCR) which is associated with longer event-free survival and overall survival. The KEYNOTE-522 trial was presented at the San Antonio Breast Cancer Symposium in December 2019 and found that patients who received pembrolizumab, an anti-programmed death 1 (PD-1) monoclonal antibody, plus NACT were more likely to achieve pCR than women who received placebo plus NACT. On July 26, 2021, the FDA approved the use of pembrolizumab in combination with NACT for high risk, early stage TNBC. KEYNOTE-522 did not collect race as a baseline demographic characteristic, and since TNBC disproportionately affects younger women and Black women, confirming the efficacy of achieving pCR in these groups is essential. Further investigation of the factors that may contribute to achieving pCR in women treated with pembrolizumab for TNBC is warranted. We set out to perform a retrospective analysis examining the rates of pCR in Black versus White patients with TNBC since the initial revelation of the KEYNOTE-522 data. Methods This retrospective chart review of a regional health care network included patients who had been diagnosed with Stage II/III TNBC, documented race as Black/African-American or White, and received treatment with pembrolizumab in the NACT setting. Exclusion criteria included ER-positivity, PR-positivity, HER2-positivity, or unknown receptor status, no pembrolizumab in the neoadjuvant setting, absence of documented race, and age < 18 years-old. Data was collected using Epic

SlicerDicer program. Results 118 patients met inclusion criteria. 59 (50.0%) were Black/African American, 59 (50.0%) were white. There were 57 (48.3%) patients who had pCR status identified through pathology reports while the remaining 61 (51.7%) are still undergoing NACT awaiting surgery. 34 Black women and 17 white women have not had surgery yet. Of women who underwent surgery, 12 Black women achieved pCR compared to 15 White women. 13 Black women and 16 White women did not have pCR Discussion Analysis of the data demonstrates an equal number of Black and White women receiving NACT with pembrolizumab. Of those women, there was relatively equal number of pCR between Black and White women. This data shows no appreciable difference in outcomes of Black and White women in terms of response to therapy. Conclusion Given the known association of pCR with increased survival, pembrolizumab should be considered in the treatment regimen for both Black and White women with stage II/III TNBC. This retrospective study is limited by a small patient population. Continued data collection is underway and will be updated.

Background: The incidence of breast cancer among younger patients (age ≤ 40) is higher in Latin America than in other regions. The multidisciplinary approach of breast cancer cases has been related with better survival, and the knowledge about specific clinicopathological features of this population is needed to optimize the therapeutic approach. The aim of our study was to describe the clinicopathological characteristics of breast cancer in younger (Y) compared with older patients (O), and to determine which characteristics were associated with the use of primary systemic therapy.

Methods: A retrospective cohort study was designed. Clinicopathological data of consecutive invasive non-metastatic breast cancer patients diagnosed between Jan 2015 to Dec 2019 in two private oncological centers in Lima, Perú were collected. Logistic regression analysis was performed to obtain models to predict primary systemic therapy as first treatment.

Results: We included 503 cases (mean age 49.8 years [SD 11.8]), 30.6% younger (n = 109) and 69.4% O (n = 394). No significant differences were found for ductal histology (89% Y vs. 87.7% O, p = 0.49) and HER2-overexpression (28.4% Y vs. 23.9% O, p = 0.39). Significant differences were found for stage III (37.6% Y vs. 20% O, p < 0.01), grade 3 (44.4% Y vs 33% O, p = 0.04) and HR-positive (64.2% Y vs. 75.1% O, p = 0.03). Univariate analysis showed significant OR = 2.1 to receive primary systemic therapy for Y (95%CI 1.37 – 3.24; p < 0.01), however, multivariate analysis adjusted for age, hormone receptors (HR), HER2, grade and stage showed non-significant OR = 1.5 to receive primary systemic therapy for Y (95%CI 0.90 – 2.50; p = 0.12) as detailed in the table below:

Conclusions: In our series we found a greater proportion of young breast cancer patients than previously reported. Clinical-pathological characteristics of breast cancer were different between younger and older patients, showing more aggressive phenotypes for younger patients with greater proportion of stage III, grade 3 and non-expression of hormone receptors.

Decision of using primary systemic therapy in our series was based on anatomic and biologic characteristics and not on age.

Univariate analysis (Primary Systemic Therapy)			
	OR	95%CI	p-value
Age ≤ 40	2.10	1.37 – 3.24	< 0.01
Multivariate analysis (Primary Systemic Therapy)			
	OR	95%CI	p-value
Age ≤ 40	1.50	0.90 – 2.50	0.12
HR-positive	0.41	0.25 – 0.68	< 0.01
HER2-positive	3.91	2.38 – 6.51	< 0.01
Grade 3	1.52	0.96 – 2.40	0.08
Stage III	7.05	4.24 – 12.04	< 0.01

Background: The GeparOLA study was designed to evaluate the efficacy and safety of the combination of paclitaxel (P) plus olaparib (O) as part of neoadjuvant chemotherapy (NACT) in patients with human epidermal growth factor receptor 2 (HER2)-negative, either hormone receptor (HR)-positive or HR-negative and homologous recombination deficiency (HRD) defined as having a g/tBRCA mutation and/or a high HRD score. Primary analysis showed a pCR rate of 55.1% (90% CI 44.5%-65.3%) with PO and 48.6% (90% CI 34.3%-63.2%) with P plus carboplatinum (Cb). The PO combination could not exclude a pCR rate of $\leq 55\%$ in the PO arm but was significantly better tolerated. Analysis on the stratified subgroups showed higher pCR rates with PO in the cohorts of patients < 40 years and HR-positive tumors (Fasching Ann Oncol 2020). Here, we report long-term data. Methods: GeparOLA (NCT02789332) was a non-comparative, multicenter, prospective, randomized, open-label, phase II trial. Patients with primary HER2-negative breast cancer, HRD and indication for chemotherapy (cT2-cT4a-d or cT1c and cN+ or cT1c and pNSLN+ or cT1c and TNBC or cT1c and Ki-67 >20%) were randomly assigned to receive either P 80 mg/m² weekly plus O 100 mg twice daily for 12 weeks or P plus Cb area under the curve 2 (AUC2) weekly for 12 weeks, both followed by four cycles of either 2-weekly or 3-weekly epirubicin 90 mg/m² plus cyclophosphamide 600 mg/m². Primary endpoint was pCR (ypT0/is ypN0) rate after NACT with PO followed by EC. Long-term efficacy endpoints included invasive disease-free survival (iDFS), distant disease-free survival (DDFS) and overall survival (OS). The time-to-event endpoints analysis is planned with median follow-up of at least 4 years and a follow-up completeness of at least 80%. Results: Between

September 2016 and July 2018, 274 patients were screened, of whom 107 were randomized and 106 (PO N=69; PCb N=37) started treatment. The median age was 47.0 years (range 25.0-71.0); 32 patients were aged < 40 years; 36.2% of patients had cT1 tumors and 31.8% were cN-positive; the majority (86.8%) had grade 3 tumors and a Ki-67>20% (89.6%). Seventy-seven patients (72.6%) had TNBC. After a median follow-up of 49.8 months (range 0.1-69.1), 18 (15 in PO; 3 in PCb) iDFS events and 7 (6 in PO; 1 in PCb) deaths were reported. The 4-year survival rates are shown in the table below. iDFS (HR PO to PCb=2.86 [95%CI 0.83-9.9], log-rank p=0.081), DDFS (HR =3.03 [95%CI 0.67-13.67], log-rank p=0.129), and OS (HR=3.27 [95%CI 0.39-27.2], log-rank p=0.244) tended to be inferior with olaparib. Patients without g/tBRCA mutation seem to benefit from the use of carboplatinum (7/30 iDFS/DDFS events in PO; 0/16 in PCb, log-rank p=0.037, HR n.a.). Conclusions: In patients with HER2-negative and HRD breast cancer the use of olaparib instead of carboplatinum although showing comparable pCR rates, tended to result in an overall inferior outcome. This was mainly driven by the patients without a g/tBRCA mutation. In patients with a g/t BRCA mutation no difference between olaparib and carboplatinum was seen. Key words: Olaparib, HER2-negative breast cancer, HRD, survival Funding: The study was financially supported by AstraZeneca

Kong Lingjun, MD, *Dr - Cangzhou Clinical College of Integrated Traditional Chinese and Western Medicine of Hebei Medical University*

Country: United States

Background: Breast cancer remains the most frequent type of cancer in women, with de novo metastatic breast cancer (dnMBC) accounting for approximately 6-10% of patients. Advances in treatment of dnMBC have led to an increase in overall survival (OS), but the role of locoregional surgery remains unclear. Aim: To determine the value of locoregional surgery compared with no surgery on OS of women with dnMBC Settings and design: This study was designed as a randomized clinical study and was approved by the Ethics Committee of the Ethics Committee of Cangzhou Clinical College of Integrated Traditional Chinese and Western Medicine of Hebei Medical University (NO.20200212). Methods: Patient characteristics were previously reported in ASCO2022. Eighty-six patients with dnMBC were randomised to surgery of the primary tumor followed by systemic therapy (surgery group) or to primary systemic therapy without surgery (non-surgery group), by a computer generated block randomisation sequence. Randomisation was stratified by site of distant metastases, number of metastatic lesions, and molecular subtypes. Follow-up visits were conducted during treatment, monthly in first year, every 3 months thereafter. The primary endpoint was overall survival analysed by intention to treat. The stratified log-rank test and Cox proportional hazards model were used to compare OS between groups. The level for significance was set at $p < 0.05$. All analyses were performed with STATA 17. Results: Between Jan 3, 2019, and Mar 29, 2021, of the 103 women presenting with dnMBC, we randomly assigned 86 patients: 44 to surgery of the primary tumor followed by systemic therapy and 42 to primary systemic therapy without surgery. At data cut-off of Dec 1, 2021, median follow-up was 27 months with 44 deaths (surgery group $n=21$, non-surgery group $n=23$). The 2-year OS was 45.2% without and 52.3% with locoregional surgery (hazard ratio=0.59; 95% CI, 0.32 to 1.12; $p = 0.11$). The median OS was 25.5 months (95% CI, 23.52 to 29.38) in non-surgery group and 33 months (95% CI, 27.43 to 34.53) in surgery group. Conclusions: Our prospective randomized trial showed that compared with non-surgery counterparts, locoregional surgery does not improve OS of patients with dnMBC. Large, well-designed studies involving a large number of cases, multi-institution trials and longer follow-up are needed to verify the finding.

Background: Trastuzumab deruxtecan (T-DXd) has been evaluated in numerous solid tumors and has been approved for metastatic HER2-positive breast and gastric/gastroesophageal cancers. We aimed to provide a precise estimate of toxicity of T-DXd observed in clinical trials. Methods: A systematic literature search was performed in PubMed and supplemented by review of abstracts from ASCO and ESMO. Eligible studies were clinical trials (dose-expansion phase 1, phase 2, and phase 3) investigating single agent T-DXd. The search was performed in June 2022. For single-arm trials, meta-analysis comprised one-sample proportions to obtain the random effects estimates of toxicity and respective 95% confidence intervals (CI) for T-DXd, while for randomized trials, the Mantel-Haenszel odds ratio method was utilized. Results: Fifteen trials comprising 1566 participants were evaluable for toxicity. ECOG Performance Status (PS) was reported in 11 studies and was ≥ 2 in only a single patient. The median age at enrollment was reported for 13 studies and was 57.5 years. Seven trials comprising 1023 (65.3%) participants evaluated T-DXd for breast cancer. From available data, 1209/1440 (84%) of participants were female and 735/1551 (47%) were from East Asia. The median follow-up time was 11.1 months (13 studies) and median previous lines of treatment were 3 (12 studies). All-grade toxicity rate of $\geq 10\%$ was reported for most toxicities; however, grade ≥ 3 toxicity rate of $\geq 10\%$ was reported only for neutropenia and anemia; 17.4% (95%CI 12-22.8) and 14.8% (95%CI 8.6-21), respectively (Table 1). Interstitial lung disease / pneumonitis (ILD) was reported in 203 (12.4%) patients, including 160 (9.41%) grade 1-2, and 23 (1.1%) grade 3-4. Treatment-related death was reported in 20 (1%) patients, and all were due to grade 5 ILD. No significant difference in ILD was identified in subgroup analysis of trials conducted in east

Asia vs. the rest of the world, breast vs. other solid tumors, 5.4mg/kg vs. other doses, median follow-up < 12 months vs. ≥12 months or median previous lines ≥3 vs. < 3. In the three randomized clinical trials, grade ≥3 toxicity was significantly higher for nausea (OR: 9.32, 95%CI: 2.53-34.32), ILD (OR: 5.35, 95%CI: 0.97, 29.48), fatigue (OR:2.5, 95%CI: 1.11-5.66), and anemia (OR:1.77 95%CI: 1.14-2.74). Conclusions: T-DXd was associated with infrequent grade ≥3 toxicities across clinical trials. Grade 1-2 ILD was more common; however, grade 3-4 ILD occurred in 1.1%. This may be related to active monitoring of this toxicity in clinical trials and discontinuation of treatment in participants with G2 ILD. There is lack of evidence for the safety of T-DXd in patients with ECOG PS ≥ 2.

Abstract Introduction HIV-positive women with breast cancer (BC) have worse overall survival than HIV-negative women with BC, and poor adherence to prescribed tamoxifen is known to contribute to poor survival. We, therefore, investigated the association of HIV infection with adherence to adjuvant tamoxifen among women with localized hormone receptor (HR)-positive breast cancer in South Africa. Methods Among 4,097 women diagnosed with breast cancer at six hospitals in the prospective South African Breast Cancer and HIV Outcomes (SABCHO) cohort study between July 2015 and December 2020, we focused on women with stages I-III HR-positive breast cancer who were prescribed 20mg of adjuvant tamoxifen daily for ≥ 3 months during the study period. We collected venous blood once from each participant during a routine clinic visit and analyzed concentrations of tamoxifen and its metabolites using a triple quadruple mass spectrometer. We defined non-adherence as a tamoxifen level $< 60\text{ng/mL}$ after 3 months of prescribed daily tamoxifen use. We compared socio-demographic, lifestyle factors, tamoxifen-related side effects, and concurrent medication use among women with and without HIV and developed multivariable logistic regression models of tamoxifen non-adherence. Results Among 369 participants, 78 (21.1%) were HIV-positive and 291 (78.9%) HIV-negative. After a median (interquartile range) time of 13.0 (6.2-25.2) months since tamoxifen initiation, the tamoxifen serum concentration ranged between 1.54 and 943.0ng/mL, with a median of 52.3ng/mL. In the full cohort, 208 women (56.4%) were non-adherent to tamoxifen; only 161 (43.6%) were adherent. Women < 40 years of age were less likely to adhere to tamoxifen than women > 60 years (73.4% vs 52.6%, odds ratio (OR)=2.49, 95% confidence interval (CI)=1.26-4.94); likewise, HIV-positive women (70.5% vs 52.6%, OR=2.16, 95% CI=1.26-3.70) were less

likely to adhere than HIV-negative women. In an adjusted model, only HIV was associated with non-adherence; HIV-positive women had twice the odds of non-adherence to tamoxifen, compared to HIV-negative women (OR=2.40, 95% CI=1.11-5.20). Conclusion Non-adherence to tamoxifen may limit the overall survival of women with HR-positive breast cancer; in our study, especially in HIV-positive women.

PI3K α is highly mutated in cancer resulting in hyperactivation of lipid kinase activity and downstream AKT signaling. H1047 is the most common site of oncogenic mutation and occurs in ~14% of all breast cancers. Initial therapeutic benefit of targeting PI3K α was established with alpelisib, an alpha-selective PI3K inhibitor that is equipotent against wild-type and mutant forms. However, wild-type PI3K α inhibition results in frequent dose-limiting toxicities including hyperglycemia, restricting the full potential of this drug. Selective targeting of H1047X-mutant PI3K α is expected to both improve anti-tumor activity and reduce toxicity. STX-478 is an allosteric, CNS-penetrant, selective PI3K α H1047X inhibitor, having excellent drug-like properties and exceptional kinome selectivity. STX-478 demonstrated minimal inhibition of CYP enzymes in vitro, supporting the potential for combinations with a wide range of therapeutics in breast cancer and a variety of other tumor types. STX-478 selectivity extended to the inhibition of other activating kinase domain mutations in biochemical assays. In a diverse panel of PI3K α H1047X mutant cell lines, STX-478 selectively reduced the cellular levels of pAKT (S473) with a strong correlation between pAKT inhibition and cell viability (R = 0.8). In a high-throughput viability screen of 467 cancer cell lines, the presence of PIK3CA H1047X and other kinase domain mutations were the single strongest predictor of STX-478 sensitivity with potency superior to alpelisib. STX-478 also selectively inhibited the proliferation of cell lines with PI3K α helical domain mutations, potentially due to the selective dependency of these cells on mutant PI3K α . When combined with fulvestrant, lapatinib, or abemaciclib, STX-478 demonstrated synergistic anti-proliferative activity in cell lines with relevant ER/HER2 status. Unlike alpelisib, STX-478 did not impair glucose metabolism or cause insulin resistance at efficacious doses. In the T47D (PI3K α H1047R) breast cancer model, STX-478 (100 mg/kg) monotherapy caused tumor regression whereas alpelisib caused only stasis. STX-478 combination with fulvestrant was well-tolerated, with more consistent and deeper tumor regression. Similar results were observed in a PI3K α H1047R mutant ER+/HER2- PDX model, where fulvestrant monotherapy showed minimal activity, while combination with STX-478 yielded tumor regressions. In an ER+/HER2+ PDX model (PI3K α H1047R/R108H), palbociclib and STX-478 (100 mg/kg) monotherapy resulted in similar efficacy while the combination was well tolerated and yielded tumor regression. Together these data indicate robust STX-478 monotherapy activity that was well tolerated and improved when dosed in combination with fulvestrant or CDK4/6 inhibitors. Finally, we investigated the effect of STX-478 treatment in an ER+ PDX model carrying a helical domain mutation. STX-478 treatment resulted in tumor growth inhibition at doses that did not result in metabolic dysfunction, suggesting that STX-478 may also be efficacious in treating PIK3CA mutant tumors with helical domain mutations. In summary, STX-478 efficacy was superior to alpelisib at a dose level that exceeds the clinically relevant exposure in mice without causing metabolic dysfunction. STX-478 has a predicted low human dose, CNS exposure, low risk of DDI, and a predicted long half-life with minimal variation in peak-to-trough plasma concentrations which further supports a favorable therapeutic index. STX-478 has the potential to provide a best-in-class profile to improve outcomes in patients harboring tumors with prevalent PI3K α H1047X mutations as well as other kinase and helical domain mutant tumors. The significant CNS exposure of STX-478 is expected to enable this treatment for patients with brain tumors and brain metastases not afforded by existing options. STX-478 is currently in IND enabling studies and is expected to enter human clinical trials in 2023.

BACKGROUND: Breast cancer (BC) is the most common cancer diagnosed in premenopausal women with an increasing incidence for age 35 or less. Although proportionally less frequent, hormone receptor (HR)-positive BC still remains the main subtype for this group, but given tumor characteristics and suboptimal adjuvant endocrine therapy (ET), present inferior long-term outcomes when compared to HR-positive BC in older women. Both Tamoxifen and Exemestane Trial (TEXT) and Suppression of Ovarian Function Trial (SOFT) have helped to optimize ET strategies for premenopausal women, identifying which patients benefit from ovarian function suppression (OFS). In Chile, we have scarce data on very young BC patients and limited access to proper OFS treatment specially in our public health system. Thus we aim to characterize a cohort of very young women regarding treatment strategies and survival, plus as an exploratory analysis evaluate Regan Score in our cohort.

METHODS We conducted a retrospective population-cohort study involving women under 36 years of age, with early HR-positive/human epidermal growth factor receptor 2 (HER2)-negative BC, treated both at a community hospital and at an academic private hospital between 2001 and 2021. We did a descriptive analysis including stage distribution and treatment strategies (chemotherapy (CT), ET of choice and OFS use). We evaluated prognosis for the entire population. Survival analysis was carried out using the Kaplan-Meier method.

RESULTS A total of 143 patients were included. Median age at diagnosis was 33 (19 - 36); 15.4% percent of patients were diagnosed in stage I, 51.4% stage II and 30.1% stage III. Eighty six percent received CT, 35.0% neoadjuvant. Ninety three percent received endocrine adjuvant treatment: 81.2% TAM alone, 6.8% TAM/OFS and 10.5% IA/OFS. Regarding OFS strategies only 38.5% received gonadotropin-releasing hormone (GnRH) agonists while the rest were oophorectomized. Regan median composite score was 2.77 (2.61 - 2.93) for the entire cohort. Rising to 2.95 (2.79 - 3.11) for patients treated with CT plus ET compared to 1.91 (1.55 - 2.27) for those treated with ET exclusively (p=0.0001). Patients that received TAM alone had a median Regan Score of 2.72 (0.77-4) compared to 3.14 (2.07-4.0) for patients that had OFS added (p=0.04).

With a median follow-up of 59 months, 5-year Disease Free Survival (DFS), Distant DFS and Overall Survival (OS) for the entire cohort were 63.5%, 66.9% and 88.7%, respectively.

CONCLUSION. To our knowledge this is one of the largest cohorts considering very young women BC in Latinamerica. We confirm their elevated overall risk with markedly higher Regan scores compared to SOFT and TEXT populations for both CT and ET exclusively treated patients. Due to access difficulties very few patients received OFS and when used, surgical oophorectomy was the main strategy of choice, with all the potential long term consequences it conveys. Thus OFS use was restricted to very high risk women, meaning that a large group of only TAM users were undertreated according to nowadays standards. This could explain the elevated recurrence risk observed in our population when compared to other under 35 years of age cohorts.

Background: In 2019, a quality improvement (QI) research project was conducted at UChicago Medicine (UCM) to evaluate bone modifying agent (BMA) use for skeletal-related event (SRE) prevention in patients with metastatic breast cancer and metastatic castration-resistant prostate cancer. Denosumab was the preferred BMA agent at UCM in this setting. Compared to zoledronic acid (ZA), denosumab was associated with higher drug cost and lower adherence rate mainly due to the difficulty of maintaining the 4-weekly frequency. Studies have shown that ZA can be de-escalated from 4-weekly to 12-weekly for SRE prevention. There is still no convincing evidence to show that this de-escalated schedule can be applied to denosumab. One study evaluated the noninferiority of 12-weekly compared with 4-weekly denosumab suggested that the health-related quality of life was non-inferior (Clemons et al., 2021). However, the study was not powered to evaluate the statistical difference in SRE rates. Based on the results of the 2019 QI project, a BMA pathway was generated at UCM in September 2020 with the purpose of guiding physician prescribing patterns, improving adherence rate, and reducing drug costs. This pathway recommended using ZA as the preferred agent for SRE prevention instead of denosumab. Methods: This was a retrospective study that included 198 patients who had metastatic breast cancer and received at least one dose of ZA or denosumab from UCM outpatient oncology clinic for SRE prevention. All included patients must have bone metastases. 107 patients from the pre-implementation study period (July 1st, 2018 to June 30th, 2019) and 91 patients from the post-implementation study period (November 10th, 2020 to November 10th, 2021) were included. Patients were divided into four groups based on study time (pre- or post-implementation period) and BMA agent (ZA and denosumab). The primary outcome was BMA therapy adherence rate, which was defined by those who received greater than or equal to 80% of appropriately scheduled doses. Secondary outcomes included the percentage of patients on ZA or denosumab, SREs, BMA-associated adverse effects, and BMA cost. Descriptive statistics were used SREs and BMA-associated adverse effects. Results: The percentage of patients on ZA significantly increased from 12% to 64% after BMA pathway implementation ($P < 0.0001$). Denosumab use decreased from 88% to 36% ($P < 0.0001$). The overall BMA adherence rate including both ZA and denosumab patients during the post-implementation period was 68%, which was not significantly different compared to the overall adherence rate of 74% during the pre-implementation period ($P = 0.5461$). The adherence rates in denosumab groups (63% in pre and 30% in post) were lower than in ZA groups (100% in pre

and 90% in post). The most common reason for the lower adherence rates in denosumab groups was scheduling convenience. During the study period, there were 2, 0, 3, and 3 patients who had SREs in the above four groups respectively. The predominant adverse events among all groups were hypocalcemia and hypophosphatemia. The cost analysis showed using ZA as the primary BMA agent saved 1.1 million dollars of drug costs during the post-implementation study period at UCM. Conclusion: Implementing a BMA pathway encouraged the providers to choose ZA as the preferred agent for SRE prevention in metastatic breast cancer patients with bone metastasis, which dramatically reduced drug costs. The overall BMA adherence rate was not significantly improved with the implementation. The difficulty of maintaining a 4-weekly denosumab frequency continued to exist.

Background Metastatic breast cancer, has a heterogeneous presentation and management, therefore its overall survival ranges from 2 to 3 years. Despite advances in breast cancer screening, diagnosis, and treatment, nearly 12-30% of early stage breast cancer patients

eventually develop metastatic disease. In Ecuador, breast cancer is the most common malignancy among women, and the leading cause of newly diagnose cancer in the general population (Globocan 2020). This study aims to determine the frequency of metastatic sites and its impact in overall survival. Methods: An observational, retrospective, descriptive, single-center study was carried out. All patients with Metastatic breast cancer who had been treated at the National Oncology Institute SOLCA Guayaquil, in the period from 2016 to 2020 were included in the analysis. All statistical analyses were performed using SPSS for Windows (version 25.0;SPSS). The Kolmogorov-Smirnov test was used to test for the normality of distribution. Correlations were determined with Spearman correlation coefficients. The number of metastatic sites were recorded and their impact on overall survival was calculated by the Kaplan-Meier method and compared by the long-rank test, multivariable adjusted hazard ratios (HR) were estimated by Cox regression models. Results: A total of 1113 patients were included in the analysis, of which 84 patients (7.5%) were metastatic disease. The distribution of metastatic sites at diagnosis were: bone 64% (n=53), lung 51% (n=42), liver 30% (n=25), soft tissues 23% (n=19) , and the least frequent were metastases to the central nervous system 17% (n=14), mediastinal lymph node 5% (n=4), peritoneal lymph node 1% (n=1). Regarding metastatic sites, 41% (N: 35) had only 1 metastatic site, 33,7% (N: 28) had 2 metastatic sites, and 25.3% (N:21) has 3 or more sites. A multivariable analysis was performed which takes into account all the metastases in the analysis. All have a higher risk of mortality vs not having any metastasis (all are greater than 1). But the only significant one is CNS with a RR 1,31 (1,08 - 1,61) P=0,005. Three or more sites of metastasis have RR 1,22 (0.95-1.57) p: 0.11. Relative Risk (RR) according to the different sites of metastasis are shown in the table#1. The association between 3 or more sites of metastasis showed a negative impact on overall survival (15 months +/-2.3 SD vs 36 months +/- 3.7 SD) compared to 1 site of metastasis. Conclusions: Approximately half of the women (N:49) with metastatic breast cancer in our population presented 2 or more sites of metastasis, which significantly decreases overall survival. The central nervous system is the site of metastasis with the highest relative risk of mortality, generating functional deterioration, adding morbidity, and only 64% (9 out of 14) of the patients access to radiotherapy as palliative treatment. Thus, better strategies for early diagnosis and adequate treatment of metastatic disease should be developed.

Background: Breast cancer immunohistochemistry subtype classification by hormone receptor has become the standard practice for therapeutic decision making. The subtype is one of the crucial factors affecting breast cancer prognostic. Despite the progress in understanding of complex mechanisms in progression of breast cancer, the treatment is a global challenge health around the world, the 5-year survival rate is 26%. Currently in develop countries, in the metastatic stage, a gain in survival in the HR+ / HER2+ subtype has been evidenced, likely attributable to major advances in HER2-targeted treatment (1). However, although in developed countries there is access to targeted therapy, in the Ecuadorian health system, difficulties complicate patients access to health care and treatment. Methods: We conducted a retrospective study about survival data in breast cancer metastatic according immunohistochemistry subtype. We analyzed all primary invasive breast cancer cases in the period from 2016 to 2020 in an oncology institute of Ecuador, the final study sample consisted for 83 patients. The overall survival was calculated by the Kaplan-Meier method and compared by the long-rank test. Multivariable adjusted hazard ratios (HR) were estimated by Cox regression models. Results: There were 31 patients (37.1%) with a HR(+)/HER2(-) breast cancer subtype, 15 patients HR(+)/HER2(+), 5 patients HER2 (+), 18 patients HR(-)/HER2(-) and 14 patients without breast cancer subtype identified. Most patients were treated with different chemotherapy protocols; additional, in the group of women with HR(+)/HER2(+) subtype and HER2 (+) subtype only 15.87% were treated with HER2-targeted treatment, the vast majority in the last year. The best survival pattern was observed among women with HR(+)/HER2(-) breast cancer subtype with 35 months (IC 95% = 14,9 – 55), followed by HR(+)/HER2(+) with 27 months (IC 95% = 13,21 – 40,79), HER2 with 24 months (IC 95% = 4.4 – 32), and 14 months (IC 95% = 0 – 29.7) for HR(-)/HER2(-), however the difference wasn't significant ($p = 0.08$). Hazard ratio of HR(+)/HER2(-) breast cancer subtype for breast cancer specific mortality risk was 1.61 (IC 95% = 0.64 – 4.19 $p = 0.29$). Conclusions: Hormone receptor subtype wasn't s a significant independent prognostic factor in female metastatic breast cancer patients in a single center of Ecuador. However, there is a trend that subtype HR(+)/HER2(-) breast cancer subtype, has a better survival than the rest of the subtypes. These results differ from those of the rest of the world, probably access to target medicine and difficulties in access to health care system are the cause. Thus, better strategies for early access to adequate chemotherapy protocols should be developed

Background: Despite demonstrated clinical benefits of first line (1L) cyclin-dependent kinases 4/6 inhibitors (CDK4/6i) and their preferred status in the NCCN guidelines, many appropriate patients with hormone receptor positive (HR+)/human epidermal growth factor receptor 2 negative (HER2-) metastatic breast cancer (mBC) in the United States (US) may still receive chemotherapy or endocrine monotherapy. US oncologists may consider treatment expectations, patient clinical characteristics, and non-clinical factors (e.g., cost, anticipated adherence) when selecting 1L mBC treatment regimens. However, little is known about how prevalent these decision factors are among US oncologists. Comprehensively understanding the decision-making process in 1L treatment selection is a critical step towards ensuring equitable care for patients with HR+/HER2- mBC.

Objective: To describe self-reported clinical and non-clinical factors considered by US oncologists in selection of 1L treatment for HR+/HER2- mBC.

Methods: Data were collected through from an anonymous cross-sectional online survey from a convenience sample of US oncologists from August-October 2021. Eligible oncologists were board certified, in practice 2-30 years, ≥50% of time spent in direct patient care, and managed ≥5 1L patients with HR+/HER2- mBC in past 3 months. Respondents were sampled from a national research database of physicians sourced from multiple databases (e.g., American Medical Association Physician Masterfile). The survey captured self-reported demographic and

practice characteristics and reported importance of the following factors in selecting 1L treatment for patients with HR+/HER2-mBC: anticipated treatment efficacy and safety, patient demographics, and clinical and non-clinical characteristics. Study variables were summarized via descriptive statistics. Correlation analyses evaluated associations between patient demographics, clinical characteristics, treatment expectations, and non-clinical characteristics and oncologists' self-reported 1L prescribing rates of CDK4/6i, aromatase inhibitor (AI) monotherapy, and chemotherapy.

Results: 250 oncologists participated; 67% from community practice and the remainder from academic institutions (Table 1). Anticipated treatment efficacy and safety/tolerability were ranked as the most important factor considered by oncologists when selecting 1L treatments. 1L CDK4/6i prescribing was most strongly correlated with patient Medicare eligibility ($r, 0.54, p < 0.05$) and postmenopausal status ($r, 0.67, p < 0.05$). 1L chemotherapy prescribing was most strongly correlated with patient premenopausal status ($r, 0.42, p < 0.05$) and perimenopausal status ($r, 0.31, p < 0.05$), and physician consideration for patient symptom burden ($r, 0.31, p < 0.05$). 1L AI monotherapy prescribing was most strongly correlated with concerns with expected patient compliance to treatment ($r, 0.42, p < 0.05$) and patient cost/logistical challenges ($r, 0.41, p < 0.05$).

Conclusion: This study found a variety of patient, clinical, and non-clinical factors may underlie US oncologists' selection of 1L treatment for HR+/HER2- mBC. Anticipated efficacy and safety/tolerability were reported as the most important factors in 1L treatment decisions. Patient demographics, clinical characteristics, and considerations for cost and compliance challenges varied in association with 1L CDK4/6i, chemotherapy, and AI monotherapy prescribing patterns among US oncologists.

Table 1. Oncologist Demographic and Practice Characteristics

Table 1. Oncologist Demographic and Practice Characteristics			
		Total Sample (N=250)	
		%	n
Primary Specialty	Medical Oncology	45.2%	113
	Hematology Oncology	54.8%	137

Introduction: The continuous advance in the early detection and treatment of breast cancer has significantly reduced mortality and, consequently, increased the number of survivors with treatment side effects that act on the quality of life, such as lymphedema, loss of upper limb strength, shoulder dysfunction, decreased functional capacity, flexibility, and joint mobility. Exercise therapy is a recognized practice for the rehabilitation of these disorders; however, acupuncture needs to be better evaluated to compare its equivalence with classical therapy. **Objective:** To compare three distinct rehabilitation treatments (exercise therapy, acupuncture and Stiper®) in women undergoing breast cancer surgery, assessing strength, lymphedema and quality of life. **Methods:** Seventy-nine women with pain above 3 on the visual analogue pain scale (VAS) and with more than 90 days of surgery were included. They were divided into three groups that received weekly treatment for 10 weeks: group I (G1) treated with standard, pre-defined exercise therapy, based on stretching of the cervical muscles, shoulder girdle and shoulder ROM exercises with a duration of 30 minutes, group II (G2) treated with 30 minutes of acupuncture using predefined points and group III (G3) treated with the same acupuncture points as group II, however, using the Stiper® (silicon oxide micronized quartz pellet) in place of needles. **Results:** Sixty-seven patients completed the treatment, being 26 from G1, 23 from G2 and 18 from G3. There was an improvement in upper limb muscle strength over time in all groups, except for abduction and internal rotation movements. During treatment, there was no increase in the number of patients with lymphedema and there was no statistical difference between the groups. Regarding the EORTC QLQ-C30 quality of life questionnaire, nine of the fifteen factors analyzed showed significant differences between sessions. The factors that did not have significant differences between the three groups were Social Function, Nausea and Vomiting, Dyspnea, Loss of Appetite, Constipation and Diarrhea. **Conclusion:** The rehabilitation of physical dysfunctions in women who survived breast cancer through exercise therapy, acupuncture and Stiper® in upper limb muscle strength, lymphedema and quality of life, proved

to be effective, without difference between groups, which leads to the conclusion that acupuncture didn't show superiority of results when compared with exercise therapy, thus being an effective approach for the rehabilitation of these women.

Naamit Gerber, MD, *Associate Professor and Program Director - Radiation Oncology, NYU Grossman School of Medicine*
Country: United States

Purpose/Objectives: Since the COVID-19 pandemic, telemedicine has become an attractive alternative to office visits in routine radiation oncology practice. The purpose of this study was to identify factors associated with patient preference for an initial consult telemedicine visit and correlation with clinical trial enrollment. Materials/Methods: We evaluated breast cancer patients seen during the open enrollment of a prospective randomized controlled non inferiority trial evaluating radiation fibrosis with five versus three fractions from 07/13/2020 to 05/13/2021. Univariate and multivariate logistic regression models were used to identify factors associated with virtual vs in-person initial consultation and enrolled vs not enrolled patients. All statistical tests were two-sided and the null hypothesis was rejected for $p < 0.05$. Results: We identified 476 patient consultations with 259 office visits and 217 telemedicine visits. On multivariate analysis, increased age, unemployment, chemotherapy receipt and radiation at NYU were associated with decreased usage of telemedicine for consultation visit. Out of 217 patients who underwent a telemedicine initial consultation, 10% were eligible to enroll on the trial and of those eligible, 76% enrolled. Out of 259 patients who underwent office visit initial consultation, 14% were eligible to enroll on the trial and of those eligible, 53% enrolled. Among eligible patients, there was no statistically significant difference in clinical trial enrollment between telemedicine and office visits. There was no statistically significant difference in patient characteristics between enrolled vs not enrolled patients. Conclusion: Though patient and disease characteristics remained similar between patients undergoing telemedicine and office visits consultations, increased age, unemployment and receipt of chemotherapy were associated with lower usage of telemedicine. Those who underwent in person initial consultation were also more likely to subsequently receive their radiation at our clinic. Further studies are needed to better define underlying reasons for patient selection and impact on care and trial enrollment in order to ensure equal access and benefit from telemedicine, especially in already vulnerable patient populations.

Background: Sacituzumab govitecan (SG, Trodelvy®) is a human trophoblast cell surface antigen 2 (TROP-2) directed antibody drug conjugate (ADC) coupled to an active form of irinotecan (SN-38) via our novel hydrolyzable linker (CL2A). SG is the only FDA-approved ADC treatment for TNBC patients in the second-line setting. TROP-2 is a transmembrane protein encoded by the tumor-associated calcium signal transducer 2 (TACSTD2) gene and highly expressed in TNBC, an aggressive type of cancer accounting for approximately 15% of all

breast cancers. TROP-2 overexpression is associated with poor survival and relapse, but its biological function in TNBC remains poorly understood. Hypothesis/rationale: To better understand TROP-2 and TROP-2-directed ADC biology, we developed and characterized TROP2^{high} vs TROP2^{low} TNBC syngeneic tumors and an SG surrogate directed to murine TROP-2. Experimental design: We established 2 syngeneic TNBC models with differential TROP-2 expression: 4T1 cells were flow sorted into high (>95%) vs low (< 7%) TROP-2 expressors and EMT6 cells were transduced with a murine TACSTD2-encoding lentivirus. Balb/c mice were subcutaneously implanted with 0.5 x 10⁶ TROP-2^{high}, TROP-2^{low}, or parental tumor cells (4T1 or EMT6). Tumor immunophenotyping and transcriptomic analyses were performed 15 and 24 days after implantation. An SG mouse surrogate was engineered to mimic SG, using an anti-TROP-2 antibody (Rab64) that cross-reacts with human and murine TROP-2 covalently attached to SN-38 by the CL2A linker. SG surrogate activity was characterized in vitro and in 4T1 syngeneic models. Results: SG surrogate demonstrated high affinity for human and mouse TROP-2 (K_D=1.1 and 1.4 nM, respectively) with SN-38 release rates and PK similar to that of SG. Flow cytometry analysis after bulk cell sorting of 4T1 or lentivirus transduction of EMT6 confirmed high TROP2 expression after at least 3 in vitro passages. Fifteen days after subcutaneous implantation, flow cytometry analysis of tumor single-cell suspensions revealed significant differences in immune infiltrates between 4T1-derived tumor groups (n=5/group; mean percentages in TROP2^{high} vs TROP2^{low} 4T1-derived tumors of cells expressing CD45: 65% vs 10%, P < 0.0001; CD8: 5.5% vs 1%, P = 0.0033; CD4: 22% vs 4%, P = 0.0055; macrophages: 12.5% vs 2.5%, P = 0.0002; myeloid cells: 52% vs 75%, P = 0.0066). In addition, TROP2^{high} 4T1-derived tumors were smaller and had significantly less necrosis than TROP2^{low} and unsorted 4T1-derived tumors 25 days after implantation. Finally, transcriptomics analyses of TROP2^{high} vs TROP2^{low} 4T1-derived tumors demonstrated the association of TACSTD2 expression levels with regulation of distinct molecular pathways. Conclusion: Syngeneic tumors derived from 4T1 cells with differential TROP2 expression levels are associated with differential cellular states and tumor microenvironment composition. In contrast, no significant phenotypic changes were observed in tumors derived from TACSTD2-transduced compared with mock-transduced EMT6 cells. Taken together, these results suggest that expression of the TACSTD2 gene is associated with, but not causative of, different tumor phenotypic states. Additional studies to investigate TROP-2 expression as a correlative marker of patient prognosis and the antitumor immune response are warranted. The effects of in vivo treatment with an SG surrogate on 4T1 tumor growth and immune phenotype will be discussed at the time of the presentation.

Introduction Patients' satisfaction after breast reconstruction can be evaluated with validated questionnaires as the Breast-Q questionnaire. The Breast-Q questionnaire includes different domains; one of them is "satisfaction with the result". Material and methods: In the multicentre, prospective studies PRO (patient related outcome)-BRA (clinicaltrials.gov: NCT01885572) and PRO-Pocket (clinicaltrials.gov: NCT03868514), patient satisfaction was assessed using the Breast-Q questionnaire. In the PRO-Bra study, 269 patients underwent subpectoral surgery using the TiLOOP® Bra polypropylene mesh (pfm medical ag, Germany). In the "PRO-Pocket" study, 311 patients underwent prepectoral surgery using the TiLOOP® Bra Pocket polypropylene mesh. For the evaluation, those patients from the PRO-Bra and PRO-Pocket studies who completed a Breast-Q questionnaire 6 and/or 12 months after surgery were included. The BreastQ score is measured from 0 to 100, with a score of 100 corresponding to "very satisfied". Satisfaction with the result of the breast reconstruction was evaluated. Results: In the PRO-Bra study, a total of 221 and 203 patients completed a Breast-Q at 6 months and/or 12 months FU, respectively. The mean age and BMI of the patients with completed Breast-Q were comparable between the two studies (PRO-Bra: 49.3 [\pm 11.6] years, 22.9 kg/m² [\pm 3.5]; PRO-Pocket: 47.7 [\pm 11.7] years, 24.5 kg/m² [\pm 4.3]). In the PRO-Pocket study, a total of 258 and 266 patients completed a Breast-Q at 6 months and/or 12 months FU, respectively. In the PRO-Bra study the mean score of satisfaction with the result at 6 months follow-up (FU) was 74.5 (\pm 19.9), in the PRO-Pocket 79.1 (\pm 19.1), at 12 months FU the mean scores were 76.3 (\pm 18.9) for PRO-Bra and 78.2 (\pm 20.4) for PRO-Pocket. Furthermore, stratification according to age (cutoff 50 years) or BMI (cutoff 25 kg/m²) did not reveal any differences between the subgroups or the two studies (see Table). PRO-Bra PRO-Pocket mean score (\pm SD) 6 months 12 months 6 months 12 months BMI \leq 25 75.1 (\pm 19.7) 76.4 (\pm 17.8) 77.7 (\pm 19.9) 78.9 (\pm 19.8) BMI > 25 72.1 (\pm 20.7) 76.1 (\pm 22.9) 82.1 (\pm 16.9) 76.8 (\pm 21.8) age \leq 50 76.4 (\pm 18.7) 77.0 (\pm 18.9) 80.1 (\pm 18.7) 78.1 (\pm 19.6) age > 50 71.5 (\pm 21.5) 75.3 (\pm 19.0) 77.5 (\pm 19.5) 78.4 (\pm 21.8)

Conclusion: Our data so far show high patient satisfaction with overall outcome of the surgery. In addition, patients' satisfaction with the result was comparable after subpectoral as well as prepectoral implant placement. This is particularly important in the PRO-Pocket study, as approximately 60% of the operations and the follow-up period took place during the COVID-19 pandemic.

Background: Inflammatory breast cancer (IBC) is associated with a poor prognosis. While many stage III IBC patients (pts) experience a sufficient response to first-line (1L) neoadjuvant chemotherapy (NAC) to permit subsequent surgical therapy, the prognostic significance of requiring additional NAC to enable resectability is unknown. We sought to describe the pathologic complete response (pCR) rates, breast cancer-free survival (BCFS) and overall survival (OS) among pts requiring 1 vs >1 lines of NAC prior to surgery. Methods: Upon IRB approval, pts with stage III IBC from 2 academic institutions (Dana-Farber Cancer Institute and MD Anderson Cancer Center) who received 1L or 2-3 lines (2-3L) of NAC prior to surgery were identified. Standard NAC regimens containing different drugs, such as AC-T or TCHP, were considered as 1L. Pts with locoregional progression or metastatic disease prior to surgery were excluded. Hormone receptor (HR), HER2 status, grade, and pCR, defined as no residual invasive cancer in the breast and the axilla, were evaluated. BCFS, defined as time from surgery to locoregional and/or distant recurrence, and OS, defined as time from surgery to death, were evaluated by the Kaplan-Meier method. Multivariable Cox models stratified by institution and containing the covariates pCR and tumor subtype were utilized to estimate the HR of 2-3L vs. 1L of therapy. Results: 808 eligible pts diagnosed between 1997 and 2020 were identified. 733 (91%) had 1L and 75 (9%) had 2-3L of NAC, and the median age was 50 years. 295 (37%) had HER2+, 282 (35%) HR+HER2-, 211 (26%) had HR-HER2- disease and for 20 (2%) pts, the receptor status was unknown. The median time from diagnosis to surgery was 6 months. Grade III disease, triple-negative and HER2-positive disease were more prevalent in pts receiving 2-3L of therapy (table). pCR was achieved in 178 (24%) pts receiving 1L of NAC, and in 14 (19%) pts receiving 2-3L of NAC. At 68 months of median follow-up, 417 (52%) pts experienced a recurrence with 376 in the 1L group and 41 in the 2-3L group. The 5-year BCFS was shorter for the 2-3L group compared to the 1L group (33% v 46%, HR=1.37; 95% CI:0.99-1.91). However, in 192 pts with a pCR, BCFS was similar, regardless of the number of NAC lines. There were 38 recurrences among 178 1L pts, and 3 recurrences among 14 2-3L pts,

resulting in BCFS of 76% and 83% in 1L and 2-3L pts, respectively. Overall, there were 308 deaths, 276 deaths among 1L pts and 32 among 2-3L pts. The 5-yr OS estimate in 1L versus 2-3L pts was 60% versus 53% (HR=1.32, 95% CI: 0.91-1.93). Conclusion: Among pts with stage III IBC, pCR was observed among 24% who had 1L and 19% of pts who required 2-3L of NAC. BCFS and OS were comparable among pts with pCR after 1L and 2-3L. Our results suggest the need to continue to optimize current treatment strategies in IBC to improve pCR rates across all disease subtypes regardless of the number of lines of NAC required.

Background: Neoadjuvant association of immune checkpoints inhibitors (ICI) and dose dense chemotherapy is promising for triple negative breast cancers (TNBC). However, response rates vary from one study to another. Timing, best chemotherapy partner and efficacy in less immunogenic breast cancer (BC), like luminal B tumors, should be further investigated. This study evaluates for TNBC and luminal B HER2(-) BC the neoadjuvant treatment with paclitaxel followed by a short combination of an anti-PD-L1 antibody with anthracyclines. Method B-IMMUNE (NCT03356860), a multicentric phase Ib/II prospective trial, included patients with stage I to III luminal B HER2(-) or TNBC treated with paclitaxel 80mg/m² weekly from week 1 to 12 followed by 4 cycles of epirubicine 90mg/m² and cyclophosphamide 600 mg/m² (EC) Q2W in a neoadjuvant setting. Phase Ib evaluated a single infusion of durvalumab (anti-PD-L1) combined with the 3rd cycle of EC. Phase II evaluated infusions of durvalumab with the 1st and 3rd EC cycles. Surgery was planned 3 weeks after the last EC cycle. Primary objectives were safety and pathological complete response (pCR) rate compared to a historical control. Secondary endpoint was the overall response rate (ORR) based on breast MRI. Eleven patients were enrolled in a control arm without durvalumab, exclusively for translational research purposes. Based on a 2-stage Simon design with an $\alpha = 0.1$ and $\beta = 0.1$, 22 TNBC patients were needed in the phase II to test a null hypothesis of 30% pCR rate against a one-side alternative of 60%, and 24 luminal B BC patients to test a null hypothesis of 15% pCR rate against a one-side alternative of 40% (including an additional accrual margin of 10% for eventual dropouts). At least 9 pCRs had to be observed among the first 20 evaluable TNBC patients and 6 among the first 22 evaluable luminal B patients to rule out the null hypothesis. Results This analysis concerns the 50 patients treated with the experimental treatment, 3 from the phase Ib and 47 from the phase II part. Median age was 51 y-old (31 to 72y), tumor subtypes were 24 TNBC, 25 Luminal B and one sarcoma excluded from the efficacy analysis. Seven (14%) patients had a stage I tumor, 17 (34%) a stage IIA, 13 (26%) a stage IIB, 8 (16%) a stage IIIA, 4 (8%) a stage IIIB and 1 (2%) a stage IIIC. Concerning safety, 232 AEs were reported on 39/50 patients and 34 (14,6%) were graded ≥ 3 . The 5 most frequent all-grade AEs were fatigue (8,2%), diarrhea (5,6%), neutropenia (5,2%), anemia and nausea (4,3%). Most frequent grade 3 AEs were anemia and neutropenia (14,7%). Among 4 immune-related adverse events, all were thyroid disorders. One patient died 10 months after the end of

treatment due to progressive disease in the liver. Forty-six of the 47 phase II patients were evaluable for efficacy. pCR was reported in 12/22 TNBC patients (55%) and 8/24 luminal B HER2(-) patients (33%). Subgroup analyses based on PD-L1 expression and TILs score are planned. Conclusions The B-IMMUNE study met its primary objective showing a significant improvement in pCR versus the historical control in both TNBC and in Luminal B HER2(-) BC cohorts with the addition of only 2 doses of durvalumab to the anthracyclines. The safety profile is comparable to those previously described with reported immune related adverse events limited to thyroid endocrine disorders.

The aim of this study was to investigate how breast cancer follow-up in the Netherlands changed during the COVID-19 pandemic, compared to 2018-2019, and to what extent follow-up during the pandemic corresponded to the patient risk of recurrence. During the early phase of the pandemic the Dutch Society for Surgical Oncology (NVCO) issued a report with recommendations on how follow-up could be postponed, as a guidance for the pandemic, based on a low, intermediate or high risk of recurrence. In this study we investigated to what extent this advice was followed. A dataset of 33160 women diagnosed with primary invasive breast cancer between January of 2017 and July of 2021 was selected from the Netherlands Cancer Registry (NCR) and Dutch Hospital Data (DHD). The pandemic, 2020 and weeks 1-32 of 2021, was divided into six periods (A to F), based on the number of hospitalized COVID patients in the Netherlands. The five-year risk of locoregional recurrence (LRR) was determined for each patient with the INFLUENCE nomogram. The LRR risk was compared to the risk groups from the NVCO report with a Kruskal-Wallis test. The percentage of patients who received a mammogram during period A to F was compared to the same periods of 2018-2019 with a chi-squared test. Correlation between the LRR risk, and if patients had a mammogram, was investigated with logistic regression. This analysis was repeated separately for the risk groups. Correlation between the LRR risk, and time intervals between surgery and the first and second mammogram was analyzed using cox proportional hazard models, this was also repeated for the risk groups. There was a significant difference in LRR risk between the NVCO risk groups. In the low-risk group (n=7673), 86 patients (1.1%) had a risk >5%. In the intermediate risk group (n=19197), 18364 patients (95.7%) had a risk of < 5%, and 65 patients (0.34%) had a risk of >10%. In the high-risk group (n=2674), 2365 patients (88.4%) had a risk <

10%. The percentage of patients who received a mammogram was significantly lower in periods B to F of the pandemic. Logistic regression showed a negative correlation between the risk of LRR and if patients had a mammogram in 2020 (OR 0.93) and 2021 (OR 0.93). There was also a negative correlation between the risk groups and mammography in 2020 (OR 0.92 for intermediate and 0.80 for high), and for the risk groups and mammography in 2021 (OR 0.98 for intermediate and 0.95 for high). There was no significant impact of LRR risk, or risk group, on time intervals between mammograms. During the pandemic, patients with a higher LRR risk, or a higher risk according to NVCO advice, had lower odds of having a mammogram. If the advice would have been followed, in 0.5% of the patients scheduled for follow-up, the recommendation was to postpone in contrast to a high estimation of the individual risk. For 62.7%, a follow-up was recommended, despite a low estimated individual risk. Because the number of high-risk patients is relatively low, individual risk prediction could be supportive, in case of future restrictions. This way the high-risk patients can be identified and prioritized for follow-up, and can also be encouraged to come to the hospital.

Background Chemotherapy with anthracyclines, such as doxorubicin (DOX), still remains a mainstay in cancer treatment. DOX kills tumor cells by direct interference with DNA replication, thus it is very effective against highly proliferating cells. Since DOX is not cell-specific drug, it displays severe side effects that limit its clinical use. Besides its direct cytotoxicity, it enhances also tumor immunogenicity, since DOX-induced immunogenic cancer cell death facilitates tumor antigens presentation. However, the generation of an adaptive immune response is one of the most highly- proliferative processes, thus it may be affected by DOX cytotoxicity, paradoxically preventing the establishment of a proper adaptive antitumor immune response. Therefore, the effect of DOX on dividing T-cells urges investigation. Methods We explored the phenotypic and functional effects of DOX on lymphocytes from healthy donors and from breast cancer (BC) patients. Purified peripheral blood mononuclear cells (PBMC) were subjected to an uptake assay and to a CFSE-based proliferation assay in vitro. Characterization of lymphocytes was made by flow cytometry (FC) and confocal microscopy. Innovative DOX nanoformulation with proved efficacy in cancer cell line, BC Patient-derived Organoids (PDO) and murine model of BC, has been assessed in parallel to liposomal DOX, evaluating both DOX uptake and their capability to preserve proliferation potential in different PBMC subpopulation. Results PBMC

incubated in vitro with DOX displayed a dose-dependent DOX uptake that results in a dramatic proliferative impairment. The same behavior has been observed in BC patient-derived PMBC, isolated immediately after the end of first cycle of chemotherapy, which show a prompt DOX internalization coupled with a dramatic impairment of proliferative potential in comparison to the match-paired PMBC isolated before the treatment. Interestingly, FC characterization showed that DOX internalization is higher in CD8+ than CD4+ T-cells and mainly affects central memory, effector memory and terminal differentiated effector. Since pivotal to every adaptive immune response is the activation and massive proliferation of T cells from their resting state, we have exploited a DOX formulation in ferritin nanocages (FerOX), that displays a TfR1-mediated tumor specific homing in order to circumvent drug internalization in those immune cells. FerOX efficacy has been proved in BC-PDO, evidencing an inverse correlation between TfR1 expression and HF_n-DOX IC₅₀. HF_n nanoformulation protects immune cells from DOX toxic effects, reducing DOX uptake and proliferative impairment, mainly preserving Naïve T-cells. The capability of FerOX to preserve T-cells competence to generate an immune response has been corroborated by an in vitro experiment aimed to mimic what could happens to patient's PBMCs if they could be treated with FerOX. Conclusions As a whole, our data indicate that preventing T-cells chemotherapy-related toxicity through FerOX could allow the host adaptive immune system to fully benefit from the DOX-induced immunogenic cell death to vaccinate against cancer. This strategy could be promising for complete tumor eradication and might generate a long-term immunosurveillance of recurrences and metastases.

Triple-negative breast cancer (TNBC) is a heterogenous subtype of breast cancer that lacks effective targeted treatment options. However, TNBC typically has a higher mutational burden and greater degree of immunogenicity than other breast tumors, making immunotherapy a viable strategy for effective treatment of this disease. Strategies to improve the response of TNBC patients to immunotherapy include the upregulation of the cGAS-STING innate immune sensing pathway and STING agonists are in clinical development for the treatment of TNBC. We demonstrate that eribulin, a microtubule destabilizer currently used in the treatment of TNBC, functions as an indirect STING agonist because it promotes the release of mitochondrial DNA into the cytoplasm. Eribulin also enhances type I interferon expression induced by STING agonists through a second TBK1-dependent mechanism downstream of STING activation that is shared by the RIG/MAVS RNA sensing pathway. Both mechanisms of eribulin-mediated activation of interferon expression occur in immune and TNBC cells and are shared with other microtubule destabilizers, including vinorelbine, but not with the microtubule stabilizing agent paclitaxel. These effects of eribulin on innate immune sensing pathways in vitro prompted further evaluations of the impact of eribulin on the in vivo immunological response to mammary tumors. We found that eribulin, but not paclitaxel, promotes the activation of CD4+ T-cells in the spleens and draining lymph nodes of tumored animals. This activation required tumor priming but was independent of any direct effect on tumor growth inhibition, demonstrating a specific role of eribulin as a tumor immune modulator. These data contribute to accumulating evidence that there are important mechanistic differences between the microtubule targeted chemotherapeutics currently used in the treatment of TNBC and suggest that eribulin elicits a more favorable innate immunological signature than paclitaxel. Purpose:

There are multiple treatment options for patients with metastatic breast cancer (MBC); however, there is minimal data on the optimal sequencing. Furthermore, limited information is available to understand the influence of prior treatment duration and class on novel therapies in real-world settings, such as cyclin-dependent kinase 4/6 inhibitors (CDK 4/6i) for patients with hormone receptor-positive, human epidermal growth factor receptor 2- negative (HR+ HER2-) MBC. Our study sought to identify the effect of prior treatments on post-CDK 4/6i survival.

Methods:

This retrospective study used the nationwide, de-identified electronic health record-derived Flatiron Health database of women with HR+ HER2- MBC who received at least one CDK 4/6i between 2011 and 2020. Hazard ratios (HR) and 95% confidence intervals (CI) were estimated for the association between duration and class of all cancer treatments prior to receipt of CDK 4/6i and overall survival (OS) adjusting for age at diagnosis, race and ethnicity, site of metastasis, and metastatic diagnosis year. Time dependent HRs were used to compare the OS for patients receiving one versus multiple CDK 4/6i.

Results:

Of 5,363 patients, most were aged 55-64 (29%), White (69%), and had visceral metastasis (70%). The median survival from receipt of first CDK 4/6 inhibitor was 3.3 years. When compared to patients with no prior treatments, patients with up to one year of prior treatments had a 30% increased hazard of death ((HR, 1.30; 95% CI 1.15-1.46; Table 1). Similarly, patients with one to less than three years of prior treatment had a 68% increased hazard of

death (HR 1.68; 95% CI 1.49-1.88) and those with three or more years had a 55% increased hazard of death (HR 1.55; 95% CI 1.36-1.76). Furthermore, patients who received prior endocrine therapy alone experienced a 29% increased hazard of death (HR, 1.29; 95% CI 1.16-1.44), while patients receiving prior chemotherapy experienced a 72% increased hazard of death (HR, 1.72; 95% CI 1.54-1.93) when compared with patients who did not receive a prior treatment. Finally, patients who received a different CDK 4/6i after their first had a 17% decreased hazard of death compared to patients who received subsequent endocrine or chemotherapy after their first CDK 4/6i (HR, 0.83; 95% CI 0.71-0.96).

Conclusion:

Prior treatment duration and class are associated with a decreased overall survival after CDK 4/6 inhibitor administration. However, patients receiving more than one CDK 4/6 inhibitor in their sequence saw survival benefits. This highlights the importance for clinicians to consider prior treatment and duration in treatment decision-making and for trialists to stratify by these factors when reporting results of future studies.

Table 1. The association between OS and treatment duration and class before CDK 4/6 inhibitor initiation (N=5,363)

Prior treatment characteristics	Adjusted hazard ratio	95% Confidence interval
Treatment Duration (years)		
0	-	-
<1 year	1.30	1.15 to 1.46
1 to <3 years	1.68	1.49 to 1.88
3 or more	1.55	1.36 to 1.76
Prior cancer Treatment class		
No prior cancer treatment	-	-
Chemotherapy	1.72	1.54 to 1.93
Endocrine therapy	1.29	1.16 to 1.44

Introduction

Breast cancer is a complex, heterogeneous disease encompassing a spectrum of subtypes with distinct biological features, each having unique responses to various treatment modalities and different clinical outcomes. The type of neoadjuvant chemotherapy (NAC) for locally advanced breast cancer is decided based on breast cancer subtype, which includes triple negative breast cancer (TNBC), hormone receptor positive breast cancer (HR+BC), HER2+ breast cancer (HER2+BC) and triple positive breast cancer (TPBC). Multiple NAC regimens exist but have not been directly compared to determine the optimal treatment regimen in patients with various stages (I-III) and subtypes of breast cancer. The objective of this study was to assess pathological complete response (pCR) rates in patients treated with various types of NAC and analyze associated clinical factors in our diverse patient population.

Methods

This study included 297 patients treated with NAC for breast cancer between 2015 and 2021 at LCMC Health, New Orleans, Louisiana. The tumor, lymph node, metastasis (TNM) system was used for clinical and pathological staging. Biologic subclassification using estrogen receptor (ER), progesterone receptor (PR), HER2 were performed. Response to NAC was documented as pCR when there was no evidence of residual invasive tumor in the breast or axillary lymph nodes. Categorical variables were summarized by reporting counts and percentages, while continuous variables were summarized by reporting means and standard deviations. Fisher exact tests were used to compare pCR status by each chemotherapy status or demographic factor. Wilcoxon Rank-sum tests were used to compare continuous variables across pCR groups. Multivariable linear regression was performed to predict overall tumor shrinkage %.

Results

Among all patients, median age was 54.75 years (min-max: 22-78). 30 (10%) patients were stage I, 175 (58.9%) were stage II, 89 (29.9%) were stage III and 3 (1%) were stage IV with oligometastatic disease. 171 (57.6%) were African American (AA), 82 (27.6%) were Caucasians and 41 (13.8%) were other race. Table 1. shows chemotherapy and pCR rates among different breast cancer subtypes. Patients with carboplatin (57.3 vs 35.3; $p < 0.001$), had a higher likelihood of complete remission than non-users. After multivariable linear regression adjustment, Paclitaxel increased the % reduction in tumor size significantly (EST= 39%, CI 2% – 77%; $p=0.042$) compared to non-users. In the subset of TNBC patients this held in terms of pCR rates (47.1% vs 25%, $p=0.036$). In TPBC, pCR was higher in younger ($p=0.028$) and non-AA ($p=0.0023$) patients.

Conclusion

Multiple NAC regimens for breast cancer exist and optimization of regimens is key. We explored the use of several different chemotherapy agents and found the use of carboplatin beneficial, while doxorubicin, cyclophosphamide and cisplatin had a decreased likelihood of achieving a pCR; however, this may be due to the intrinsic nature of the subtypes that would be treated with these NAC regimens. We plan to explore by subtype and treatment regimen in future analysis.

Interestingly, AA have significantly less pCR in TPBC, compared to non-AA, although this finding was not seen in other subtypes. Future studies are needed to investigate this further.

Table 1. Chemotherapy and pCR rates among different breast cancer subtypes.

	TNBC	HR+BC	HER2+BC	TPBC
Total number of patients	119 (40%)	77 (25.9%)	50 (16.8%)	51 (17.1%)
Median age	55.15	54.35	56.16	53.06
African Americans	79 (66.4%)	40 (51.9%)	29 (58%)	26 (51%)
Patients with pCR	4 (35%)	9 (11%)	33 (66%)	27 (53%)
100% absolute reductions in primary mass size	47 (39%)	12(15%)	38 (76%)	28(54%)
Most common chemotherapy received	ACT	ACT	TCHP	TCHP

Abbreviations: ACT (doxorubicin/cyclophosphamide/paclitaxel); TCHP (docetaxel/carboplatin/Herceptin Perjeta);

Background

Clinical decision-making by multidisciplinary teams (MDTs) is getting more complex as treatment advice for the individual patient must be based on an increasing amount of patient and tumor characteristics, and scientific evidence on treatment efficacy. Clinical decision support systems (CDSSs) can make an important contribution to assist but also optimize MDT decision-making. However, implementation of CDSSs in clinical practice is challenging.

Aim & methods

The aim of our study is to set up a CDSSs implementation model for multidisciplinary decision-making in solid cancer. It is based on a scoping review of the currently reported CDSSs for MDT decision-making in solid cancers with identification of reported barriers and facilitators for implementation of these CDSSs. For this we systematically searched the Cochrane Library, MEDLINE (accessed through PubMed) and Scopus up to September 1st 2021.

Results

Of the 710 screened abstracts, 38 papers met the inclusion criteria (table 1). Sixteen different CDSSs were identified. For implementation of CDSSs, 87 barriers and 73 facilitators were reported. The reported barriers could be categorized in the same categories as those of the facilitators (a factor can be reported as a barrier if the factor is not addressed well, and as a facilitator if the factor is properly addressed).

The most frequently reported barriers for CDSS implementation for MDT decision making

mainly concerned CDSS maintenance (e.g. not incorporating guideline updates), loco-regional feasibility of the CDSS recommendation (e.g. no access to diagnostics or treatment), validity, not incorporating patient preference in decision making, data accuracy, noncoverage of certain patient subpopulations, lack of an information standard, usability, data availability and no interoperability of the CDSS with the electronic health record. The most frequently reported facilitators included, besides the categories as mentioned above, the category shared decision making (reporting of alternative treatment options) and technical skills (involvement of a computer scientist). Table 2 shows the most frequently reported categories of barriers and facilitators, and scores for each included study the number of reported barriers (B) and facilitators (F) in each category.

Conclusion

Based on the identified barriers and facilitators, we developed a CDSS implementation model to guide more successful CDSS integration in the clinical workflow to support MDTs (the model will be shown at the congress). The usability of this theoretical model should be explored in future studies.

INTRODUCTION: The HER2-targeted peptide vaccine nelipepimut-S + GM-CSF (NeuVax) has been shown to be safe, immunogenic, and potentially synergistic with trastuzumab. Here we present the results of a randomized phase 2 trial assessing the ability of nelipepimut-S/GM-CSF versus GM-CSF alone, added to the standard adjuvant Trastuzumab, to prevent recurrences in high-risk HER2-positive breast cancer patients. **METHODS:** The study was a multi-center, prospective, randomized, controlled, single-blinded, phase 2 trial. Enrolled patients had high risk HER2+ breast cancer defined by the presence of residual disease post neoadjuvant therapy or by the presence of positive lymph nodes after upfront surgery. Eligible patients had completed an approved trastuzumab-chemotherapy containing regimen and they were receiving adjuvant Trastuzumab monotherapy. Enrollment was limited to patients with HLA-A2, A3, A24, and/or A26 alleles. Patients received intradermal injections of nelipepimut-S + GM-CSF or placebo + GM-CSF every three weeks for six total vaccinations with concurrent, standard monotherapy with iv trastuzumab. After completion of the primary vaccine series, booster inoculations were administered every six months for four doses. The primary outcome measure was invasive disease-free survival (iDFS) at 36 months. Secondary outcome measures were distant recurrence-free survival (DRFS), toxicity assessment, and evaluation of immune response. **RESULTS:** 100 patients were enrolled and randomized 1:1 to nelipepimut-S/GM-CSF or GM-CSF alone. There were no significant clinicopathologic differences between the groups. There was no difference in related local ($p=0.49$) or systemic toxicities ($p=0.41$). Kaplan-Meier estimates of iDFS at 36 months were 79% in the nelipepimut-S arm and 92% in

the placebo arm (log rank, $p=0.11$). DRFS at 36 months was estimated to be 90% in the nelipepimut-S arm and 95% in the placebo arm (log rank, $p=0.40$). Delayed type hypersensitivity (DTH) response to nelipepimut-S was measured and considered positive if there was more than 5 mm induration after 48 hours. DTH response converted from negative to positive in 11% of patients in the vaccine group versus 5% of patients in the placebo group ($p=0.36$). In both groups, iDFS at 36 months was 100% for those with a positive DTH response post-inoculation and 88% for those with a negative DTH response post-inoculation (log rank, $p=0.29$). CONCLUSION: Combination immunotherapy with concurrent nelipepimut-S + GM-CSF and trastuzumab is safe, however there was no difference in iDFS or DRFS among high-risk HER2+ breast cancer patients who received nelipepimut-S + GM-CSF compared to GM-CSF alone. We observed a trend towards improved iDFS in patients with a positive DTH response to nelipepimut-S, though it was not statistically significant.

Background: In patients with metastatic breast cancer (mBC), Circulating Tumor Cells (CTC) counts have a strong prognostic impact on progression free survival (PFS) and overall survival (OS). Changes 4 weeks after the start of a new line of therapy, inform on treatment efficacy. Despite improvements in systemic treatment, metastatic BC remains mainly incurable with alteration of health-related quality of life (HRQOL) during the course of the disease. The aim of this work was to assess impact of clinical factors and biological factors as CTC on HRQOL. Methods: The French cohort COMET is a prospective study including first line HER2 negative patients receiving weekly paclitaxel and bevacizumab according to EMA approved combination. The aim of this cohort was to evaluate clinical, biological and radiological parameters associated with patients' outcome (CTC, CEC, serum markers, ctDNA, pharmacogenomic polymorphisms, metabolomic parameters, visceral fat assessed by initial CTscan, serum estradiol level, and quality of life). HRQOL was assessed at baseline, at every cycle until progression and then every 3 months up to death using the EORTC QLQ-C30 questionnaire and its breast cancer specific module, the EORTC QLQ-BR23. Five dimensions of HRQOL were analyzed for the primary analyses: Global health status (GHS), physical functioning (PF), Emotional functioning (EF), fatigue (FA) and pain (PA). Time until definitive deterioration (TUDD) in HRQOL was defined as the interval between inclusion and the first decrease in HRQOL score ≥ 5 compared to baseline HRQOL score with no further improvement or in case of death. CTC counts were determined using the standard CellSearch system [Menarini Silicon Biosystems]. Results: Out of 510 patients included in COMET study, 432 patients with available HRQOL data were analyzed in this study. At baseline, patients reported a mean score for GHS of 57.6 (SD=22.7), for PF of 75.8 (23.2), for EF of 62.2 (25.8), for FA of 42.2 (29.60) and for PA of 38.1 (31.5). The Median TUDDs for the 5 targeted dimensions was 10.1 months [7.5-16.9] for GHS, 6.1 months [4.1-8.9] for PF, 21.6 [18.7-31.2] for EF, 10.8 [6.2-16.6] for FA and 13.6[10.1-22.5] months for PA. CTC counts were available in 261 patients at base line and in 229 patients after 4 weeks of treatment, before second cycle of chemotherapy. CTC high count was independent of main clinical and biological characteristics except lobular subtype. We confirmed the poor outcome of patients with high CTC count at base line and after one cycle of

treatment with the threshold of > 4CTC/7.5 ml of blood. Out of the 5 dimensions of HRQOL, TUDD of EF was significantly correlated with a high CTC level at base line ($p=0.0262$) and even more with still an elevated count of CTC after one cycle of chemotherapy($p=0.0137$). There was no association of CTC with the other dimensions of HRQOL. Conclusion: This is the first study ever reporting an analysis of QoL and CTC. We observed an association of high CTC count with one component of HRQOL scale. This suggests that CTC could be complementary to clinical factors that could influence HRQOL in HER2 negative metastatic BC treated with first line chemotherapy.

Background There is an increase in the use of neoadjuvant chemotherapy (NACT) to downstage breast cancer. Sentinel lymph node biopsy (SLNB) has replaced Axillary lymph node dissection (ALND) as a standard of care for the treatment of breast cancer patients with negative axilla at presentation. However, the reliability of SLNB after NACT in patients with initially node-positive breast cancer is still controversial and debatable. This meta-analysis was conducted to investigate the accuracy and feasibility of SLNB after NACT in patients presented

with positive axillary lymph nodes. Methods A comprehensive literature search was conducted using Medline, PubMed, Embase, Central, and SCOPUS for studies from their date of inception till April 2021 on the performance of SLNB following NACT in clinically node-positive breast cancer patients. We included prospective studies including breast cancer patients with positive lymph nodes at diagnosis, receiving neoadjuvant chemotherapy before undergoing an SLNB, irrespective of their molecular subtypes or breast cancer stage. We excluded retrospective studies, case reports, review articles, and letter to editors. The main outcomes of interest were the false negative rate (FNR) and the identification rate (IR). We also aimed to investigate the accuracy, negative predictive value (NPV), positive predictive value (PPV), specificity, and sensitivity of the SLNB procedure. Results An aggregate of 33 studies were included in this meta-analysis enrolling 4624 patients. The pooled identification rate (IR) was 88% (95% CI: 86-90; heterogeneity I²: 80.93 %) and the false negative rate (FNR) was 13% (95% CI: 11-15; heterogeneity I²: 72.31%). The pooled accuracy, NPV, PPV, specificity and sensitivity were 91.8% (95% CI: 69.39 -114.3), 82.8% (95%CI: 60.19-105.52), 98.2% (95%CI: 65.86 -130.63), 93.7% (95 CI%: 32.4 -155.03), 82.1% (95%CI: 58.38- 107.24) respectively. Conclusion In this comprehensive meta-analysis, we were able to review the largest number of studies (N=33) and patients (N=4624). We carried out this study with the intention to overcome the limitations of previously conducted meta-analyses such as including retrospective studies and a mixed population of clinically node-positive and node-negative breast cancer patients. Based on current findings, the usage of SLNB instead of ALND for the treatment of node-positive breast cancer patients is acceptable. However, further analysis is needed for the improvement of SLNB performance. Keywords: Sentinel lymph node biopsy; Breast cancer; Node positive; Neoadjuvant chemotherapy.

Introduction: CUB-domain containing- protein 1 (CDCP1) is a transmembrane receptor involved in the progression of several cancers. Recent studies demonstrate that CDCP1 is a rational target for the development of innovative targeted therapies for cancer including theranostics agents and antibody-drug conjugates. Objective/Methods: To determine the therapeutic potential of CDCP1 in breast cancer, we investigated its expression in multiple cohorts of breast cancer tissues by immunohistochemistry, as well as in various preclinical models including cell lines, primary cells and patient-derived xenografts using flow cytometry, western blot and immunofluorescence staining. Then, we evaluated the capacity of the CDCP1-targeting chimeric antibody ch10D7 to specifically accumulate in breast cancer lesions in in vivo preclinical models including patient-derived xenografts and breast cancer metastasis models. Finally, we determined the efficacy of the ch10D7-MMAE antibody-drug conjugate to kill breast cancer cells in vitro and breast tumours ex-vivo and in vivo. Results: The CDCP1 receptor is expressed at targetable level in a significant proportion of breast cancer cases with high/intermediate expression detected in ~30% of localized ER-positive cases, ~50% of metastatic ER-positive cases and >70% of Triple negative or HER2-positive cases. Similar proportion of expression was detected in cellular models. We demonstrated that ch10D7 antibody labelled with the radionucleotide Zircodium-89 specifically accumulates in breast cancer lesions in vivo allowing the detection of mammary-fat pad implanted patient-derived xenografts and of breast cancer metastasis by PET/CT imaging. Finally, we confirmed that the ch10D7-MMAE antibody-drug conjugate is very efficient at inducing cell death in vitro as well as controlling primary tumour and metastatic tumour burden in pre-clinical models, conferring a significant survival advantage compared to classical therapy. Conclusion: Our work

demonstrates that CDCP1 is a potential target to detect and limit the progression of breast tumours and that biomolecules specifically recognising this receptor are promising agents which could improve survival of patients.

Introduction

Targeted axillary dissection (TAD) after neoadjuvant chemotherapy (NAC) is a new axillary staging technique that consists of surgical removal of biopsy-proven, positive, clipped axillary nodes (CLN) in addition to the sentinel lymph node biopsy (SLNB), and provides for more conservative axillary surgery¹. A question was recently raised whether clipping a positive node for later assessment indeed leads to a management change². The purpose of our study is to report the feasibility of TAD and to evaluate false negative rate (FNR), impact on surgical and oncological management.

Materials and methods This retrospective, single-institution, study included 73 consecutive women operated between 2019 and 2021 after NAC for cN+ disease confirmed by cytology or histology, whose diseased lymph-node was marked with a clip before therapy. At surgery, in case of clinical-radiological complete response, patients underwent TAD (dual mapping with radiocolloid and blue dye + CLN) (n=43), or TAD plus ALND if any residual disease (n=30). The chemotherapeutic regimen were anthracycline/taxane based, with trastuzumab in case of HER2+ tumors. Patients were routinely evaluated with a breast MRI both before and after NAC.

Results Clinical and pathological details of the 73 enrolled patients are listed in Table 1. The mean age at diagnosis was 49.53±10 years. Pathologic complete response was achieved in 32 out of 73 patients (43.8%) with the greatest rate in HR-/HER2+ tumors (n=10/12; 83.3%). The identification rate of the CLN was 91.8% (68/73), and it was one of SLNs in 68.5% (50/73) of the cases. In cases in which one, two or three or more SLNs were identified, the CLN was in the SLN specimen in 42.9%, 77.8% and 81.8% of cases, respectively. The FNR of the SLN was 18.5% (CI: 4.9-38.1). In 18 cases the CLN was not in the SLN specimen; eleven out of 18 CLNs were positive, leading to ALND, and three of them had additional positive LNs. Only in one case the CLN was negative and the SLN was positive. In 3 cases (4.1%), the CLN was positive in the absence of residual tumour in the breast leading a potential change in the oncological management.

Conclusions Removal of CLN after NAC is feasible, allowing de-escalation of surgical management of cN+ women in case of clinical-radiological complete response, as 59% of women avoided a formal ALND. The CLN coincides with SLN in about 70% of cases (more than 80% if three or more SLNs are identified) and reflects the overall status of the axilla in 97.3% of the cases. Adding CLN to SLNB contributes to reduce significantly the FNR of the latter from 18% to 0% (FNR for SLNB =18.5% vs FNR for TAD=0%). Potential changes in surgical (CLN+/SLNs-) and oncological management (CLN+/SLNs- and absence of residual tumor in breast) occurs in 15.1% (11/73) and 4.1% (3/73) of cases, respectively.

Objective: Multimodality treatment in breast cancer is a key to the improved survival outcomes. The effects of delays in multimodality treatment in HER2 amplified breast cancer were studied. Patients and Methods: Of the patients with primary HER2 amplified breast cancer who were treated between 2009 and 2018 in a single institution, 1,075 patients met the inclusion criteria. The patterns of the multimodality treatments and the prognostic effects of treatment delays were studied. Kaplan-Meier method was used to estimate the relapse free survival (RFS) and overall survival (OS). Hazard ratio (HR), their 95% confidence interval (CI) and p value were computed using the Cox proportional-hazards model adjusting for 11 covariates including age, ethnicity, clinical T stage, clinical N stage, ER, PR, Ki67, LVI, histologic grade, surgery type (mastectomy versus lumpectomy), neoadjuvant versus adjuvant chemotherapy. The Harrell's C statistics were used to determine the Cox model accuracy. Adjusted multivariate analyses of recurrence/death and death were computed using Cox proportional-hazards model. Delays in treatment were defined as starting treatment beyond 60 days after diagnosis or after the completion of the leading treatment. Results: Of the patients included, 49% received neoadjuvant chemotherapy/HER2 target treatment and surgery, 43% had adjuvant treatments and surgery and 8% had surgery only without chemotherapy. Timely commencement of treatment in the 3 groups were 85.7% , 72.1% and 78.4% respectively. The 5-year RFS was 88.7% and OS was 98.2%. Patients who received neoadjuvant and adjuvant chemotherapy were combined, and six treatment groups with delays in various treatments were compared: no delay in chemotherapy/target treatment and surgery (1); surgery delay (2); chemotherapy delay (3); delays in both treatments (4) and surgery only groups with (5) or without delays (6). Concordance statistics showed that the covariate adjusted Cox proportional-hazards model had a better accuracy than the unadjusted. Compared to those without delays, patients with both chemotherapy and surgery delayed had worse recurrence/death (adjusted HR = 4.11, 95% CI: 1.39-12.5, p= 0.0161). Delays in either surgery or chemotherapy also increased recurrence/death, although to a lesser magnitude. The adjusted death in surgery delay, chemotherapy delay and delays in both had HR 2.91; 2.22; and 2.29 respectively when compared to the group without delays in either treatment although not significant at p < 0.05.

Adjusted recurrence/death and death were similar between neoadjuvant and adjuvant groups (HR 0.99 & HR 0.85 respectively). The group that received surgery only without chemotherapy was associated with worse recurrence/death (adjusted HR=1.78, 95% CI: 0.19 – 16.9)
Conclusion: Delays in any treatment adversely impacted recurrence and death and chemotherapy/target treatment is a critical component in treating patients with operable HER2 positive breast cancer.

Background: Olaparib (O) is approved for the treatment of HER2[-] patients (pts) with early or metastatic breast cancer and a germline BRCA mutation. Nevertheless, there is no evidence that HER2[+] tumors are resistant to PARPi. Preclinical data support that HER2[+] cells are sensitive to PARPi and strongly suggest that PARP inhibition augments the efficacy of trastuzumab (T). To test whether PARPi is synergistic with anti-HER2 therapy, the OPHELIA study has assessed the efficacy and safety of O in combination with T in pts with HER2[+] germinal BRCA-mutated advanced breast cancer (ABC). Methods: OPHELIA (NCT03931551)

is an open-label, multicenter, single-arm, phase II trial. The study enrolled pts aged ≥ 18 years diagnosed of HER2[+] ABC with germinal deleterious mutations in BRCA1 or BRCA2 who had received at least one prior systemic regimen for advanced disease (including a pertuzumab- or trastuzumab emtansine based regimen). Pts received O (300 mg oral, twice daily) plus T (either loading dose of 8 mg/kg IV infusion, and subsequent 3-weekly doses of 6 mg/kg IV infusion; or 600 mg SC injection, on day 1 of every 21-day cycle) until disease progression, unacceptable toxicity, or consent withdrawal. Primary endpoint was investigator-assessed clinical benefit rate (CBR) for at least 24 weeks as per RECIST v.1.1. Secondary endpoints included overall response rate (ORR), duration of response (DoR), progression-free survival (PFS), overall survival (OS); and safety and tolerability as per NCI-CTCAE v.5.0. The primary analysis evaluated CBR ($H_0: \leq 5\%$; $H_1: \geq 30\%$) based on exact binomial test. Sample size was designed to attain a 90% power at 10% one-sided alpha level. Results: From Mar 25, 2019, through Mar 2, 2022, 5 pts (from a total of 42 pts evaluated) were enrolled at 17 sites in Spain. Median age was 37.0 (range 32–54) years, 1 (20.0%) patient was male, 4 (80.0%) pts carried germinal BRCA2 mutations, 4 (80.0%) pts had received ≥ 3 advanced disease treatments lines, and 4 (80.0%) pts presented ≥ 2 metastatic sites. At data cutoff (Mar 2, 2022), with a median follow-up of 18.7 months (min: 11.7; max: 22.1), 40.0% of pts remained on therapy. CBR at 24 weeks was 80.0% meeting the primary endpoint (4 of 5 pts; 95% CI, 28.4% to 99.5%, $p < 0.001$). ORR (1 complete and 2 partial responses) was 60.0% (95% CI, 17.4% to 94.7%), and median DoR was 3.8 months (95% CI, 2.5 to 8.3 months). Two (40.0%) pts had PFS events due to disease progression at 5.2 and 1.2 months, respectively. Rest of pts were treated for 5.5, 11.2, and 19.0 months. There were 2 (40.0%) deaths at 14.0 and 18.5 months. The most common non-hematological treatment emergent adverse events (TEAEs) of any grade (G) were fatigue (60.0%; 0% $G \geq 3$), nausea (60.0%; 0% $G \geq 3$), vomiting (40.0%; 0% $G \geq 3$), and back pain (40.0%; 0% $G \geq 3$). Anemia (40.0%; 20.0% $G \geq 3$) and lymphopenia (40.0%; 20.0% $G \geq 3$) were the most frequent hematological TEAEs. One (20.0%) patient discontinued treatment because of a drug-related TEAE (leukopenia). A dose reduction of O was reported in 1 (20.0%) patient. No treatment-related deaths were reported. Conclusions: HER2 overexpression in germline BRCA-mutated ABC is infrequent. The activity observed in these 5 pts indicates that O+T combination might be of help in this group of pts. We strongly believe that randomized data are not needed, and RWE studies might help us to understand the real activity of this combination. Toxicity was as expected.

Background: HER2-low breast cancer (BC) is a new therapeutic entity, but it is uncertain if this subgroup of BC differs from HER2-negative tumors in clinical characteristics, prognosis, and response to therapy. The objective is to describe the clinical characteristics and outcomes of 422 patients (pts) with HER2-low BC documented before 1st line, having been diagnosed with advanced BC (ABC) before 2019 and included in the RegistEM study (n=1,663).

Methods: In this analysis (cut-off date 08/April/2022; database is ongoing), two subgroups of pts have been considered based on HER2 results: HER2-low (n=422) (immunohistochemistry [IHC] 1+ or IHC 2+ and in situ hybridization [ISH] negative) and HER2-IHC 0 (n=590), as reference. Hormone Receptor (HR) expression has also been considered for subgroup analysis.

Results: At first ABC diagnosis, < 1% pts had unresectable locally advanced BC (ULABC) in both groups, 31% de novo metastatic BC in HER2-low and 20% in HER2-IHC0 groups. Less than 1% were male, 99% Caucasian and ~71% postmenopausal. Median age was 60 years, being similar between both groups (range 26-96). Family history of BC and/or ovarian cancer was reported in 32% pts in HER2-low and 29% in HER2-IHC0. Germline BRCA1/2 mutation was higher in HER2-low (14/40=35%) in reference to HER2-IHC0 (14/64=22%) (p=0.14).

Relevant information summarized by HR expression and HER2 status are detailed in the table below. Visceral disease was similar in both total groups (58% in HER2-low vs HER2-IHC0 56%), but slightly higher in HR- HER2-low pts (81% vs 64%), and 84% and 90% pts had ≤3 metastatic locations, in HER2-low and HER2-IHC0 groups, respectively. Distribution of 1st-line therapies was also similar between both groups, being endocrine therapy (ET) plus biological therapy (BT) (HER2-low 39% vs HER2-IHC0 36%) and ET (HER2-low 30% vs HER2-IHC0 28%), while chemotherapy (CT) (HER2-low 13% vs HER2-IHC0 16%) and CT plus BT (HER2-low 9% vs HER2-IHC0 10%) were more frequent in HR- pts. A 2nd-line therapy was reported in 70% HER2-low pts and 67% HER2-IHC0 pts. The median time to progression (TTP) at 1st-line therapy in HER2-low pts was 11 mo (0-66), being similar in HER2-IHC0 pts, but the higher difference was observed in relation to HR expression. Treatments in 2nd-line were similar in both groups, CT and ET/BT were the most frequent totally. Median duration of 2nd-line therapy was ~6 mo; progressive disease (PD) was reported in 85% pts. A 3rd-line therapy was reported in 74% HER2-low and 69% HER2-IHC0 pts. The median time to progression (TTP) to 3rd-line therapy was 6 mo, being similar in HER2-low and HER2-IHC0 pts. The most frequent 3rd-line therapies were CT and ET/BT in both groups, as in 2nd-line. Median duration of 3rd-line therapy was 4 mo; PD was reported in 84% HER2-low pts and 82% HER2-IHC0 pts. Median (95% confidence interval [CI]) PFS at 1st, 2nd and 3rd lines (mo) were 14 (12-16), 6 (5-7) and 6 (5-6) in HER2-low pts, being similar in HER2-IHC0. OS was comparable in all subgroups analyzed, however, differences were observed regarding HR status.

Conclusions: Our results show that HER2-low BC pts have similar characteristics than HER2-IHC0 BC pts. There are differences in therapy outcomes in terms of survival and prognosis, particularly in HR- tumors, being better in HER2-low BC pts. It could be related to the fact that these tumors have a specific biology, but more evidence is needed.

Background: With dramatically rising obesity rates in the US, obesity at breast cancer diagnosis is common; further compounding the problem is that breast cancer treatment often results in additional weight gain. Among women undergoing breast cancer treatment, both obesity at diagnosis and post-diagnosis weight gain are associated with increased all-cause mortality and increased breast cancer mortality. We tested a WFPB dietary intervention in metastatic breast cancer patients to improve cardiometabolic and cancer-related outcomes, as it has been shown to reduce weight and improves cardiometabolic health in overweight and obese individuals.

Methods: Women with stage 4 breast cancer receiving treatment were randomized 2:1 into 2 arms: 1) a WFPB diet (N=21) or 2) usual diet (N=11) for 8 weeks with assessments at baseline, 4, and 8 weeks. Our WFPB diet consisted of an ad libitum whole food, plant-based diet; 3 meals/day were provided to WFPB subjects, which included fruits, vegetables, whole grains,

nuts and seeds, and excluded meat, dairy, eggs, and added oils/solid fats. WFPB subjects received weekly education regarding diet. Subjects in the usual care group were asked to continue their usual diet for the next 8 weeks. Outcomes include cardiometabolic risk factors, related sex hormones, and cancer progression markers. Effects of the WFPB diet on the outcomes were assessed by comparing marginal means by arm estimated at 8 weeks from the analysis of covariance model controlling for the baseline value.

Results: Of the 32 subjects randomized, 30 subjects (20 WFPB and 10 usual care) completed all 3 assessments. Reductions in weight, BMI, total cholesterol, and LDL cholesterol were statistically significant as well as clinically meaningful, both within the WFPB group and between the groups. In the WFPB group, subjects lost a mean of 6.2% of their body weight versus 0.7% body weight loss in the control group ($p < 0.01$). LDL cholesterol was reduced by a mean of 20.0% in the WFPB subjects versus a 10.6% increase in control subjects ($p < 0.01$). Reductions in insulin and HOMA-IR, a measure of insulin sensitivity, were statistically significant within the WFPB group and trended towards significance between the groups. Sex hormone binding globulin (SHBG) levels increased significantly both within the WFPB group and between groups. There was a significant decrease in both IGF-1 and free testosterone within the WFPB group from baseline to week 8.

Conclusions: Our WFPB intervention resulted in improvements in several cardiometabolic and hormonal markers. The intentional weight loss, which was clinically large given the duration of the trial, was accompanied by reduced cholesterol, insulin resistance, free testosterone, and IGF-1. Given the moderate to large effect sizes noted, further study is warranted to evaluate the sustainability of benefits over time and to assess their potential impact on cancer-related outcomes.

Background: The growing population of elderly patients with breast cancer imposes challenges for treatment when frailty and comorbidities may coexist. Age alone should not be a cutoff for cancer treatment decisions: benefit and risk should be taken into account, considering comorbidities burden, functionality, life expectancy and patient preferences. Primary endocrine therapy (PET) represents an alternative when primary surgery or neoadjuvant chemotherapy would not be adequate treatment choices for patients with hormonal receptor positive (HR+) non-metastatic breast cancer. We aimed to evaluate the prognostic factors associated with survival among elderly patients treated with PET with or without surgery. Methods: We retrospectively reviewed electronic medical records of a cohort of patients who were 70 years of age or older and were treated with PET for operable non-metastatic breast cancer in an academic cancer center from 2009 to 2021. Study endpoints were progression-free survival (PFS), overall survival (OS), and factors associated with PFS and OS. For PFS, the events considered were disease progression in patients treated with PET alone, disease recurrence in those who underwent surgery, or death from any cause. Survival was estimated using the Kaplan-Meier method and compared with the log-rank test. Prognostic factors evaluated were age, histological type, grade, Ki67 index, stage, ECOG-performance status (ECOG-PS) and comorbidities burden, according to Charlson index. Univariate and multivariable analysis were performed using Cox regression. Results: PET was the first treatment for 197 pts aged 70 years or older. The median age was 81 years (range 70-101). Most patients had ductal (N=149; 75%) or lobular carcinomas (N=22; 11%), grade 1 (N=48; 24%) or grade 2 (N=114; 58%), and stage II (N=67; 34%) or stage III (N=94; 48%) disease. Half of the patients had an ECOG-PS 3 (n=65) or 4 (n=35); 165 pts (83%) had an Charlson index < 6. Seventy-two pts (36%) underwent surgery. Thirty pts (15%) had a disease recurrence or progression and 60 pts (30.5%) died; most deaths (n=38; 63%) were not related to breast cancer. In a multivariable analysis, pts with grade 3 disease had higher risk of recurrence/progression/death (HR 3.31, 95% CI 1.45-7.58, P=0.005), while those treated with surgery had a decreased risk (HR 0.37, 95% CI 0.21-0.65; P=0.001). Median PFS was 55.2 mo for pts treated with PET alone and 99.7 mo in those treated with ET followed by surgery. Median OS was 63 mo and 111.9 mo, respectively. Conclusion: In this cohort, deaths observed were mostly unrelated to breast cancer, suggesting that PET is an appropriate choice for selected pts. Nevertheless, patients with grade 3 disease and those who were not treated with surgery after PET had a higher risk of disease progression/recurrence or death. Prognostic factors can be useful to select candidates for PET.

Background: The cyclin-dependent kinase 4 and 6 (CDK4/6) inhibitors transformed the care of patients with hormone receptor-positive (HR+), human epidermal growth factor receptor-2 (HER2)-negative (HR+/HER2-) advanced-stage breast cancer (aBC). Breast cancers with no expression of HER2 are recently classified into two groups: HER2-Zero subtype which include those with HER2-immunohistochemistry (IHC) score of 0 (IHC-0) and "HER2-low", defined as HER2-IHC score of 1+ or (2+ with negative in situ hybridization (ISH) assay). There is increasing interest in the HER2-low subtype which is becoming a new distinct entity with promising data from recently reported clinical trials using novel anti-HER2 antibody-drug conjugates (ADC) in this subgroup. This study investigates the differences in treatment outcomes between patients with aBC with HER2-low versus those with HER2-Zero (IHC-0) disease treated with CDK4/6 inhibitors and endocrine therapy (ET). Methods: We retrospectively reviewed patients with (HR+/HER2-) aBC who received CDK4/6 inhibitors with an aromatase inhibitor (AI) or fulvestrant from June 2017 to May 2020 at a single cancer center. Data was extracted from patients' electronic medical records and from our institutional cancer registry. Progression-free survival (PFS), defined as the time from the initiation of CDK4/6 inhibitors to the date of radiological or clinical progression or death, and was estimated by the Kaplan-Meier method and compared by the log-rank test. Multivariate Cox regression modeling was performed with covariates including progesterone receptor (PR) status, prior

chemotherapy, site of metastasis (visceral versus bone-only disease), line of treatment (first-line or beyond), menopausal status, age (less than or \geq 45) and number of metastatic sites (< or \geq 3). P-value < 0.05 was considered statistically significant. Results: During the study period, a total of 256 patients with advanced-stage breast cancer who received ET and CDK4/6 inhibitors (ribociclib in all patients) were included, median age was 48 (22-87) years. Majority (n=162, 63.3%) received ribociclib as a first-line therapy while the others had it as a second line and beyond. 136 (53.1%) patients had de novo metastatic disease, and 122 (47.7%) were premenopausal. In total, 114 (44.5%) of the patients were HER2-Zero (IHC-0), while 142 (55.5%) others had HER2-low disease as defined above. The overall response rate (ORR) for the HER2-Zero group was 52% versus 39% for the HER2-low group (P= 0.005). The median PFS was 23.0 (95% confidence interval [CI], 19-40) months for HER2-Zero versus 17.0 (95% CI 14-20,) months for HER2-low; P= 0.0035. In multivariate analysis, HER2-low expression remained significant determinant of inferior PFS after adjusting for other factors including the line of treatment (aHR:2.10, 95% CI 1.03-4.27, P=0.041) , age (aHR 2.20, 95% CI 1.29-3.77, P=0.004) , number of metastasis (aHR:1.96, 95% CI 1.32-2.91, P=0.001), and site of metastasis (aHR:1.64, 95%CI 1.058-2.55, P=0.027). Conclusion: In patients with advanced-stage breast cancer treated with CDK4/6 inhibitors and ET, level of HER2 negativity may affect treatment outcomes; patients with HER2-Zero had better PFS compared to those with HER2-low disease. These findings, if confirmed in larger studies, should help oncologists select patients with HER2-low for better treatment options including a combination of anti-HER2 therapy and CDK4/6 inhibitors.

Background: 74% of women have urogenital symptoms classified as Genito-urinary Syndrome of menopause (GSM) during breast cancer treatment. Promestriene is effective and safe in the treatment of GSM. However, some women and oncologists are not comfortable with long-term use. Therefore, new options for and alleviating GSM have been considered, such as microablative fractional CO2 laser (CO2L) and microablative fractional radiofrequency (RF).

Objective: To compare the effect of promestriene, CO2L, and RF treatments of GSM in women with breast cancer in the use of antiestrogens therapy, concerning clinical and histological

findings of vulvar vestibule.

Methods: This is a secondary analysis of a Multi-arm randomized controlled trial (NCT04081805). Were eligible for the study 100 women with breast cancer using adjuvant endocrine therapy referring moderate to severe symptoms of GSM (itching, dyspareunia, fissures, thinning of vaginal rugae, and tropism reduction). After providing written informed consent, they were evaluated according to pre and post-treatment protocol by filling the VAS of GSM and by clinical evaluation including a standardized gynecological exam with vestibular biopsy. Women were then randomized to either CO2L, RF or promestriene groups. The CO2L and RF groups received 3 consecutive monthly outpatient vulvovaginal energy applications. The CT was oriented for domiciliary use of promestriene, 1g/d for 21 days and, subsequently, twi4 month seek for 4 months. The follow-up visit was performed 120 days after interventions and also included an evaluation of global patient impression of improvement (5 points Likert scale).

Results: 94 women were randomized as follows: 32 in the CO2L group, 32 in the RF and 30 in the promestriene. 70 patients concluded the treatment and had adequate pre and post-treatment material to analyze, 23 CO2L, 21 RF and 26 promestriene. Pre-treatment demographic and clinical data are presented on table 1.

The evolution of GSM according to each treatment is demonstrated on table 2. Was also reported a high satisfaction after the treatment protocol in all groups evaluated by Likert Scale: CO2L 4,783 (□0,518), RF 4,150 (□0,813) , CT 4,280 (□1.13), p=0,055.

The histological parameters were presented on table 3. Histological atrophy was surprisingly identified in only 4 women (5.7%), pre-treatment. No injuries to the histological structure of the vulvar vestibule or relevant clinical adverse events were identified post-treatments.

Conclusion: CO2L, RF, and promestriene provided significant and similar improvement of GSM in women with breast cancer using anti-estrogens. The use of energies did not cause structural tissue damage or relevant clinical complications.

Background : The treatment of Human Epidermal Growth Factor -2 (HER2) positive breast cancer has advanced since Trastuzumab and subsequently Pertuzumab were introduced and approved as antibody-targeted therapy. With the incorporation of anti-HER2 therapy, cardiotoxicity poses a significant risk and is a well know side effect. This toxicity can increase with concomitant use of Anthracyclines. Left Ventricular Global Longitudinal Strain is assessed using speckle tracking analysis on 2D echocardiogram and a relative reduction in LV global longitudinal strain (GLS) of 10-15% from baseline appears to have specificity to predict downstream reduction in Left Ventricular Ejection Fraction (LVEF). There is growing use for identification of GLS changes in these patients and its incorporation into medical decision making that impacts oncological and cardiac care. **Methods :** We conducted an analysis of 200 patients receiving anti-HER2 therapy at Henry Ford Cancer institute from Jan 1, 2016 to June 1, 2022 to determine if there was a 10-15% reduction in GLS detected prior to a decrease in ejection fraction and if and how these detections resulted in the implementation of cardio protective measures and downstream effects on cancer therapy. **Results :** There were 198 patients with GLS and LVEF data. 175 patients (88.3%) completed one year of cancer therapy 107/198 patients (54%) had no change in GLS or LVEF. 91/198 patients (45%) had changes in GLS and or LVEF. 41/91 (45%) patients with LVEF decline did not have cardioprotective intervention implemented. Despite this, 34 (83%) of these patients completed cancer treatment. 50/91 (55%) patients did have cardioprotective interventions with 40 (78%) patients from this subgroup completing cancer treatment. 81% of patients with EF decline were able to complete treatment. 50% of patients with EF decline had EF recovery within 6 months of completion of cancer therapy. The odds of LVEF decline were 9.8 times higher for those with GLS decline (OR=9.0, p< 0.001). Patients with LVEF decline were more likely to have cardio preventive intervention (OR=18.8, p< 0.001). Multivariate analysis did not find an association between

cardiac risk factors such as hypertension, diabetes mellitus, smoking, obesity and hyperlipidemia with GLS decline. There was no disparity by race. Conclusion : Our study revealed that early changes in GLS and LVEF did not impact the completion of cancer treatment irrespective of implementation of cardioprotective measures.

Purpose/Objective(s): Several randomized clinical trials and non-randomized studies have consistently shown that achievement of pathologic complete response (pCR) in the breast with negative axillary nodes is associated with excellent long-term outcomes. NSABP B-511 is a phase III trial aimed to determine if chest wall and regional nodal irradiation (CWRNI) post-op reduces invasive breast cancer recurrence-free interval in patients (pts) with positive axillary lymph nodes (LN) who achieve pCR after neoadjuvant chemotherapy (NAC). However, physicians might be biased towards avoiding enrollment of young patients (≤ 45 years) in this trial. Which in turn, could give way to this population becoming under-represented at the time of

determining the standard of care. Our primary objective is to determine if the omission of CWRNI is associated with an increased risk of recurrence in a young patient population. Materials/Methods: Data were obtained from two institutions in South Florida. Patients aged \leq 45 years, with non-metastatic invasive breast cancer, and positive clinical (LN) involvement, diagnosed between 2010 to 2017 and treated with NAC were identified through retrospective chart review. Disease recurrence including local and distant recurrence data were collected. The Kaplan-Meier survival function was used for plotting patients treated with CWRNI vs no CWRNI and the log-rank test was used to evaluate the recurrence-free survival according to groups. We reported recurrence probabilities at 5 years. Additionally, we also estimated hazard ratios (HRs) of patients treated with CWRNI vs no CWRNI using Cox proportional hazards regression analysis. Results: A total of 154 patients were identified. Median age was 39 years (24-45). Patients were 57% ER+, 33% HER2+, 29% triple negative and 59.1% were stage 3, with only 1 male patient in the cohort. pCR was achieved in 22.1% (34/154) of pts, and CWRNI frequency in these patients was 81.3%. Overall, 79.9% of pts received post-op CWRNI. Recurrence frequency in patients with a pCR who received CWRNI was 4/26 vs 2/6 in pts that did not receive CWRNI. The Kaplan-Meier survival curves indicated an overall probability of recurrence at 5 years of 31.9% (95%CI 3.8% – 51.8%) in patients that did not receive CWRNI vs 27.49% (95%CI 18.42% – 35.56%) in patients that received CWRNI (log rank $p=0.55$) however, statistical significance was not met. Cox regression indicated that omission of CWRNI was not associated with an increased risk of recurrence (HR 1.3, 95%CI 0.54 – 3.11, $p=0.55$). In patients that had a pCR after NAC, omission of CWRNI was not associated with an increased risk of recurrence (HR 2.004, 95%CI 0.36 – 10.9, $p=0.42$). However, the sample size for these analyses was too small to achieve significance. Conclusion: This data highlights the tendency of giving CWRNI to younger patients with clinically node-positive disease at diagnosis regardless of response to NAC. Overall, absolute recurrence in this cohort was very low. Although an absolute number of recurrences favored CWRNI in the setting of pCR, this was not statically significant given the small sample size.

Background: Clinical trials are key to improving outcomes in metastatic breast cancer (MBC). However, participation is low. Little data exists regarding the attitudes and experiences of patients in relation to clinical research. This study co-developed by a patient living with MBC and researchers aims to explore the experiences and issues related to accessing and participating in clinical research. Material and Method: A mixed methods study consisting of an online survey and qualitative interviews. Participants responded to an online questionnaire which contained closed and open questions, this was live between 17th May 2021 and 30th November 2021. Qualitative interviews from a sample of patients who gave their consent were carried out between 15th August 2021 and 22nd November 2021. Descriptive statistical analysis of the quantitative results from the closed questions and thematic analysis of the qualitative data generated by the open-ended questions and interviews were utilised. Data were extracted on 1st December 2021. Results: 768 eligible responses were received (765 female, 2 male, 1 unknown gender). The greatest proportion of responders were aged 51-60 years (37%), 92% were white (n=708) and 45% employed (n=345). 31% (n=235) were diagnosed with MBC within the last year with 14% (n=107) >5 years ago. 86% (n=660) knew what a clinical trial was. With 23% (n=173) reported an oncologist raising trial participation while 32% (n=243) of

patients raising participation with their oncologist. Responses to such inquiries varied from positive and supportive to 'vague and dismissive'. Accessing new treatments (96%, n=737) and playing a more active role in own health (81%, n=619) would encourage trial participation while being unsure of potential benefits (43%, n=333) was the commonest reason for possible non-participation. Preferred sources of information on trials were a consultant (80%, n=612), nurse (61%, n=467) or trial database (29%, n=220). 36% (n=276) were willing to travel for a study increasing to 56% (n=430) if travel costs were covered, and 43% (n=306) would travel worldwide for a study. £0 to over £100 per month for travel was reported to be affordable. Of the 14% (107 of 768) who had taken part in clinical trials; 72% (n=77) found it a positive experience. Free text responses indicated this was related to additional/longer monitoring. The lack of information relating to trials was a recurring theme. 21 participants were interviewed for the qualitative sub study, with three complementary themes emerging from these namely (1) information about clinical trials/research, (2) barriers to participation and (3) research priorities. Conclusion: This large UK study provides insights into the experiences and attitudes of patients with MBC in relation to clinical research. It demonstrates that patients are keen to be involved in research but face barriers to inclusions. Key messages include the need to develop patient facing trial databases, the importance of clinical staff in the provision of study information and a willingness to travel for a trial but the need for financial support. Addressing the issues identified in this survey are key to ensuring MBC patients not only have opportunities to participate in clinical research but also the ability to take these opportunities up.

Background: Over the last years, the treatment of HER2-positive (HER2+) breast cancer (BC) patients (pts) has been changing because of the development of new anti-HER2 agents. In the current analysis, we describe the features, treatment patterns, progression-free survival (PFS) and overall survival (OS) outcomes of BC pts with HER2 + (immunohistochemistry [IHC] 3+ or IHC 2+ and in situ hybridization [ISH]+), following ASCO/CAP 2018 guidelines in the most recent tumor lesion before the 2nd-line.

Methods: The RegistEM study is an ongoing BC registry study that is providing prospective data from around 1900 pts diagnosed with advanced BC (ABC) between 01/Jan/2016 and 31/Dec/2019, in 38 Spanish institutions from GEICAM network. In this analysis, 296 HER2+ BC pts have been included, representing the 18% of pts available in the database at the cut-off date (08/Apr/2022), with ABC diagnosis before 2019 (n=1559).

Results: At first ABC diagnosis, 58% (n=173) pts had recurrent disease (>36 months [mo] from initial BC diagnosis in 62%), 41% (n=120) de novo metastatic BC and 1% (n=3) unresectable locally ABC (ULABC); the median age was 58 years, 68% were postmenopausal and there was only 1 male pt. From total 296 pts, 66% had hormone receptor expression [HR+]; the BC subtype was assessed in tumor tissue from the breast (58%) or a metastatic lesion (34%), and in 8% pts, HER2 positivity was observed after the 1st-line. Family history of BC and/or ovarian cancer was reported in 28% pts, and a hereditary-risk genetic test was performed in 26% pts (n=74/282). Germline BRCA1/2 and TP53 genetic testing were reported in 14 and 26 pts

respectively, being mutated in 3/14 (21%) and 5/26 (19%) pts. Bone (50%), lymph nodes (49%), liver (35%), lung (31%), soft tissue (8%) and central nervous system (CNS), mostly in brain (8%), were the main metastatic sites. One hundred pts were diagnosed with CNS metastases: 24 at baseline, 48 during the 1st-line and 28 in subsequent lines. Additional data according to HR status and type of ABC are detailed in the table below, showing a worse prognosis in absence of HR expression. In HR- pts, bone metastases were less frequent and lymph nodes metastases more frequent compared to HR+ pts. Visceral disease was present in 69% (66% in HR+ and 74% in HR-; non-statistically significant) pts and ≈80% had ≤3 (54%, ≤2) locations involved. The most common therapies by line were: 1) 1st-line: Chemotherapy (CT) + biological therapy (BT) (38%), CT + BT+ endocrine therapy (ET) (35%), and ET + BT [11%]; 2) 2nd-line: BT (55%), CT + BT (20%) and ET + BT (15%); 3) 3rd-line: CT + BT (49%) and BT (31%). The median (95% confidence interval [CI]) progression-free survival (PFS) on 1st, 2nd and 3rd line was 18 (15-22), 8 (7-9) and 6 (5-8) mo, respectively. The median (95% CI) overall survival (OS) from ABC diagnosis was 43 (40-49) mo. These survival outcomes were higher in HR+ pts, however, the differences were only statistically significant in OS (p=0.006; log-rank). At database cut-off date, death was reported in 47% pts.

Conclusions: In spite of the anti-HER2 therapies administered in the advanced setting, the HR expression is a relevant prognostic factor, with a clinically and statistically significant impact in OS, improving the outcomes of HR+ pts.

Since Coronavirus Disease 2019 (COVID-19) was declared pandemic in March 2020, there have been 545.226.550 cases up to 4 July 2022 (1). Several studies concluded that patients (pts) with cancer are at increased risk of COVID-19 infection, morbidity and mortality. Those undergoing neoadjuvant treatment are at particularly risk of disease progression if chemotherapy or surgery are delayed. Also, is known that a higher NLR (neutrophil to lymphocyte ratio) is related to worse outcomes (3). Our hospital is located at the Northwest of Spain and in the last months we noticed a never seen number of infections in cancer population. The aim of this study is to evaluate the severity of COVID-19 and its impact on chemotherapy and surgery delay in pts undergoing neoadjuvant chemotherapy breast cancer.

METHODS:

We conducted a ambispective, unicenter, observational study of breast cancer pts, treated with neoadjuvant chemotherapy, between March 2020 and May 2022 at University Hospital A Coruña (Spain). We analyzed type of infection, need of hospitalization, chemotherapy and surgical delay, and its association with tumor type; BRCA germline mutation; clinical stage; treatment; vaccination status; and neutrophils, lymphocytes, and NLR before COVID-19 disease.

RESULTS:

During the study period, from 1 March 2020 to 31 May 2022, 183 pts underwent neoadjuvant chemotherapy. A total of 23 (12.5%) pts experienced COVID-19 infection, of which 21 were diagnosed between January and May 2022. The median age was 47,91 years [range 33 – 69 years]. Luminal B HER 2 negative comprised the most common molecular subtype (40.9%), followed by Triple Negative (36.4%), Luminal B HER 2 positive (13.6%), and HER 2 enriched (9.1%). Germline mutations in BRCA account for 13.6% pts. At diagnosis, 4.5%, 72.7%, and 22.7% had stages I, II, and III respectively. Chemotherapy treatments included: paclitaxel followed by Adryamicine-Cyclophosphamide (AC) (45.4%); carboplatin – paclitaxel – trastuzumab - pertuzumab (18,2%); carboplatin – paclitaxel followed by AC (18,2%); KEYNOTE-756: pembrolizumab/placebo - paclitaxel followed by AC (13.7%); and paclitaxel – trastuzumab – pertuzumab followed by myocet – cyclophosphamide – trastuzumab - pertuzumab (4.5%). The association of G-CSF occurred in 9 pts (40.9%). 22 pts were fully vaccinated, 8 pts (36.4%) with two doses and 13 pts (59.1%) with three doses. 77.3% pts experienced mild respiratory symptoms with 9.1% hospitalizations. The median duration of delays was 15 days for chemotherapy and 29,58 days for surgery.

NLR percentil 25 was associated with COVID-19 type of infection. For those pts with a lower rate, infection was asymptomatic and for those with a higher rate symptoms were moderate ($X^2= 5,119$, $p = 0,024$).

CONCLUSIONS:

COVID-19 disease become a high prevalent infection in pts undergoing neoadjuvant breast cancer chemotherapy. Most pts are fully vaccinated and experienced an indolent infection. NLR is an easily measurable and cost-effective parameter that could be useful as a prognostic marker of severity in COVID-19. We will continue to follow-up these pts to see the impact of chemotherapy or surgery delay in pathological complete response and disease-free survival until the congress in December 2022.

TABLE 1: Clinical characteristics of patients

Characteristics	N=22 (%)
Age	
- Median (range)	47,91 (33-69 years)
Gender	
- Female	22 (100%)
- Male	0 (0%)
Molecular subtype	
- Luminal A	0 (0%)
- Luminal B HER2 Positive	3 (13,6%)
- Luminal B HER2 Negative	9 (40,9%)
- HER2 Positive	2 (9,1%)
- Triple Negative	8 (36,4%)
BRCAG mutations	
- BRCAG wild type	12 (54,5%)
- BRCAG mutation	3 (13,6%)
Type of chemotherapy	
- Paclitaxel weekly x12 --> AC x4	9 (40,9%)
- Paclitaxel weekly x12 --> AC x4 DD	1 (4,5%)
- Carboplatine d1 Paclitaxel d1, d8 Trastuzumab d1 Pertuzumab d1 x6	4 (18,2%)
- Carboplatine Paclitaxel x4 --> AC x4	4 (18,2%)
- CT keynote 756	3 (13,6%)
- CT Carabela	1 (4,5%)
- Paclitaxel weekly – trastuzumab – pertuzumab x4 - -> myocet – cyclophosphamide – trastuzumab - pertuzumab x4	0 (0%)
Clinical Stage	
- Stage I	1 (4,5%)
- Stage II	16 (72,7%)
- Stage III	5 (22,7%)
G-CSF (before or after COVID infection)	
- No	13 (59,1%)
- Yes	9 (40,9%)
Vaccination Status	
- Unvaccinated	1 (4,5%)
- One dose	8 (36,4%)
- Two doses	13 (59,1%)
- Three doses	13 (59,1%)
- Four doses	0 (0%)

TABLE 2: Blood cell count in percentils

	Blood Cell Count	N=22
25th percentil		
- Neutrophils (n/ml)	1765	4
- Lymphocytes (l/ml)	1252	5
- NLR	1,37	5
50th percentil		
- Neutrophils (n/ml)	2950	11
- Lymphocytes (l/ml)	1735	11
- NLR	1,70	11
75th percentil		
- Neutrophils (n/ml)	3650	17
- Lymphocytes (l/ml)	2155	17
- NLR	2,52	17

Background Radiological complete response (CR-MRI) to neoadjuvant chemotherapy (NAC) by MRI predicts pathologic complete response (pCR) rates in pts with TNBC treated preoperatively with A/TX-based regimens and in some studies, it correlates with disease-free survival (DFS). The main aim of this study was to assess the relevance of the MRI response to primary chemotherapy associated with clinical stage and HER2 expression (Zero vs Low), in a cohort of 143 TNBC pts treated with A and TX +/- carboplatin (CP) in the NAC setting. Methods Retrospective study of pts treated with NAC for TNBC between January 2002 and June 2021, who underwent MRI to assess tumour response before NAC, after 4 cycles of anthracycline and cyclophosphamide (AC) and after TX. Survival analysis was based on the Kaplan-Meier and survival curves were compared using the log-rank test. A p value of less than 0.05 was considered as statistically significant. Results A total of 143 TNBC pts with a median age of 52 years; 7, 63 and 73 pts had stage I, II and III disease, respectively. The NAC regimen consisted in 117 pts 4 cycles of AC followed by TX and in 24 pts the same adding CP (in 21 pts with non-CR-MRI, 2 with CR-MRI and 1 without MRI after AC). PCR was observed in 41%. Of 30 pts with CR-MRI after AC, 83% obtain a pCR ($p < 0.001$), and of 52 pts with CR-MRI at the end of NAC, 70.7% obtain a pCR ($p < 0,001$) of which 90% had a CR-MRI after AC. Adding CP

increased pCR by 6% ($p=0.564$). According HER2-zero vs low expression, the pCR was 38% and 47% respectively, with no significant differences. With a median follow-up of 60 months, 34% recurred and 16% died of TNBC. In pts with pCR, the DFS at 5 years (y) was 96% and 47% for pts without pCR ($p < 0.001$), with a DFS of 91% if CR-MRI at the end of NAC and 48% if non-CR-MRI ($p < 0.001$). In HER2-Zero tumours the DFS at 5 y was 64% vs 66% in HER-2 low. Interestingly, overall survival (OS) at 5 y was 72% in HER2-Zero and 84% in HER2-low ($p=0.080$). Conclusions Performing serial MRI in the course of NAC in TNBC may be a reliable indicator of pCR, adding platinum to TX in pts with CR-MRI may increase pCR rate. HER2-Zero expression in TNBC, seems to confer worse OS rates.

Background Ductal carcinoma-in-situ (DCIS) is a growing health problem in the world. Before the advent of screening mammography, the incidence of DCIS was low, and patients presented with DCIS that had become clinically symptomatic. Upon this evidence, a strategy of aggressive surgical therapy like the approach with invasive cancer was adopted. The status of the regional lymph nodes is the most important prognostic factor and predictor of survival in breast cancer, but as DCIS is a malignant proliferation of the epithelial inside the breast duct and, therefore, does not have the capacity to generate metastasis. However, an upstaging after surgery is possible. The need for sentinel node biopsy (SNB) in patients with a preoperative biopsy diagnosis of DCIS is still controversial but is done in selected cases. Objectives Our main objective in this study was to evaluate the surgical approach in the axilla (SNB or axillary dissection – AD) of patients diagnosed with DCIS in a single institution and describe the surgical treatment (mastectomy or breast conservative surgery – BCS). In addition, we aimed to find the reasons that led our surgeons to choose one or the other treatment. Methods A retrospective analysis was made using the Pérola Byington Hospital's database, from January 2011 to December 2019. During this period, 11,373 cases of breast cancer were treated in the institution and 812 (7.4%) were DCIS. Data was available and we could analyze 494 patients who underwent core biopsy or vacuum-guided biopsy guided by mammography or ultrasound and were diagnosed with DCIS and underwent surgical treatment at the Hospital. We grouped the patients into 3 age groups: under 40, 40-49, and 50 and over. In all groups, we had patients who underwent SNB using the patent blue technique or axillary dissection (AD) and were evaluated using the H&E method. We had also evaluated the type of surgery (BCS or

mastectomy) in each age group. Results DCIS was diagnosed through mammographic alterations in 62% of all cases and nuclear grade 2 was the most common, with 47%, followed by grade 3 and 1, 46% and 4%, respectively. In 2% of cases the data was missing. Comedonecrosis was present in 78% of our specimens. The type of surgery (radical or BCS) was evaluated and BCS was made in 360 patients (72,87% of the cases), with the axillary approach being performed in 125 patients of these patients (50,20% of cases that went to axillary approach including 9 patients that were submitted to AD). In 27,1% the surgical approach was a radical surgery (total mastectomy or skin sparing mastectomy) and in this group 92,5% were submitted to axillary approach. There was a strong correlation in the type of surgery and axillary approach (p-value 0,000) In the group of patients younger than 40 years, 74% of patients (17 out of 23 in total) underwent an axillary approach regardless of the type of surgery (p-value 0.036) When evaluating the predetermined age groups, we saw that most of our patients were 50 years or more (69%), followed by patients between 40-49 years (26%) and 5% in patients under 40 years. In only 3% of cases (16 in 494) we reclassified the lesion as invasive carcinoma after the surgery. None of them had a lymph node involved by malignant cells after surgery and that's include the cases reclassified as invasive carcinoma. Conclusion The results obtained in this analysis showing no axillary involvement will make us rethink the indications for the concomitant surgical approach of the breast and the axilla in cases with a diagnosis of DCIS to reduce the axillary surgical overtreatment. It was not our goal to compare the costs, mobility, and complications of the surgical treatment as the survival in these patients that can be addressed in another studies.

INTRODUCTION

Approximately one-fourth of patients presenting with early-stage breast cancer develop distant metastatic disease, a prominent cause of mortality. The role of metastasis-directed intervention is still uncertain in this cohort. The aim of this study is to evaluate whether intervention to metastatic lesions impacts overall survival (OS) and post-distant recurrence survival (PDRS), defined as survival after first occurrence of metastatic disease.

METHODS

Our prospectively maintained international multi-center database of patients diagnosed with distant recurrence was retrospectively reviewed. Patients initially presenting with stage I-III breast cancer and diagnosed with metastatic disease to the bone, liver or lung from 2014-2020 were divided into cohorts receiving intervention to their metastases (IM, n=180) versus no interventions to their metastases (NI, n=120). The characteristics of the patients were compared with X2 test. OS curves were calculated by Kaplan-Meier method and multivariable analysis by Cox regression. Statistical significance was set at $p < 0.05$.

RESULTS

No significant differences in OS and PDRS were noted between the two groups when comparing age at diagnosis, menopausal status, tumor histopathology, pathological stage, axillary lymph node involvement, and hormone receptor and HER2 status. However, median OS and PDRS were significantly longer for patients who received IM compared to those who did not. The hazard of death was 59% lower with IM than with NI for both OS (HR 0.59: 95% CI 0.42 – 0.83; p=0.002) and for PDRS (HR 0.59: 95% CI 0.42 – 0.84). On multivariable analysis, OS was improved among patients with IM, and among those with lung metastases, compared to liver and bone metastases.

CONCLUSIONS

Metastatic site intervention had both an OS and PDRS benefit in this cohort. In order to explore the potential for interventions to their metastases, patients who develop limited metastatic disease following initial breast surgery should be discussed at a multidisciplinary tumor board.

Post-Distant Recurrence Survival in Patients with Breast Cancer Receiving Intervention to Metastatic Lesions (IM) Versus No Intervention (NI)

	N	Death	Median (months)	HR (95%CI)	P
IM	180	75	47	0.59 (0.42-0.84)	0.003
NI	120	59	24	Ref	-

Introduction: The treatment of breast cancer can trigger physical dysfunctions and psychological difficulties such as pain, depression, limitation of upper limb function and shoulder range of motion (ROM) deficits. Exercise therapy is a treatment well established in the literature for these disorders and another form of treatment is acupuncture. However, most studies using acupuncture only assess pain. Objective: To compare three distinct rehabilitation treatments (exercise therapy, acupuncture and Stiper®) in women undergoing breast cancer surgery, assessing pain, depression, upper limb function and range of motion parameters (ROM). Methods: Seventy-nine women with pain above 3 on the visual analogue pain scale (VAS) and with more than 90 days of surgery were included. They were divided into three groups that received weekly treatment for 10 weeks: group I (G1) treated with standard, pre-defined exercise therapy, based on stretching of the cervical muscles, shoulder girdle and shoulder ROM exercises with a duration of 30 minutes, group II (G2) treated with 30 minutes of acupuncture using predefined points and group III (G3) treated with the same acupuncture points as group II, however, using the Stiper® (silicon oxide micronized quartz pellet) in place of needles. Results: Sixty-seven patients completed the treatment, being 26 from G1, 23 from G2 and 18 from G3. There was an improvement of pain over time in all groups (first session compared with the fifth ($p < 0.001$) and with the tenth ($p < 0.001$), but not between groups. There was a statistically significant difference in depressive symptoms using the Beck questionnaire over time in the three groups (between the first and tenth sessions ($p = 0.001$), between the first and fifth sessions ($p = 0.052$), but not between groups. Regarding the DASH questionnaire for shoulder function, there were significant differences overtime at all evaluated moments ($p < 0.001$), but not between groups. There was a statistically significant difference in ROM over time in the three groups, but not between groups. Conclusion: The rehabilitation of physical dysfunctions in women who survived breast cancer through exercise therapy, acupuncture and Stiper® in pain, depression, upper limb function and ROM, proved to be

effective, without statistically difference between the groups, which in leads to the conclusion that acupuncture don't showed the superiority of results when compared with exercise therapy, thus being an effective approach in the rehabilitation of these women.

Abstract Introduction: Axillary web syndrome (AWS) is a complication in women with breast cancer and occurs immediately after axillary surgery. It is characterized by pain, limited shoulder range of motion (ROM), and presence of cords. Objectives: This study aimed to evaluate the impact of physical therapy interventions, such as physical exercise with tissue mobilization and exercise alone. Methods: A randomized clinical trial was conducted at the Division of Breast Cancer disease of the Universidade Federal de São Paulo. Seventy-three women with AWS were randomized into the mobilization (ME) group (N=37) and exercise (E) group (N=36) and followed up for 3 months after breast cancer surgery. Both groups were provided with specific guidelines for performing regular shoulder exercise at home, while tissue mobilization was performed in a specific group with a maximum of six sessions, according to the patient's need. ROM, pain, and presence of cords were evaluated in each postoperative period (PO). Results: In both treatment groups, at the end of 90 days, improvement in flexion was observed as well as less pain and number of cords. In terms of abduction, the E group was better than the ME group. Conclusions: Physical exercise after breast cancer surgery is extremely important for functional recovery, resumption of activities of daily living, improvement of pain, and reduction in the number of cords. Tissue mobilization appears as an adjunct for causing a more immediate improvement in ROM, pain, and presence of cords, but at times not sustaining the gains for the following PO. Keywords: breast neoplasms, axillary web syndrome, physical exercise, articular range of motion, pain

Background: Triple negative breast cancer (TNBC) is well known for its more aggressive course and poorer prognosis compared to other BC subtypes. RegistEM study provides real world data to understand the distribution of BC subtypes in the advanced setting, being its primary objective. Biological samples collection is part of its procedures. This is a non-interventional cohort study and 1,907 patients (pts) have been enrolled up to now (females and males) with advanced BC (ABC), diagnosed from Jan-2016 to Dec-2019, either after recurrence or as first BC diagnosis, in 38 Spanish sites. These pts will be followed for at least 5 years.

Methods: In the current analysis (cut-off date 08/April/2022, database ongoing), we describe characteristics, treatment patterns and outcomes, including comparison between recurrent and de novo disease, of 157 pts with advanced TNBC included in the RegistEM study. Those pts represent the 10% of pts available in the database at the cut-off date and with ABC diagnosis up to December 2018 (n=1559). The BC clinical subtypes were histologically confirmed on the most recent tumor lesion (metastatic [M] or primary BC) before starting with the 1st-line therapy.

Results: At first ABC diagnosis, 73% pts had recurrent early BC (EBC), 26% de novo MBC and 1% unresectable locally ABC (ULABC). Median age was 57 years (range 30-88), all pts were women, 98% Caucasian and 65% postmenopausal. Family history of BC and/or ovarian cancer was reported in 37% pts, and a hereditary-risk genetic test was performed in 59 of 147 pts. Germline BRCA1/2 and TP53 were the most frequently mutated genes, 21% (6/28) and 47%

(8/17) pts, respectively. Visceral involvement was present in 69% pts (similar between recurrent EBC and de novo ABC, although brain metastases were only present in the recurrent EBC group), and ≤ 2 metastatic locations in 59%. In 61% (70/115) pts with recurrent EBC, the subtype was assessed in metastatic lesions, and 39 pts of them also had TN subtype in primary BC. In terms of the most frequent therapies by line: 1) 1st-line: chemotherapy (CT) (60%) and CT/biological therapy (BT) (39%). Of the 87 pts with CT alone, monotherapy was the preferred option in 57% pts (capecitabine 25%, taxanes 16%, and eribulin or vinorelbine, 5% each). Bevacizumab was the most frequent BT (79%) combined with CT (single agent in 56% pts, mostly taxanes and capecitabine). Progressive disease (PD) was reported in 85% pts (similar in pts with both recurrent and de novo MBC or ULABC); 2) 2nd-line: CT (79%) (monotherapy capecitabine, eribulin, taxanes) and CT/BT (17%) (CT-containing bevacizumab 82%). Progression was reported in 92% pts; 3) 3rd-line: CT (90%) (eribulin 33%, platinum-based 25%) and CT/BT (9%) (CT-containing bevacizumab 67%). Progression was reported in 88% pts. At database cut-off date, death was reported in 133 (85%) pts, mainly because of PD. Overall survival (OS) was similar between both groups, recurrent and de novo MBC. Conclusion: In this population of Spanish TNBC pts with ABC, three quarters had recurrent disease. De novo ABC pts had a higher proportion of non-visceral metastases, with absence of brain involvement at the first diagnosis. Single-agent CT and CT plus bevacizumab were the most frequent therapies, and OS was similar between recurrent and de novo MBC pts, although numerically higher in the later group.

Introduction A major barrier to timely breast cancer diagnosis and care in Nigeria is attributable to the out-of-pocket cost of accessing healthcare services, despite the presence of a National Health Insurance Scheme (NHIS). Excessive out-of-pocket payments are often associated with a catastrophic health care expenditure (CHE). Despite the rising incidence of breast cancer in Nigeria, there is a paucity of economic data on the cost of care and the impact healthcare expenditure may have on a household. This study provides a comprehensive, prospective analysis of out-of-pocket spending for breast cancer care at a single tertiary care institution in South West Nigeria. **Methods** Consecutive patients undergoing curative intent surgery for a new diagnosis of breast cancer at Obafemi Awolowo University Teaching Hospital (OAUTH) between August 2019-April 2022 were approached for enrolment. A novel, context specific questionnaire was developed for this study and administered by trained personnel. The questionnaire was delivered to patients and caregivers during hospital admission and again during six-month follow-up. Participants were asked to estimate monthly household income and expenditures. Out-of-pocket direct and indirect expenses for breast cancer diagnosis and care were elicited. Where feasible, hospital accounting records and individual receipts were used to minimize recall bias. Sequelae of the out-of-pocket costs were also elicited, such as the use of debt financing and important forgone expenditures, such as childhood education. Capacity-to-pay was calculated for each household from the provided data as the sum of annual non-food expenditures. A CHE was defined as an aggregate healthcare expenditure that exceeded 40% of a household's capacity-to-pay. All monetary figures were collected in the local currency (Naira) and converted to USD using the Nigerian Central Bank conversion rate of 415.83N to 1USD. Research ethics board approval was obtained for this study from OAUTH. **Results** Data were collected from 57 eligible patients with a mean age of 49.8 years (SD 12). The median household size was five (range 1-10) and the majority (75.4%) had completed at least secondary education. Seventy four percent (73.6%) of patients had \geq Stage III disease at presentation and 89.5% received systemic chemotherapy. Only seven percent (4/received

adjuvant radiotherapy. The mean annual capacity-to-pay for the cohort was \$2,840.8 (\$2,913.6). The mean cost of care, including direct and indirect expenditure was \$3,379.7 (SD \$3032.2). Excluding indirect costs, such as the cost of travel and self-reported lost income, the mean cost of direct expenditures associated with diagnosis and treatment was \$1,705.3 (SD \$1,236.6). Out of the 57 patients enrolled in the study 52 (91.2%) experienced a CHE as a result of their breast cancer treatment. As a result, 56% of households had to borrow money and seven percent withdrew children from school. Sixty-three percent of patients had no form of health insurance. Conclusions Over 90% of breast cancer patients at a tertiary care facility in Nigeria experience a CHE as a result of out-of-pocket costs associated with accessing care. This limits access to costly evidence-based adjuncts (i.e. radiotherapy) and has a negative impact on the wellbeing of the broader household. There is a need for national and global initiatives to ensure financial protection from the cost of breast cancer care.

Background:

Evidence-based recommendations for the management of metastatic breast cancer (MBC) endorse confirmation of recurrence with biopsy and reassessment of biomarker status. National guidelines support numerous treatment options and do not capture the nuances of real-world practice. Real world data may demonstrate disparities in adherence to guidelines.

Methods:

We collaborated with Hutchinson Institute for Cancer Outcomes Research (HICOR) to link enrollment and insurance claims records with Washington State cancer registries from 2008-2017. Our cohort comprised of women > 18 years old with MBC who met enrollment criteria in one of four payors (Premara, Regence, Medicare, or Medicaid). We identified receipt of biopsy and biomarker re-assessment at time of recurrence, receipt of first line treatment, categorized as CDK4/6 inhibitors (CDKi), chemotherapy (CT), or hormone therapy (HT) and examined factors influencing these practice patterns.

Results:

We identified 1,101 patients with MBC (recurrent MBC, N = 715; de novo MBC, N = 386) with a median age of 66 (range 54 – 74). Of the patients with MBC, there were a total of 677 patients with ER+/HER2- MBC. Table 1 shows demographic data. Most of the cohort were White (89%). Approximately 15% of patients lived in areas of high deprivation (area of deprivation index, ADI,

8-10). Patients had either Commercial (47%), Medicaid (4%), Medicare (35%) or multiple (13%) insurance. Of the patients with recurrent MBC, 49.5% received a biopsy to confirm metastatic diagnosis. Similarly, 48.7% of recurrent MBC patients underwent biomarker reassessment. Patients with highest co-morbidity index (2) were more likely to undergo biopsy confirmation (20.3% vs 13.0%, $p = 0.02$). Biopsy was more often performed at recurrence in patients receiving care at a high-volume center (74.3% vs 67.6%, $p = 0.03$) compared to low volume center (18.6% vs 26.6%, $p = 0.03$). First line treatment selection was directly associated with receipt of biopsy and biomarker testing. Hormone therapy only was more common in patients who did not undergo biopsy (62.3% vs 37.7%, $p < 0.001$) or biomarker reassessment (62.7% vs 37.3%, $p < 0.001$). Of the patients with ER+/HER2- MBC, the majority of patients received ET alone (69%), followed by chemotherapy (22%), and CDK4/6i + ET (9%). Dual agent CT was the more commonly prescribed compared to single agent in those who received CT (56% vs 44%). The majority of patients who received CDKi + ET were < 65 years old (65.2%, $p < 0.02$). Insurance influenced first line therapy selection and patients with commercial insurance were more likely to receive CDK4/6i + ET compared to those with Medicare/Medicaid. (60.9% vs 26.1%, $p = 0.10$). Patients with de novo MBC were more likely to receive CT (43.1% vs 13.4%, $p < 0.001$) and less likely to receive ET alone (47.9% vs 78.0%, $p < 0.001$). Almost all patients treated with CDK4/6i + ET received care a high-volume center (91.3%, $p = 0.11$).

Conclusion:

Our findings highlight key gaps for future investigations in the management of MBC and serve as a launching point for new patient-centered and quality-promoting research initiatives.

Background: Image-guided tumor ablation is a non-surgical minimally invasive therapy available for the local treatment of carcinomas as an alternative to surgical treatment. However, studies evaluating this therapy in early breast cancer present variable success rates, raising the question of whether omitting surgery is permissible. Ongoing studies such as the Frost and Ice3 Trial may change the context of cryoablation in the treatment of early breast cancer. Objective: The main objective of this study is to assess the effectiveness of cryoablation in the local treatment of early breast cancer. The secondary objectives are to analyze the negative predictive value of magnetic resonance imaging (MRI) in predicting response to therapy and to assess ice ball size in relation to the largest tumor size. Methods: Non-randomized, single-arm, multicenter clinical study conducted in Brazil. The inclusion criteria will be patients with unifocal invasive breast carcinoma, tumors smaller than or equal to 2.5 cm, lesion visualized on ultrasound, and surgery indicated as the first treatment option. The exclusion criteria will be in situ ductal carcinoma, multifocal or multicentric tumors, clinical axillary involvement, lesion-to-skin distance of less than 5 mm, presence of distant metastasis, and neoadjuvant treatment. All patients will undergo local cryoablation treatment, which will be followed by conventional surgical treatment after an interval of 14 to 28 days. Imaging tests (mammography, ultrasound, and breast MRI) will be performed before and after cryoablation. Cryoablation effectiveness will be assessed through its success rate, defined as the absence of invasive or in situ malignant neoplastic cells in the surgical specimen. If the expected cryoablation success rate corroborates the 92% rate presented in the ACOSOG Z1072 study for patients without multifocal disease, this study will need at least 32 patients to verify if the technique is satisfactory (success rate > 70%) considering power of 95% and an alpha of 5%. The study was approved by the local ethics committee and registered in the Clinical Trials. Recruiting has started in 2020 and is expected to end in 2024. Results: Until now, eight patients have been included, all of them with invasive breast carcinoma of no special type, RH positive and HER 2 negative, histological grade 1 or 2. The mean age of the patients is 57 years, and the mean tumor size is 1.1 cm (0.5–1.8 cm). All patients underwent two cycles of 6-minute freezing and 4-minute thawing with only one cryoprobe coupled to the Argon and Helium gas system. The

complete ablation rate was 87.5% (7 of 8 cases) and the ablation rate considering only absence of invasive lesion was 100%. In our study, only one patient had in situ focal ductal carcinoma in one margin. The mean ice ball size on ultrasound was 3.8 x the size of the breast lesion. The negative predictive value of breast MRI was 100%. Conclusions Cryoablation is a promising therapy and may be an alternative to surgical treatment in patients with early breast cancer. This study confirms that this ablative technique is feasible. However, the results of other ongoing studies need to confirm the role of cryoablation in breast cancer treatment. ClinicalTrials.gov Identifier: NCT05398497

Background: Non-metastatic breast cancers (BC) are increasing treated with neoadjuvant therapy (NAT). Complete pathological response (pCR) is associated with improved survival. Early identification of care needs during NAT is crucial. We report our institution's experience with NAT. Methods: A prospectively recruited cohort diagnosed with BC, referred to NAT program at SingHealth acute hospitals between June 2020 and June 2021. Demographics, clinical data, pCR (absence of invasive carcinoma in breast and axilla), and Functional Assessment of Cancer Therapy Breast (FACT-B) as quality of life (QOL) measure were collected. Definition of young BC (YBC) were ≤ 40 years, older adults (OA) ≥ 65 years. Results: Among 119 eligible patients, 7 (6%) were clinically stage 1, 71 (60%) stage 2, and 41 (35%) stage 3. Twenty-eight (24%) were triple negative (TNBC; defined as HER2- hormonal receptor 0-10% [HR-]), 26 (22%) HER2+ HR-, 45 (38%) HER2+ HR+, 20 (17%) HER2- HR+. Among 71 HER2+ BC, two-thirds received anthracycline (A) based chemotherapy, a quarter A-sparing and remaining 9% taxane only. Majority (89%) received dual HER2 blockade. Among TNBC, 28 (71%) received additional platinum and 2 (7%) immunotherapy. Majority (77%; n=92) completed NAT. Toxicity was main reason for incompleteness. Three patients did not undergo surgery: 1 defaulted, 1 demised and the last patient's surgery was not due at analysis. Of the 116 who underwent surgery, 23 (20%) had breast conservation and 93 (80%) mastectomy.

Forty-nine (42%) achieved pCR - 12 (43%) TNBC, 17 (65%) HER2+ HR-, 20 (44%) HER2+ HR+ and 0 in HER2- HR+ ($p < 0.001$). The pCR rates were also lower by increasing age (Multivariable OR 0.93; 95% CI, 0.90-0.97). Baseline median FACT-B scores was 117 (IQR 102-126) for the cohort: 108 for YBC, 116 for OA and 120 for the rest ($p=0.200$). At baseline, median score was 28, 24, 18, 22 and 27 in physical, social, emotional, functional wellbeing and BC subscale, respectively, and YBC and OA patients had lower social wellbeing scores than the remaining cohort (22 vs 24, $p=0.011$). Conclusion: Highest pCR were observed with HER2+ followed by TNBC. Pre-operatively, FACT-B scores were comparable by demographics, staging and tumor subtypes. However, care must be paid to social wellbeing for women in age extremes undergoing NAT.

During the COVID-19 pandemics we have all witnessed the clinical importance of mRNA as current vaccines and future therapeutics. mRNA therapies have a potential to revolutionize cancer treatment. Delivery of mRNA requires lipid nanoparticles (LNP) to protect the cargo from degradation. mRNA has a negative charge and depends on positively charged lipids to be encapsulated in LNP. These lipids can be either ionizable at certain pH or constantly cationic. Even though previous studies had evaluated the formulation properties of ionizable and cationic LNP systems, there is the need to understand their specificity in terms of mRNA delivery and protein expression in breast cancer tumor microenvironment. The objective of this work was to assess the kinetics of LNP cellular uptake and mRNA expression in breast cancer (BC) cells and fibroblasts, the most frequent cell type in the tumor microenvironment cells, while studying the mechanisms involved in differential behaviors of LNP formulated with cationic and ionizable lipids. To achieve this goal mRNA-LNP containing ionizable lipids (LNP-A) and cationic lipids (LNP-B) were designed and formulated using Nanoassembler® Benchtop microfluidics mixer (Precision NanoSystems). mRNA-LNP were characterized for size, zeta potential using dynamic light scattering (DLS) and mRNA encapsulation efficiency using RiboGreen assay. LNP were tagged with rhodamine lipid to investigate the uptake kinetic and a reporter GFP mRNA to evaluate mRNA expression in murine 4T1 and human MCF7, MDA-231, SUM-159 and T-47D breast cancer cells and BJ fibroblasts. Live fluorescence microscopy imaging, IncuCyte S3®, was used to determine the LNP uptake and GFP mRNA expression. In vitro biocompatibility was assessed with WST-1 assay. Additionally, expression of mRNA delivered from LNP in tumor microenvironment was evaluated in vivo in a syngeneic 4T1 breast cancer model using mRNA luciferase and IVIS imaging. mRNA-LNPs possessed an average diameter of 77 - 107 nm, narrow size distribution, neutral zeta potential and high mRNA encapsulation efficiency (>94%). Our results demonstrated that mRNA expression was higher in breast cancer cells when delivered from LNP-A formulation and in BJ fibroblasts when delivered from LNP-B. LNP-A, the ionizable LNP, was tested in the breast cancer cells to confirm the efficacy of the delivery. The highest transfection efficacy, from high to low, T-47D, MCF7, SUM-159, 4T1 and MDA-231. We have further investigated the cellular uptake mechanisms of LNP using uptake pathway inhibitors for caveolae endocytosis, clathrin endocytosis, and phagocytosis. Our data

confirm that there are differences in mechanisms that govern the uptake of mRNA LNP in breast cancer cells and fibroblasts. Clathrin-mediated endocytosis was active in 4T1 breast cancer cells for ionizable and cationic LNP. Interestingly, despite in vitro differences in uptake and mRNA expression, in vivo results show that both formulations efficiently delivered luciferase-mRNA in the tumor microenvironment. Histology results demonstrated similar luciferase expression for both LNP in tumors. Additionally, we were able to confirm the prominent presence of fibroblast and similar distribution in the 4T1 subcutaneous model which could explain the similar efficacy of cationic and ionizable LNP. Understanding uptake and mRNA expression of different LNP formulations in the tumor microenvironment can help in achieving the necessary protein expression for breast cancer therapies. Furthermore, determining the most efficient carrier in early stages may reduce the time required for clinical translation. Background: The Theralink Reverse Phase Protein Array-based (RPPA) CLIA assay is a novel molecular assay developed to assist physicians in therapy selection for patients diagnosed with advanced/recurrent breast cancer. The assay was specifically designed to quantitatively measure protein activation/phosphorylation of 32 FDA-approved and Phase III drug targets and pathway-linked downstream substrates, providing functional information on actionable oncogenic drivers in individual tumors. Given the recent commercialization of the Theralink assay (TLA), knowledge gaps exist regarding its use in routine clinical practice and the impact of the test on clinical decision-making in real world practice. The primary objective of this analysis was to assess how the TLA has been integrated in therapy selection for breast cancer patients with a focus on understanding its target population, the rationale for patient selection by the treating physician, and the utilization of the molecule information generated by the assay as part of the therapeutic decision-making process. Findings from this study will help optimize patient selection and maximize the clinical impact of the test as a tool for advancing precision oncology. Methods: We prospectively collected data from 124 women with advanced breast cancer whose tumors were profiled using the Breast Cancer TLA from February, 2021 to May, 2022. All patients were confirmed as actively managed for advanced/recurrent breast cancer. Eight μm FFPE sections (n=5) from a recently collected tissue biopsy were used to isolate tumor epithelia via Laser Capture Microdissection and to generate RPPA-based molecular profiles. Clinical management and therapy selection information for 68 patients was gathered via surveys completed by treating physicians. Results: Median age of the 124 participants was 53 years (range 26-82) and 111 (89.5%) patients had stage IV disease. The cohort included 66 hormone receptors positive (of which 5 were HER2+), 51 triple negative, and 7 HR-/HER2+ breast cancers. The TLA yielded molecular information for all specimens and profiles were generated on average in 11 days. One or more targets were highly activated (highly actionable)

in 91 patients (73.4%) and moderately activated (partially actionable) in 29 patients; only 4 patients had no actionable target (3.2%). Previous treatment information was available for 118 (95.2%) patients. The TLA was requested to assist with the selection of first-line treatment in 36 patients (of which 24 had previously received neoadjuvant treatment), second-line treatment in 35 patients and third- or subsequent-lines of treatment in 47 patients. Clinicians provided feedback on the use of the assay for 68 patients included in the study. The survey revealed that the TLA impacted treatment selection in 50 (73.5%) cases and was used to either expand options beyond standard of care (30 cases), refine/re-prioritize available treatments (11 cases), narrow treatment from a plethora of options (2 cases) or a combination of the three (7 cases). When TLA data were used for treatment selection, physicians defined the assay highly and moderately beneficial for patient management in 15 and 27 cases, respectively. Conclusion: Our study suggests the TLA yields useful information for selecting treatment for breast cancer patients with advanced/recurrent disease. In this prospective analysis, the assay identified actionable targets in more than 90% of patients, which is significantly higher than what has previously been reported for genomic profiling alone. Overall, physicians found the information yielded by the assay useful for selecting treatment. The inclusion of the TLA in oncology may offer important insights for advancing precision medicine for breast cancer patients.

Purpose: Epidemiologic and clinical evidence have shown an association between obesity and increased risk for breast cancer (BC) incidence and mortality. Data from human and animal studies support a potential role for weight loss in counteracting tumor-promoting properties of obesity in BC. However, dietary intervention clinical trials often show low patient adherence, especially among African American (AA) women compared to Caucasian (CC) women. They also show that AA women are disproportionately obese and lose less weight during behavior lifestyle interventions compared to CC with similar risk factors. We evaluated the efficacy and feasibility of a 10-week caloric restricted diet in patients undergoing radiation and have performed analysis to determine if adherence to dietary alterations is feasible in underrepresented patients. Methods: In an IRB approved clinical trial, we determined the feasibility and toxicity of dietary intervention during radiation in breast cancer patients 18 years and older who were undergoing breast conservation therapy with T1-2N0 cancers. The dietary intervention consisted of caloric intake reduction of 25% from baseline for a total of 10 weeks during their six-week radiation treatment which was administered to the whole breast to a dose of 50Gy with a 10Gy boost to the tumor bed. To optimize adherence to caloric restriction (CR), patients received personalized counseling, maintained food diaries, and were educated on behavioral modifications at weekly visits. To characterize the effects of CR, baseline physiologic and blood parameters were collected and compared with post intervention measurements and samples. Biometric and biological data collected during the study comparing compliant participants before and after the CaReFOR intervention was stratified by race and analyzed via two-sample paired t-test. The difference between AA and CC study participants was determined to be significant if the calculated p-value was less than < 0.05 (CI 95%). Results: A total of 32 female patients were enrolled in the CaReFOR trial, 16 were AA and 16 were CC. Participant demographics were similar across age, primary tumor size (pT), nuclear grade, and hormone receptor status. Evaluation of patients' baseline diet demonstrated similar macronutrients across races, with AA showing less fruit/vegetable and grains. AA patients were more overweight compared to their CC counterparts. They also showed a more inflamed state compared to CC patients. The baseline inflammatory biomarker levels for ESR

and cholesterol were significantly higher while adiponectin was significantly lower in AA than that of CC patients. The trends for insulin, HbA1c, and leptin were also higher for AA compared to CC. Following the 10-week diet, AA patients (87.3%) were more compliant than CC's (81.3%). Both AA and CC patients lost weight during the trial, with AA having a significant loss in body fat and gain in muscle mass compared to CC. Similarly, after completing the CR diet, biological inflammatory markers improved in AA and CC patients. Particularly, in AA, there was a significant decrease in cholesterol levels, while insulin, leptin, and ESR serum levels trended downwards, suggesting a decreased inflammatory state. Conclusions: Contrary to published studies, we found AA patients are successful in adhering to dietary alterations and have a benefit with respect to physiologic and biologic parameters. Our dietary intervention was able to positively affect our AA patients adverse baseline factors such as obesity and inflammation. Future studies should consider dietary alterations as a possible means to decrease AA patient disparate outcomes in breast cancer.

Background. In the last five years, several new drugs have been approved for BC in the United States, many of which target HER2, including neratinib, margetuximab, tucatinib, and trastuzumab deruxtecan. These approvals depend on a drug's benefits outweighing its risks in clinical trials (CTs). However, limited information on safety is available from single CTs. The objective of this study is to identify recently published phase III CTs that report AEs in patients (pts) with HER2+ BC and perform a meta-analysis to estimate the frequency of the most common AEs reported in ≥ 2 CTs. Methods. A literature search was conducted (Ovid, ClinicalTrials.gov) to identify phase III CTs published from 2017-2021. Search terms included BC, HER2+, phase III, CT, and others. Articles were independently screened by two researchers in two levels (title/abstract; full text) and were included if they reported AEs in pts with HER2+ BC. Meta-analysis was performed in Comprehensive Meta Analysis v3 to estimate frequency of AEs using random effects models. Results. Of 519 articles identified, 33 were included for analysis (455 excluded in level 1 screening; 31 excluded in level 2 screening). Most excluded articles were not phase III or did not include only pts with HER2+ BC. BC treatments most commonly included chemotherapy and HER2-targeted agents (e.g., trastuzumab), including antibody-drug conjugates (ADCs; e.g., trastuzumab emtansine). Most trials (N=27) included ≥ 1 treatment arm with pts who received chemotherapy in combination with a HER2-targeted agent. Fewer trials (N=10) included ≥ 1 treatment arm with pts who received only a HER2-targeted agent. Across all 33 trials, 181 unique AEs were reported. Specific chemotherapy agents used were not always reported, but included taxanes, anthracyclines, cyclophosphamide, 5-fluorouracil, capecitabine, and carboplatin. In chemotherapy treated pts (with or without reported concomitant HER2-targeted agent), the most frequent any grade AEs were hand-foot syndrome (63.8%, N=1814), alopecia (56.6%, N=9677), and diarrhea (39.9%, N=12628); the most frequent grade ≥ 3 AEs were neutropenia (21.7%, N=14349), hand-foot syndrome (12.2%, N=2252), and leukopenia (8.4%, N=3852). HER2-targeted agents included trastuzumab emtansine, trastuzumab, pertuzumab, lapatinib, and neratinib. In pts treated with any HER2-targeted agent (without reported concomitant chemotherapy), the most frequent any grade AEs were diarrhea (31.7%, N=5518), nausea (30.8%, N=5518), and epistaxis (24.9%, N=3622); the most frequent grade ≥ 3 AEs were thrombocytopenia (4.8%, N=3980), anemia

(4.2%, N=3845), and aspartate aminotransferase increase (3.3%, N=3975). In the subgroup of pts treated with an ADC (trastuzumab emtansine), the most frequent any grade AEs were nausea (41.4%, N=3622), fatigue (31.6%, N=2895), and headache (28.0%, N=3622); the most frequent grade ≥ 3 AEs were similar to those in pts treated with any HER2-targeted agent. Significant heterogeneity was detected among trials for the outcomes reported here (Q statistic ranged from 12-2176, $p < 0.05$). No analysis was conducted in pts who received hormone therapy due to limited available information about this group in the included trials. Conclusion. When evaluating pooled data, the most commonly reported AEs in CTs of patients with HER2+ BC varied by drug classes included in treatment regimens. This meta-analysis provides a more comprehensive understanding of the most frequent AEs in this population by pooling patient data from several CTs and will contribute to better contextualize the safety of products used in this population. Future research including real-world studies can be used to better understand the safety profile of these medications.

Background: Advances in screening and treatment have led to increase in breast cancer (BC) survival in recent years but prognoses for metastatic BC remain poor with poorer outcomes as health-related quality of life (HRQOL). Treatment as bevacizumab and paclitaxel for metastatic BC, although that can increase time to progression of disease, often carry toxicity and is not curative but rather palliative in intent with the goal to improve or maintain HRQOL. The aim of this work was to assess impact of clinical factors such as disease progression, toxicity on HRQOL. Methods: COMET study is a multicenter prospective single-arm cohort study in France whose main objective was to identify biological factor that could predict the clinical benefit of bevacizumab-paclitaxel combination therapy as first treatment in HER2 negative metastatic BC. HRQOL was assessed at baseline, at every cycle (every for 4 weeks) until progression and then every 3 months up to death using the EORTC QLQ-C30 questionnaire and its BC specific module, the EORTC QLQ-BR23. In this ancillary study, we targeted 5 dimensions HRQOL for the primary analyses: Global health status (GHS), physical functioning (PF), Emotional functioning (EF), fatigue (FA) and pain (PA). The primary endpoint was time until definitive deterioration (TUDD) in HRQOL scales that defined as time between inclusion and the first decrease HRQOL score ≥ 5 points compared to baseline score, with no further improvement of at least 5 points. Multivariable Cox model with time dependent covariate was performed to

assess clinical factors associated with TUDD for each of the 5 target dimensions HRQOL. We performed 3 models for each dimension: model 1 including all covariate with $p < 0.10$ in univariable; model 2 including model 1 and adjusted on cancer subtype and model 3 included model 1 stratified by cancer subtype. P value < 0.01 were considered statistically significant. Results: Out of 510 patients included in COMET study, 432 patients with available HRQOL data were analyzed in this study. Median age at inclusion was 58 years (range: 29-83), and 24.4% of patients had triple negative tumor subtype. About 79 % of cancers were invasive ductal carcinoma and 43 % patients had least 3 metastasis sites at baseline. At baseline, patients reported a mean score for GHS of 57.6 (SD=22.7), for PF of 75.8 (23.2), for EF of 62.2 (25.8), for FA of 42.2 (29.60) and for PA of 38.1 (31.5). The Median TUDDs for the 5 targeted dimensions was 10.1 months [7.5-16.9] for GHS, 6.1 months [4.1-8.9] for PF, 21.6 [18.7-31.2] for EF, 10.8 [6.2-16.6] for FA and 13.6[10.1-22.5] months for PA. In multivariable analyses, Disease Progression was associated with TUDD of GHS (HR [99%CI] =2.4 [1.2-4.9] and TUDD of PF (2.1 [1.1-3.7]). After adjusted on cancer subtype, association persisted with TUDD of GHS ($p=0.009$). Performance Status was associated with TUDD of PF (1.6 [1.2-2.3]), and TUDD of Pain (1.6 [1.1-2.3]). Performance Status association with TUDD of PF continued after adjustment on cancer subtype ($p=0.0003$). Prior endocrine therapy was associated with TUDD of pain in patients with tumor with positive hormone receptor (HR+) (2.4 [1.2-4.7]). There was no factor associated with TUDD of EF and TUDD of FA. Conclusion: Results of this study have shown that among the 5 targeted dimensions HRQOL, Physical Functioning was deteriorated in the shortest time. Disease progression, base line performance status and prior endocrine therapy for HR+ subtype, are clinical factors that could influence HRQOL in HER2 negative metastatic BC treated with first line chemotherapy.

BACKGROUND: Neoadjuvant therapy with trastuzumab and pertuzumab (HP) combined with chemotherapy (ChT) is the standard of care in \geq cT2cN0 or N+ HER2-positive early breast cancer (EBC). Although cardiotoxicity is a known adverse effect of anti HER2-therapy and

anthracyclines, recently BERENICE final analysis showed cardiac safety of HP in combination with standard or dose-dense anthracycline-based ChT. However, real-world data is lacking, specifically in patients (pts) with identified cardiovascular (cv) risk factors. Our study aimed to evaluate cardiac safety of HP and anthracyclines in HER2+ EBC and explore potential impact of body mass index (BMI). METHODS: This retrospective analysis included HER2+ EBC pts receiving neoadjuvant HP and anthracycline- and taxane- based ChT, at our institution, between 2016 and 2021. Baseline clinical, demographic, histopathological and immunohistochemical features were reported. Pts were categorized as underweight (< 18.5kg/m²), normal (≥18.5;< 25kg/m²), overweight (≥25;< 30kg/m²) and obese (≥30kg/m²), according to basal BMI WHO categories. The primary objective was to evaluate cardiac safety, assessed by incidence of left ventricular ejection fraction (LVEF) declines (≥10% from baseline and to a value < 50%) and NYHA class III/IV heart failure. Univariate and multivariate logistic regression analysis were performed using BMI as a categorical variable. Safety data were compared in subgroup analyses for underweight/normal and overweight/obese pts. Statistics were performed with IBM™ SPSS software, version 23. RESULTS: Our analysis enrolled 112 female pts, with a median age of 54 years (30-78), including 22pts (19.6%) with ≥65years and 55 (49.1%) postmenopausal women. Most pts (n=89; 79.5%) had HR-positive disease. 44pts (39.3%) had stage II and 68pts (60.7%) had stage III disease. According to BMI, pts were classified as underweight (n=3; 2.7%), normal (n=40; 35.7%), overweight (n=47; 42%) and obese (n=22; 19.6%). No association was found between BMI and tumor stage (p=0.829), grade (p=0.753) and HR status (p=0.212). Other baseline cv risk factors were identified: former/active smoker (n=34;30.4%), diabetes (n=10;8.9%), hypertension (n=30;26.8%), and dyslipidemia (n=32;28.6%). Most pts had ≥2 cv risk factors (n=66;58.9%). Two different regimes were used FEC100-D+HP (2016-2019, n=84) and ddAC-wkPaclitaxel+HP (2020-2021, n=28). Overall, pCR was achieved in 62 pts (55.4%). Regarding cardiac safety evaluation, 4 pts (3.6%) experienced at least one LVEF decline ≥10% from baseline and to a value < 50%, including 3 pts that were overweight/obese. Declines were reversible in all pts, with recovery by next assessment. Two pts (1.8%) experienced one NYHA class III heart failure event. Both pts were overweight/obese and had another concomitant risk factor for cardiovascular disease. Both pts discontinued treatment. No statistically significant association was found between overweight/obesity and cardiac events (OR 1.26, 95%CI 0.22-7.20; p=0.792). Median follow-up duration was 39 months. No new safety signals were identified. CONCLUSION: Cardiac safety of neoadjuvant HP in combination with anthracyclines in HER2-positive EBC in our real-world data is consistent with previous studies. Despite most cardiac events occurred in overweight/obese pts, no statistically significant effect was found. Further studies are needed to evaluate cardiotoxicity in pts with cv risk factors and evaluate impact of therapeutic interventions.

Background:

SG was approved in 2020 for the treatment of metastatic triple negative breast cancer (TNBC). The most common grade 3/4 adverse event in the ASCENT trial was neutropenia (51.2%) with a 6% incidence of febrile neutropenia. 1 Package insert recommendations do not endorse primary prophylactic growth factor support, rather only initiating if severe neutropenia occurs on treatment.²

Objective:

This study retrospectively reviewed the utilization of growth factor support in patients (pts) with metastatic TNBC initiated on SG at each Mayo Clinic Enterprise site.

Methods:

We performed a multi-center, retrospective review of all pts with TNBC who received SG from January 2021 to December 2021 at Mayo Clinic sites in Minnesota, Florida, Arizona, and its community-based health system network. Data collected included history of neutropenia with previous cycles of SG resulting in a treatment delay, number of cycles, grade of neutropenia and cycle/day of treatment plan when growth factor added. Pts who received only one dose of SG were excluded. The Fisher's exact test was utilized to compare the difference in the use of primary prophylaxis between sites.

Results:

67 pts received at least two doses of SG. Within this cohort, 42 pts (63%) received growth factor support during treatment with SG. Growth factor support was most often added during the first two cycles (59.5%). A total of 12 patients initiated growth factor with no history of delays related to neutropenia and without neutropenia at the time of administration. Eleven of these pts had growth factor support added on Cycle 1 as primary prophylaxis. Primary prophylaxis was most common at Mayo Clinic – Rochester compared to the other sites (Table 1), however there was not a statistically significant difference ($p=0.27$). There were 26 pts (39%) with a treatment delay due to neutropenia while receiving SG, of which 21 (81%) were managed with the addition of growth factor (13 pegfilgrastim, 8 filgrastim). The median number of cycles for all pts was 5 (range: 1-25). Pts who received growth factor were treated with a median of 5 cycles (range: 1-25) and pts who did not receive growth factor were treated with a median of 4 cycles (range: 1-19) ($p=0.10$).

Conclusions:

We observed wide variability in the use of prophylactic growth factor between Mayo Clinic sites with SG. The optimal practice of growth factor use with SG warrants further exploration.

Background: Triple-negative breast cancer (TNBC) is an aggressive disease characterized by lack of targeted therapy; main-stay of treatment being limited to surgery and chemotherapy. Older patients with TNBC are often underrepresented in the clinical trials, due to competing mortality risks. This study aims to assess the treatment and outcomes of triple negative breast cancer (TNBC) in older women relative to younger women. Methods: This was a retrospective cohort study of patients who presented with primary TNBC, age 34-94 years; stage I-III from Jan 1, 2013 to Dec 31, 2015. Patients' demographics, clinical characteristics, treatment and outcomes were retrieved from the CANISC Register and individual patient (N=88). Breast cancer-specific survival (BCSS) was estimated by using Kaplan--Meier method, and adjusted for age, tumor size, tumor grade, nodal status and chemotherapy, using SPSS-19. Results: Fifty-one patients were less than 70 years old (57.9%) and 37 were 70 years and older (42.1%). There was no difference in the stage at presentation (stage I: 43% vs. 35%; stage 2: 49% vs. 49%; stage 3: 8% vs. 11%; P=.061). Older patients were less often treated with adjuvant chemotherapy (75% vs. 24%; P< 0.001). Mean follow-up was 48 months. Five-year BCSS was significantly poor for older patients (54% vs. 75%, P=.032). 5-year overall survival was also significantly worse for patients who did not receive adjuvant chemotherapy (50% vs. 88% P =0< 021). Conclusions: Overall survival in triple negative breast cancer is much worse in older women as compared to younger women and there is a significant benefit with adjuvant chemotherapy.

Introduction: Breast Cancer is one of the most prevalent malignant disease in women and its first line neo- and/or adjuvant treatment on hormone positive (HR+) subtypes is the endocrine therapy. Even though Adjuvant Endocrine Therapy (AET) had significantly increased overall survival in the long-run, some studies have reported suboptimal treatment adherence rates, varying from 40-95.7%. One possible cause for this great variability on AET adherence is the patients' expenses on treatment. Recent studies have demonstrated that as the cost of treatment increases the treatment adherence decreases. Nonetheless, as far as the authors have searched, no studies have tried to understand such relationship in Brazil, where medications can be taken without any out-of-pocket expenses through the Sistema Único de Saúde (SUS), or through Health insurance companies; and through direct out-of-pocket expenses. Methods: This was an observational cross-sectional pilot study, carried out with an online questionnaire applied to patients from the Centro de Tratamento Oncológico Pro Onco [Pro Onco Oncological Treatment Center] and Centro de Apoio ao Paciente com Câncer de Londrina [Londrina Cancer Support Center] (State of Paraná, Brazil). The questionnaire applied

in this study included objective questions that aimed to understand the systemic endocrine therapy adherence among Breast Cancer patients. In order to do that, the Morisky-Green (MG) test was used. A linear regression model was built using the MG test as dependent variable, and how the patients obtained the drugs as independent variable, controlled by other sociodemographic and clinical covariates. Results: Between December 2021 and March 2022, 95 patients were included in this study. Mean age was 50.71 (SD = 10.00) and mean age at diagnosis was 45.86 (SD = 8.66). Patients obtained the drugs mainly via Health Insurance (45 patients or 47.37%), followed by the SUS (44 patients or 46.32%) and private health expenses (6 patients or 6.32%). It was found that how the patient obtained the medication was statistically significant in predicting adherence. Patients that obtained the medication via the SUS had poorer adherence compared to those that obtained the medication via Health Insurance (coeff.=-0.38 [-0.68;-0.09]; p-value = 0.010) and via Private Health Expenses (coeff.=-0.81 [-1.42;-0.21]; p-value = 0.008). It was also found that considering all three main options available to obtain the medication, 30 patients (68.18%) that obtained the medication via the SUS had already forgotten to take the medication once; whereas only 18 patients (40%) that obtained the medication via Health Insurance had done (Chi-Square = 7.1116; p-value = 0.008). Besides that, it was found that only 22 patients (50%) that obtained the medication via the SUS knew the type of cancer they had. Considering only patients that obtained the medication via Health Insurance, 35 patients (77.78%) knew the type of cancer they had (Chi-Square = 7.4546; p-value = 0.006). Conclusion: The results of this study do not match the literature on the topic, and it could be explained by a poorer doctor-patient relationship at SUS as non-clarification on the importance of adjuvant treatment can be related to a poorer adherence.

Country: United States

Background: Contralateral axillary lymph node metastasis (CAM) in breast cancer (BC) is uncommon with an incidence of 1.9-6%. It is considered as stage IV disease based on the TNM classification in the 8th edition of the American Joint Committee on Cancer (AJCC) staging manual. However, in the absence of other distant metastases, patients with CAM have been found to have better outcomes compared to those with stage IV disease. Recent studies suggest that CAM may represent locoregional spread of tumor through lymphatics rather than hematogenous spread and patients should be classified as N3 rather than M1. There are no clear guidelines on the optimal management of these patients and it is unclear if patients with isolated CAM should be treated as curative intent or as metastatic disease with palliative treatment. The goal of this study was to describe the management and outcomes of patients with BC and isolated CAM seen at our institution.

Methods: We performed a retrospective chart review on all patients with BC and isolated CAM but no other distant metastases who were seen at our institution between 2000-2021. We collected information on demographics, tumor characteristics, intent of therapy (curative versus palliative), types of treatment (systemic treatments including chemotherapy (CT), hormone therapy, targeted therapy; radiation therapy; surgery), and response to frontline treatment.

Results: We identified a total of ten eligible patients who were diagnosed between 2011-2020. The median age of diagnosis was 57 years and 70% had de novo cancers while the remainder had recurrent disease. The table below describes each patient's cancer, treatment, and response. Patients are listed in chronological order, with those at the top diagnosed in 2011 and bottom in 2020. Four patients had hormone receptor (HR)-positive and HER2-negative BC, 3 patients had triple negative BC, 2 had HER2-positive BC and 1 had HR-positive and HER2-positive BC. Regarding treatment, 50% of patients were treated with curative intent, of whom 3 have no evidence of recurrence at a follow up of 23-137 months. Of the other two patients, one had response to systemic treatment but remains surgically unresectable and the other patient developed recurrent disease. In the 5 patients treated with palliative systemic therapy as Stage IV disease, 3 patients had clinical response to first line treatment with control of disease. One patient who passed away had triple negative disease. The last patient developed progression of disease and is on second line systemic treatment.

Conclusions: At our institution, among patients treated with palliative intent systemic therapy, most (60%) had a response to first line treatment. In the 5 patients treated with curative intent, 3 patients remain without evidence of recurrence of whom 2 have had 9 years of follow up. The current study illustrates the heterogeneity in management for patients with CAM. Our findings highlight the need for larger studies focusing on BC patients with CAM to optimize their treatment and outcomes. Limitations of our study include its retrospective nature and small sample size given rarity of CAM.

Table 1. Treatment and Outcomes of Patients with CAM

Table 1. Treatment and Outcomes of Patients with CAM

Disease Status	Receptor Status	Intent of Treatment	Initial Treatment	Follow Up (mos)	Outcome
De novo	HER2+	Curative	Neoadjuvant CT, surgery, RT	137	No evidence of recurrence
De novo	Triple negative	Curative	Neoadjuvant CT, surgery	132	No evidence of recurrence
Recurrent	ER+/PR+	Palliative	Hormone therapy, CDK 4/6i	49	Clinical response; remains on 1st line tx
Recurrent	Triple negative	Curative	Neoadjuvant CT, surgery, adjuvant CT	39	Recurrent disease 3 months after completing adjuvant tx
De novo	HER2+	Palliative	HER2-targeted therapy	33	Clinical response; remains on 1st line tx
Recurrent	Triple negative	Palliative	CT, immunotherapy	33	Progression of disease, death
De novo	ER+/PR+	Curative	Neoadjuvant CT, surgery, adjuvant RT, hormone therapy	23	No evidence of recurrence
De novo	ER+/PR+	Curative	Neoadjuvant CT followed by hormone therapy, CDK 4/6i	18	Clinical response but remains surgically unresectable
De novo	ER+/PR+	Palliative	Hormone therapy, CDK 4/6i	16	Clinical response; remains on 1st line tx
De novo	Triple positive	Palliative	CT, HER2-targeted antibodies	16	Progression of disease; on 2nd line tx

Background: Current management for triple negative breast cancer (TNBC) involves chemotherapy and immunotherapy systemic treatments. TNBC treatment remains a challenge, with up to 40% of those treated using standard methods for stage I to III TNBC experiencing recurrence. Currently, the optimal carboplatin regimen for TNBC is yet to be defined. In our previous study, we identified an optimal carboplatin containing chemotherapy regimen that improved patient outcomes. In this study, we expanded the cohort as an extension of the previous prospective study to further verify these promising results.

Patients and Methods: We performed a retrospective review of 37 TNBC patients who had < 10% estrogen and progesterone receptor positivity and were human epidermal growth factor receptor-2 (HER2) negative. This study was originally done in an adjuvant setting, but patients with locally advanced tumors received neoadjuvant chemotherapy. Patients received dose-dense Adriamycin, cyclophosphamide, and paclitaxel every two weeks for sixteen weeks. Adriamycin (60 mg/m²) and cyclophosphamide (600 mg/m²) were given intravenously every two weeks for four cycles, followed by paclitaxel (175 mg/m²) every two weeks for four cycles. Carboplatin with an area under the curve of 6 was added to cycles two and four of paclitaxel. Last, we changed the parameters of continuing chemotherapy to allow platelet counts > 70,000

x 10⁹. Only paclitaxel could be modified for neuropathy.

Results: Of 37 patients enrolled in this trial, 35 patients survived without recurrence, one required a dose reduction in paclitaxel, and one has incomplete staging as grade is still pending. The two patients that did experience recurrence died. Of these two patients, the first had American Joint Committee on Cancer (AJCC) 7 stage IIIC cancer, and the second had two separate TNBCs at presentation – AJCC-7 IIB cancer of the right breast and AJCC-7 IIA cancer of the left breast. Under the AJCC-8 system, the first patient had AJCC-8 IIIB cancer, while the second patient had AJCC-8 IIIB cancer of the right and left breasts. These data suggest a completion rate of 97%, overall survival (OS) rates of 95% (AJCC-7 & 8), and progression free survival (PFS) rates of 95% and 94% (AJCC-7 & 8, respectively; Table 1). Additional stage-specific survival metrics and patient staging information are available in Table 1. Median follow-up in this study was 3.14 years. This is consistent with data from our previous study with significant PFS benefit over historic chemotherapy. All patients completed this regimen with no dose reductions of carboplatin and a 32% dose reduction in paclitaxel due to neuropathy. Toxicity was established in our previous study. The favourable toxicity profiling of the regimen allowed maximal tolerance for patients.

Conclusion: Although administration of carboplatin with chemotherapy for TNBC is known to be beneficial, the ideal carboplatin containing regimen has not been identified because of concerns regarding toxicity and low completion rates. Here, an optimal carboplatin-containing regimen identified in our previous clinical trial led to 95% overall survival rates (AJCC-7 & 8), 95% and 94% progression free survival rates (AJCC-7 & 8, respectively), and a 97% completion rate for 37 TNBC patients. A limitation is that this is a small single center trial, and plans are underway to test this regimen with immunotherapy in a larger randomized control trial.

Table 1: Patient Staging and Survival Metrics.

Metric of Interest		AJCC-7	AJCC-8
Patients per Stage	Stage 1	2	5
	Stage 2	27	21
	Stage 3	8	10
	Stage 4	0	0
Survival	Overall PFS	95%	94%
	Overall Survival	95%	95%
	Stage 2 PFS	96%	100%
	Stage 2 OS	96%	100%
	Stage 3 PFS	88%	80%
	Stage 3 OS	88%	80%

Introduction: Axillary web syndrome (AWS) is a common complication in the immediate postoperative period in women after breast cancer surgery. The symptoms are defined as the presence of cords, pain, and limited shoulder range of motion (ROM). Pathophysiology has been described as lymphatic thrombosis, which could be a risk factor for the development of lymphedema. Considered by some to be self-limiting, it has been described as a chronic complication, persisting for years after initial onset. Objective: To determine the prevalence of AWS in a longitudinal cohort of women in a late follow-up after breast cancer surgery and to assess shoulder ROM, presence of pain, permanence of cords and correlation with lymphedema. Methods: A longitudinal cohort study was carried out at the Division of Breast Cancer Disease of the Universidade Federal de São Paulo. Twenty-five women were followed up and reassessed regarding the permanence of cords, pain, ROM, and presence of lymphedema. Results: Of the 25 patients analyzed, 64% (16 patients) showed prevalence of AWS. On recall, all cords were palpable and 87.5% were in the axilla. There was no correlation between AWS and lymphedema. Conclusions: AWS is an important complication in the immediate postoperative period, that persists for several years, without restrictions on function, pain or shoulder ROM limitations. We must therefore consider it as a complication that becomes chronic but has no impact on quality of life. The correlation with lymphedema was not significant in our study. Key words: breast neoplasms, axillary web syndrome, physical exercise, articular range of motion, pain, lymphedema.

Background: Neoadjuvant chemotherapy is the standard of care for early stage breast cancer. Human epidermal growth factor receptor 2 (HER2) positive disease constitutes a large proportion of breast cancer patients, and HER2 overexpression is associated with poor prognosis. The induction of HER2+ targeted therapies, such as trastuzumab and pertuzumab, has resulted in improved outcomes in HER2+ breast cancers. Neoadjuvant chemotherapy in combination with HER2 targeted therapies aims at achieving pathological complete response (pCR) and an improved survival.

Methods: We performed a retrospective review of HER2+ breast cancer patients who were treated at Medanta – The Medicity Hospital, Gurugram, Haryana, India, between 2011 and 2021. A total of 108 HER2+ breast cancer patients who received neoadjuvant chemotherapy with platinum, anthracycline or taxane-based regimens, along with trastuzumab alone or in combination with pertuzumab, were included.

Results: Of 108 enrolled patients, 66 and 42 patients received single-blockade (trastuzumab) and dual-blockade (trastuzumab and pertuzumab) neoadjuvant anti-HER2 therapy, respectively. The majority of patients were aged < 60 years. The patient populations were comparable in terms of clinical stage, hormone receptor status, histopathology category (IDC being most common) and Ki67 status for single- and dual-blockade groups. All patients had IHC3+/FISH+ HER2 expression. No significant (p=0.896) difference was observed for breast conserving surgery between the groups. A higher pCR rate after surgery was reported in the dual-blockade group versus single-blockade group (50% vs. 39.2%; p=0.271). The median follow-up duration was 21.9 and 15.2 months in the single-blockade and dual-blockade groups, respectively. For dual- vs. single- blockade groups, the 1-year OS rates were 100% vs. 100%, and 3-year OS rates were 100% vs. 98.48%. For dual- vs. single- blockade groups, the 1-year DFS rates were 100% vs. 95.45%, and 3-year DFS rates were 92.85% vs. 80.3%.

Conclusion: Neoadjuvant chemotherapy with dual HER2-blockade had higher pCR and survival rates compared with the single HER2-blockade strategy in HER2 positive breast cancer.

Table. Patient characteristics

Parameter	All patients (N=108)	Chemotherapy + trastuzumab (n=66)	Chemotherapy + trastuzumab + pertuzumab (n=42)	P-value
Age (n, %)				
<60 years	80 (74.1)	54 (81.8)	26 (61.9)	0.0213
≥60 years	28 (25.9)	12 (18.2)	16 (38.1)	
Cancer stage, n (%)				
II	47 (43.52)	28 (42.42)	19 (45.23)	0.7737
III	61 (56.48)	38 (57.57)	23 (54.76)	
Hormone receptor status (n, %)				
HR positive	57 (52.78)	37 (56.06)	20 (47.61)	0.3916
HR negative	51 (47.22)	29 (43.94)	22 (52.39)	
Pathology (n, %)				
IDC	104 (96.3)	63 (95.5)	41 (97.6)	0.456
ILC	2 (1.9)	2 (3.0)	0

Local delivery of immunotherapeutics as an in situ vaccine in triple negative breast cancer

Presenting Author(s) and Co-Author(s):

Siena Mantoath, n/a, *Graduate Student - NC State University*
Country: United States

David Zaharoff, PhD, *Associate Professor - NC State University*
Country: United States

Introduction. Breast cancer (BC) is among the most common types of cancer among women, with an estimated 287,850 new cases and 43,250 deaths in 2022 [1]. Triple negative breast cancer (TNBC), characterized by lack of ER/PR/HER2 receptors, constitutes 10-15% of diagnosed BC and correlates with the worst prognosis and most aggressive form of the disease [2]. Additionally, compared to the other BC subtypes, TNBC have higher rates of recurrence and highest therapy resistance [2]. Because TNBC lacks a clearly defined target, in situ vaccination may pose a viable therapy option, to locally stimulate an immune response and thereby reduce the tumor burden and prevent recurrence and metastasis. To this end, we developed an injectable delivery medium to effectively localize immune agonists at the site of the tumor. **Materials and methods.** Hydrogel delivery medium: Low-viscosity, high-deacetylated chitosan was crosslinked with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride and N-hydroxysuccinimide at room temperature overnight. The mixture was dialyzed and freeze-dried. A hydrogel was formed by dissolving the chitosan in deionized water at concentrations from 25-50 mg/mL. **In vivo tumor treatment:** 1e5 E0771 breast cancer cells were implanted subcutaneously in the right flank of C57BL/6 mice. When tumors were 50-100mm³, mice were treated intratumorally with 50ug Poly(I:C) + 50ug CpG in 30 mg/mL chitosan gel, with 50ug Poly(I:C) + 50ug CpG in saline, or with gel alone. In the second experiment, to enhance the anti-tumor effect of the immunotherapeutic, 2ug of the cytokine interleukin-12 in the chitosan gel will be delivered intratumorally. All experiments involving laboratory animals were approved by the Institutional Animal Care and Use Committee at North Carolina State University. **Results and Discussion.** The gel was effectively localized within the tumor environment upon injection. The localized Poly(I:C) + CpG in the gel demonstrated an enhanced anti-tumor effect, compared to gel alone. Ongoing work will determine the efficacy of administering the cytokine IL-12. **Acknowledgements.** This work is supported by an NSF Graduate Research Fellowship. **References.** [1] Siegel R, et al. *CA A Cancer J Clin* (2022) 72(1):7-33. Background: Breast cancer is the most common type of neoplasm in women. According to statistics from Globocan 2020, the incidence of breast cancer in Ecuador, as well as worldwide is 47.8 per 100,000 people/year, with a mortality rate of 13.6 per 100,000 people/year. Our health system provides coverage to approximately 60% of the population by the Ministry of Public Health (MSP), 30% by The Ecuadorian social security Institute (IESS) , 5% by other entities (ISSFA, ISSPOL, MUNICIPIOS), and < 3% of the population have private medical coverage. Medical care attentions for breast cancer, covered by the MSP was 7,134 consults in 2013, with an increase to 8,767 in 2018. SOLCA Guayaquil, as a national reference Center, provides 24.425 oncologic consults per year, with 38% corresponding to breast cancer. The presentation of breast cancer, at diagnosis, corresponds approximately to 63% in localized stage, 29% as locally advanced, 6% as metastatic disease, with a 5-year overall survival of 99%, 85% and 29% respectively. The proportion of clinical stage IV breast cancer diagnoses varies from 5-10%, with an average of 6% in urban areas, reaching up to 50% in rural areas, so metastatic breast cancer is a public health challenge, especially for countries with emerging economies like ours. Methods: An observational, retrospective, descriptive, single-center study was carried out. All patients with metastatic breast cancer who had been treated at the National Oncology Institute SOLCA Guayaquil, in the period from 2016 to 2020 were included in the analysis. The clinical and pathological characteristics were recorded and their impact on overall survival was calculated by the Kaplan-Meier method and compared by the long-rank test, multivariable adjusted hazard ratios (HR) were estimated by Cox regression models. Results: 3700 patients were identified between January 2016-December 2020. A total of 2587 patients were excluded. Of a total of 1113 remaining patients, 84 debuted as metastatic disease. No male patients were reported with metastatic breast cancer in the past 5 years. Median age at diagnosis was 53,31 years (28-88 years). The most frequent metastatic sites, were: bone 63.86% (N:53), lungs 50.6% (N:42), liver 30,12% (N:25), soft tissue 22.89% (N:19), CNS 16.87% (N:14); A multivariable analysis was performed, all metastatic sites have a higher risk of mortality vs not having any metastasis, but the only significant one is CNS metastases RR 1.31 (1.08-1.61), $p < 0.005$. A total of 28 patients (33.73%) had 2 metastatic sites at presentation; 21 patients (25.30%) had 3 or more metastatic sites at presentation with a RR 1,22 (0.95-1,57) $p:0,011$, with overall survival -OS- (36 months vs 15 months) (long Rank 0,001). ECOG 1 was reported in 59 patients (71.08%), ECOG 2 in 18 (21.69%) and ECOG 3 in 5 (6,02%). A multivariable analysis was performed with ECOG 2-3, RR 1.03 (0,43-2-44), $p:0,94$. Principal reported comorbidities where: hypertension in 28 patients (33,73%), dyslipidemia in 16 (19,28%), obesity 14 (16,87%), Diabetes 8 (9,64%). By grouping 2 or more comorbidities, the RR 1,04 (0,83-1.30), $p:0,71$. Surgery was classified as done or not, where 33 patients (39,77%) underwent rescue mastectomy. Multivariable analysis shows Not Surgery with a RR 1,88 (1.07-3,3) $p:0.02$. Median OS was estimated for surgery 44,48 months $\pm 4,7SD$; Not surgery 20,72 months $\pm 2,8 SD$. Conclusions: In our population, metastatic breast cancer occurs in 7.6% (84 patients out of 1113 total), similar to that reported worldwide. Being a neoplasm with multiple immunophenotypes, and therefore, different treatment options, OS depends on multiple clinicopathological variables. This study showed that CNS metastases

have a negative impact on OS, it is an independent variable for RR of mortality. ECOG and comorbidities did not show an impact on OS. Ultimately, mastectomy was offered to patients with good clinical response to systemic chemotherapy, and shows positive impact in OS.

Background: For HR+/HER2- metastatic breast cancer (MBC) patients, after resistance to endocrine therapy (ET), treatment options are mostly limited to traditional chemotherapies (CT) that offer poor survival and quality of life (QoL), creating an area of unmet need. The antibody-drug conjugate sacituzumab govitecan (SG) comprises an anti-Trop-2 antibody coupled to SN-38 via a hydrolyzable linker. In the phase 3 TROPiCS-02 trial, heavily pretreated patients with relapsed/refractory HR+/HER2- MBC received SG vs single-agent chemotherapy treatment of physician's choice (TPC). The study met its primary endpoint of improved progression-free survival with SG vs TPC. Here, we report the effect of SG vs TPC on patient-reported outcomes (PROs) from TROPiCS-02.

Patients and Methods: Patients who had received ≥ 1 CDK 4/6 inhibitor, ≥ 1 ET, and 2-4 prior lines of CT were randomized to receive SG (10 mg/kg intravenous on days 1 and 8 of a 21-day treatment cycle) or TPC (capecitabine, eribulin, gemcitabine, or vinorelbine). In the PRO-evaluable population (all randomized patients with an evaluable assessment at baseline (BL) and ≥ 1 post-BL visit) SG and TPC were compared regarding time to first clinically meaningful worsening (TTD) or death from BL on the EORTC QLQ-C30 domains (≥ 10 points), EQ-5D-5L health utility index (≥ 0.08 points), and EQ-VAS (≥ 7 points). For the EORTC QLQ-C30 function and global health status/QoL domains, patients with a BL score ≥ 10 and for symptom scales, patients with a BL score ≤ 90 were included. In the safety population (all randomized patients who received ≥ 1 dose of study drug), SG and TPC were compared regarding worst level of toxicities during treatment for the PRO-CTCAE items. For TTD, a stratified Cox proportional hazards regression analysis was conducted and the PRO-CTCAE items were summarized descriptively (numbers and percentages).

Results: Of 543 randomized patients, 446 (82%), 445 (82%), and 517 (95%) were included in the PRO-evaluable population (EORTC QLQ-C30: SG vs TPC n=236 vs 210 and EQ-5D-5L: n=238 vs 207) and in the safety population for PRO-CTCAE (SG vs TPC n=268 vs 249), respectively. TTD of EORTC QLQ-C30 global health status/QoL, physical functioning, emotional functioning, fatigue, dyspnea, insomnia, and financial difficulties and EQ-VAS were significantly longer in the SG vs the TPC arm (Table). TTD of EORTC QLQ-C30 diarrhea was significantly shorter for SG vs TPC. For PRO-CTCAE items, decreased appetite, nausea, vomiting, constipation, abdominal pain, shortness of breath, and fatigue were similar between SG and TPC arms, whereas frequency of diarrhea and amount of hair loss were higher in the SG vs TPC arm.

Conclusions: In this trial, SG significantly delayed worsening of overall QoL, physical and emotional functioning, and symptoms like fatigue, dyspnea, and insomnia. Overall, our findings suggest that SG has more favorable effects on PROs compared with TPC in pts with HR+/HER2- MBC.

Table: Time to First Clinically Meaningful Deterioration of PRO Scores

Domain	Median time to first clinically meaningful deterioration (TTD) (months)		Hazard ratio	95% confidence interval
	SG	TPC		
EORTC QLQ-C30 (N=446)				
Global health status/QoL	4.0	2.9	0.736	0.593-0.913**

Background: Triple-negative breast cancer (TNBC) is an aggressive subtype of breast cancer. Among TNBC subtypes, the luminal androgen receptor (LAR) subtype expresses high levels of androgen receptor (AR), tends to be less proliferative, and generally responds poorly to neoadjuvant therapy. Previous studies have shown that AR inhibition suppressed proliferation of AR+ or LAR subtype TNBC cells and tumor growth in xenograft models. Thus, AR is a

promising therapeutic target for this TNBC subtype. Here, we identified kinase targets for enhancing the antitumor efficacy of the AR inhibitor enzalutamide in preclinical models and investigated the underlying molecular mechanisms. Methods: We performed a nonbiased high-throughput kinome siRNA screening (targeting 709 genes) to identify a synergistic partner for enhancing the antitumor efficacy of the AR inhibitor enzalutamide in AR+ LAR TNBC. The growth inhibitory effects of enzalutamide alone or combined with kinase inhibitors were determined using the sulforhodamine B staining assay and clonogenic assay. The effect of treatments on the expression of target proteins of interest was examined by Western blot analysis. Results: Enzalutamide was not effective as a single agent to inhibit the proliferation of AR+ TNBC cells (IC50 >15 μ M in MDA-MB-453, CAL-51, CAL-148, MFM223, HCC2185, SUM149, SUM159, and SUM185 cells). Nonbiased high-throughput kinome siRNA screening identified PI3K/AKT/mTOR, cell cycle, and JNK pathways as potential canonical targets for combination with enzalutamide to enhance its antitumor efficacy in AR+ LAR TNBC. Among these pathways, inhibition of cell cycle progression using the CDK7 inhibitor UD-017 showed the most synergistic anti-proliferation effect with enzalutamide in AR+ LAR MDA-MB-453 (50.61% reduction in proliferation compared with enzalutamide alone, $P < 0.001$; and 48.98% reduction in proliferation compared with UD-017 alone, $P < 0.001$) and SUM185 (40.41% reduction in proliferation compared with enzalutamide alone, $P < 0.05$; and 42.76% reduction in proliferation compared with UD-017 alone, $P < 0.05$) TNBC cells. Furthermore, CDK7 knockdown using siRNA significantly enhanced the sensitivity of MDA-MB-453 (60.98%, $P < 0.01$) and SUM185 (30.99%, $P < 0.01$) cells to enzalutamide, and AR knockdown significantly enhanced the sensitivity of MDA-MB-453 (32.64%, $P < 0.01$) and SUM185 (43.62%, $P < 0.01$) cells to UD-017, in both cases with a sensitivity similar to that of enzalutamide plus UD-017. This result suggests that the synergy of enzalutamide and UD-017 results from specific targeting of AR and CDK7. Downstream target analysis revealed that the combination of enzalutamide and UD-017 dramatically reduced the expression of c-MYC. c-MYC knockdown using siRNA dramatically suppressed colony formation in both MDA-MB-453 and SUM185 cells at a degree similar to that of enzalutamide plus UD-017, whereas c-MYC overexpression reversed the synergistic effect of the combination treatment. This result suggests that UD-017 synergizes with enzalutamide through inhibition of c-MYC-mediated tumorigenesis. Conclusion: Our results suggest that enzalutamide synergizes with UD-017 by inhibiting c-MYC-mediated oncogenic activity. These in vitro data warrant future in vivo studies of the antitumor synergy of enzalutamide plus UD-017 in AR+ LAR TNBC models.

Background Phosphoinositide 3-kinase alpha (PI3K α) H1047R mutations are activating oncogenic events that occur in ~15% of breast cancers (BC). Early generation PI3K α inhibitors target both wild-type (WT) and mutant PI3K α and, as a result, their efficacy may be limited by on-target WT PI3K α -mediated toxicities, including hyperglycemia, skin rash, and diarrhea. LOXO-783 is an oral, potent and highly mutant-selective, brain-penetrant allosteric PI3K α H1047R inhibitor that is currently in phase 1 testing. Preclinically, LOXO-783 as a single agent is highly selective for PI3K α H1047R over WT PI3K α and other PI3K isoforms, and induces single-agent tumor regressions in ER+, HER2- PI3K α H1047R-mutant breast cancer models without causing hyperglycemia or increases in plasma insulin / C-peptide. LOXO-783 also demonstrates brain penetration in vivo with dose-dependent tumor growth inhibition in brain metastasis models. Here we report the efficacy of LOXO-783 with SOC treatments in preclinical breast cancer models. Methods Cell proliferation assays and in vivo studies to evaluate combination effects were performed in various PI3K α H1047R mutant HR+, HER2- and triple negative breast cancer models. For each combination in vitro, a combination index (CI) based on the Loewe Additivity Method was calculated ($CI > 2$ antagonism, $0.5 < CI < 2$ additivity, $CI < 0.5$ synergy). For the in vivo studies, the Bliss Independence Method was used to evaluate the statistical significance of the combination effects. Results Combining LOXO-783 with either fulvestrant (FUL; CI at 50% inhibition = 0.28) or imlunestrant (CI at 50% inhibition = 0.43) showed increased efficacy in cell proliferation assays using the HR+, HER2-, PI3K α H1047R-mutant T47D model. LOXO-783 also demonstrated an additive effect in combination with these endocrine therapies in vivo. Similar results were observed in a T47D model engineered to express ESR1 D538G, as well as in an HR+, HER2- PI3K α double in-cis mutant model (H1047R/D350G) also harboring ESR1 D538G and derived from a patient who had progressed on prior letrozole plus taselisib. Moreover, LOXO-783 plus abemaciclib demonstrated an additive effect in vitro (CI at 50% inhibition = 0.61), and in T47D xenograft and PDX models in vivo. Combinations of LOXO-783 with abemaciclib plus imlunestrant resulted in a mean tumor regression of -48.1%; LOXO-783 with abemaciclib plus FUL showed mean tumor regression of -43.9% in T47D xenografts. Similar efficacy was not observed in the absence of LOXO-783 (mean tumor regression was -7.3% with abemaciclib plus imlunestrant, and 3.2% with abemaciclib plus FUL). We observed comparable results in PDX models. These data collectively demonstrate the additive effect of LOXO-783 with SOC treatments. Extending these studies to additional treatment settings, LOXO-783 was similarly efficacious as a single agent in abemaciclib-resistant and abemaciclib/FUL double-resistant models, and was additive in combination with paclitaxel in a triple negative breast cancer model in vitro and in vivo. Conclusions LOXO-783 shows additive effects when combined with SOC in breast cancers harboring the PI3K α H1047R-mutation (as single or double in-cis mutations) in both HR+ and triple negative settings. LOXO-783 is also efficacious in ESR1 mutant as well as in abemaciclib and abemaciclib/FUL double-resistant models. A phase 1 trial of LOXO-783 alone or in combination with anticancer therapies is ongoing (PIKASSO-01; NCT05307705).

Operation of eIF4A1-PD-L1 axis in therapy-naïve and drug-resistant TNBC

Operation of eIF4A1-PD-L1 axis in therapy-naïve and drug-resistant TNBC Background and Premise: Triple-negative breast cancer (TNBC) is an aggressive, metastatic disease with high mortality. The standard-of-care neoadjuvant chemotherapy (NACT) in TNBC shows an initial response but followed by an increase in tumor relapse and distant metastases. Furthermore, metastatic TNBC (mTNBC) patients often develop resistance to NACT and targeted therapies. Immunotherapy with therapeutic antibodies such as anti-programmed death ligand-1 (PD-L1) has shown efficacy in treating a subset of TNBC patients, but currently only 20% of patients qualify for that treatment. Hence, there is an unmet need for developing a precision approach against novel actionable targets along with immunotherapy to treat mTNBC. Eukaryotic initiation factor 4A1 (eIF4A1) is an integral part of the translational machinery for many oncogenic mRNAs including survivin, c-MYC, Rho kinase1, and Cyclins D1 and D3, which all require the helicase activity of eIF4A1 for their translation. Our lab previously established that the eIF4A1 is a vulnerable target in breast cancer stem-like cells (BCSCs) and bulk tumor cells. We further demonstrated a key role for eIF4A1 in cancer stemness and drug resistance. Interestingly, we also observed a reduction in levels of PD-L1 when eIF4A1 is pharmacologically inhibited or genetically ablated. Many downstream effectors of eIF4A1 such as c-MYC, STAT1 and ARF6 (involved in recycling of PD-L1 back to the plasma membrane) are indeed upstream regulators of PD-L1 gene expression and cell surface expression of PD-L1. In this study, we examine human TNBC biospecimens for total eIF4A1 level, levels of STAT1, c-MYC, ARF6 and PD-L1. This will help establish the differential operation of the eIF4A1-PD-L1 axis in therapy-naïve and drug-resistant primary and mTNBC. Approach: Human biospecimens were obtained from CHTN NIH repositories and now we have a collection of more than 100 TNBC tumor samples as well as some lymph node, lung and brain metastases and one sample of male breast primary tumor. These specimens are analyzed for role of eIF4A1 in translation of oncogenic mRNAs that contribute to the gene expression of immune checkpoint PD-L1 and other emerging immune checkpoint markers such as VISTA, TIGIT, and LAG3. To mimic the inclusion criteria for current PD-L1 monoclonal antibody treatment, TNBC tumors are examined for PD-L1 expression via immunohistochemistry after subjecting the samples to deglycosylation for effective detection and also by immunoblotting. Results: The levels of total eIF4A1 from 16 matched, therapy naive TNBC tissue were compared to adjacent normal breast tissue from the same patient via immunoblotting. Total eIF4A1 levels were found

to be significantly elevated in TNBC compared to adjacent normal tissue. The downstream effectors of eIF4A1 such as STAT1 and ARF6 were also significantly elevated indicating a robust helicase activity of eIF4A1 in tumor samples. Importantly, PD-L1 levels was found to be elevated. Additionally, the total eIF4A1 level from tumor lysates from TNBC patients that had received a variety of NACT (i.e., patients with demonstrated drug resistance) were compared against normal untreated breast tissue from volunteers who underwent reduction mammoplasty by immunoblotting. The total eIF4A1 was found to be elevated in drug-resistant TNBC specimens compared to control, therapy-naïve TNBC samples. Conclusion: The eIF4A1-STAT1-PD-L1 axis is highly active in TNBC especially in drug-resistant situations. Currently, we are evaluating emerging immune checkpoints such as VISTA, TIGIT, and LAG3.

Background: Metaplastic breast cancer (MpBC) is a rare, lethal, and highly chemoresistant breast cancer subtype, with no FDA-approved therapeutic options. Most MpBCs are triple-negative, yet have a worse prognosis than non-metaplastic triple-negative breast cancer (non-MpTNBC). MpBC tumors are enriched for markers of epithelial-to-mesenchymal transition (EMT)/cancer stem cells (CSC), produce high nitric oxide (NO) levels, and have a hyperactive phosphoinositide 3-kinase (PI3K) signaling pathway. Increased PI3K and inducible nitric oxide synthase (iNOS) activity are poor prognostic indicators in MpBC. NO can activate multiple oncogenic pathways spatially and temporally, such as PI3K and transforming growth factor beta (TGF β), a critical regulator of EMT. Therefore, our study evaluates whether pan-NOS inhibitor NG-monomethyl-L-arginine (L-NMMA) augments the efficacy of alpha isoform-specific PI3K inhibitor alpelisib in MpBC in vitro and in vivo models. Methods: MpBC cell lines (SUM159, BT549, Hs578T, HCC1806) and Patient-Derived Xenograft (PDX) models were used in our studies. Droplet digital polymerase chain reaction (ddPCR) was conducted to evaluate the iNOS-associated mutation (RPL39 A14V) and PIK3CA hotspot mutation rates in PDX models. Cell viability (SRB/Cell Titer-Glo), combination index (CI), immunoblotting, and immunofluorescence of treated MpBC cell lines and tumor tissues were evaluated. Results: Immunostaining analysis revealed that MpBC PDX tumors had elevated co-expression of iNOS and pAkt (60% vs 23%, $p=0.0495$) relative to non-MpTNBC PDX tumors. MpBC PDX tumors had higher RPL39 A14V (66% vs 4.7%, $p<0.0006$) and PIK3CA hotspot mutation rates (50% vs 19.1%, $p=0.1247$) than non-MpTNBC PDX tumors. Combining L-NMMA with alpelisib was synergistic in MpBC cell lines harboring PIK3CA/PIK3R1 mutations ($CI<1$) and antagonistic in PIK3CA-wild type and PTEN-deleted models ($CI>1$). In vivo evaluation using MpBC PDX tumors found that L-NMMA significantly augmented the efficacy of alpelisib in reducing tumor volume in PIK3CA-mutated MpBC PDX models. Transcriptomic analysis found gene sets associated with EMT reversal, such as the formation of cornified envelope ($P_{adj}=0.0254$) and keratinization pathway ($P_{adj}=0.048$) were enriched pathways in MpBC PDX tumors that responded to combination therapy. Pharmacological and genomic inhibition of iNOS reversed EMT in MpBC cells, as shown by decreased expression of Zeb1, TGF β , Snail, Vimentin, and increased expression of E-cadherin and ZO-1 in immunoblotting analysis. MpBC cells with NOS2 knockout acquired an epithelial-like cellular morphology and this reversal of EMT rendered MpBC cells more sensitive to alpelisib and taxane-chemotherapy. MpBC PDX tumors that responded to combination therapy also exhibited a reversal in EMT, with an associated decrease in aldehyde dehydrogenase (ALDH1), a CSC marker. L-NMMA and alpelisib therapy also resulted in the loss of tumor-initiating ability, enhanced chemosensitivity, and improved overall survival in MpBC PDX models. These studies paralleled results from a phase 1b/2 clinical trial with L-NMMA combined with taxane chemotherapy in a cohort of anthracycline-refractory MpBC patients ($n=15$, NCT02834403). The clinical benefit rate was 40% (6/15), the overall response rate was 20% (3/15), and one patient achieved a pathologic complete response. Relative to baseline tumors, the responder end-of-treatment tumors had undergone reversal of EMT, with enhanced expression of E-cadherin, and decreased expression of iNOS, Zeb1, and ALDH1. Conclusion: Our findings suggest that combining L-NMMA and alpelisib is a novel therapeutic strategy to treat MpBC by reversing EMT and decreasing CSCs, rendering MpBC tumors more chemosensitive. This combination therapy is being tested in a first multicenter phase 2 study targeting this orphan disease.

Background: Disruption of circadian processes has been linked to cancer initiation, progression, metastasis, resistance, and mortality. Clock proteins are an emerging target for therapy in breast cancer. Circadian rhythms are controlled by a network of transcription/translation feedback loops primarily driven by BMAL and CLOCK and the transcriptional repressors period (PER1-3) and cryptochrome (CRY1-2). We investigated the molecular and clinical associations of clock genes in breast cancer. Methods: A total of 9563 breast tumors underwent molecular profiling (Caris Life Sciences). Analyses included next-generation sequencing of DNA (592 genes-NextSeq, WES-NovaSeq) and RNA (NovaSeq). Clock gene Score (CS) was determined using expression of clock pathway gene Z scores (positives of BMAL, CLOCK and negatives of PER1/2 and CRY1/2) and then stratified into quartiles. xCell was used to quantify immune cell infiltration in the tumor microenvironment (TME). ER/PR was tested by IHC and HER2 was tested by either IHC or CISH. Significance was determined as P values adjusted for multiple comparison (Q) of < 0.05. Real-world survival information was obtained from insurance claims data and was calculated from either tissue collection to last contact or time on treatment (TOT); comparison was done by Kaplan-Meier test. Results: TNBC had the highest median CS score, while HR+/HER2- had the lowest CS (0.96 vs 0.26 $q < .001$). In TNBC, PDL1 was significantly associated with higher CS (56% Q4 vs 28% Q1, $q < .05$). TP53 mutation was associated with higher CS (88% Q4 vs 75% Q1), while CDH1 and STK11 mutations were associated with lower CS (3.4% Q4 vs 8.7% Q1 and 0.1% Q4 vs 2.2% Q1). For the TME (xCell) in TNBC, CD8+ T cells, B cells, monocytes and NK cells were positively associated with CS, whereas CD4+ central and effector memory T cells, eosinophils, and endothelial cells were associated with lower CS (Q1 vs Q4 all $q < .05$). In HR+/HER2- tumors, PDL1 was also associated with higher CS (24% Q4 vs 14% Q1, $q < .05$). TP53 mutations (39% Q4 vs 23% Q1), HMGA2 (2% Q4 vs 0.4% Q1) and LGR5 amplifications (3% Q4 vs 0.4% Q1), and LOH (WES) (35% Q4 vs 21% Q1) were associated with higher CS. CDH1 (12% Q4 vs 23% Q1), KMT2C (6% Q4 vs 10% Q1) and PIK3CA mutations (37% Q4 vs 45% Q1) were associated with lower CS (all $q < .05$). In HR+/HER2- tumors there was a decrease in CD4+ central memory cells, common myeloid progenitor cells, endothelial cells, and eosinophils in high CS tumors. Activated myeloid dendritic cells, B cells, CD4+ memory T cells, CD8+ naïve T cells, M1 macrophages, and Tregs all had higher abundance in high CS tumors. In HR+/HER2+ tumors, PDL1 trended positively with CS but did not reach significance likely due to sample size. For all tumors, PDL1 expression positively correlated with CS (17% Q1 vs 37% Q4) while ER (75% Q1 vs 55% Q4) and PR (49% Q1 vs 38% Q4, all $q < .05$) were negatively associated; no association was seen with HER2. Expression of TIMELESS (HR:0.7, CI: 0.65-0.77) and CLOCK (HR: 0.8, CI: 0.72-0.86) below median were associated with longer OS, while expression of CRY2 (HR: 1.4, CI: 1.3-1.6); PER2/3 (HR: 1.1, CI:1.0-1.2; HR:1.3, CI:1.2-1.4) above median was associated with longer OS. In TNBC, TOT IO therapy was prolonged with higher expression of CLOCK (HR: 0.5, CI: 0.41-0.72), TIMELESS (HR: 0.7 CI: 0.53-0.91), ARNTL (HR: 0.7 CI:0.54-0.92) and CRY1/2 (HR: 0.6, CI: 0.46-0.80; HR: 0.75 CI: 0.57-0.98). Conclusions: Dysregulation of clock

genes is strongly associated with breast cancer subtype and survival. Higher CS is associated with TNBC and PDL1 expression and supports the use of checkpoint inhibitors. Prognosis is better with low expression of TIMELESS and CLOCK and high expression of CRY2 and PER2/3, suggesting a role in tumor development and maintenance. HR+/HER2- tumors have lowest CS, fitting with less aggressive phenotype and better prognosis. Clock genes are novel predictive and prognostic molecular markers and emerging targets for the development of new treatments in breast cancer.

Inhibition of the NUDT5 Phosphatase Suppresses the Growth of Triple-negative Breast Cancers Jing Qian¹, Yanxia Ma¹, Abhijit Mazumdar¹, Cassandra Moyer¹, Brent D. G. Page³, William Tahaney², Jamal Hill¹, Darian Coleman¹, Powel. H. Brown¹, 2 1 Department of Clinical Cancer Prevention, UT MD Anderson Cancer Center, Houston, TX 2 Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX 3 Faculty of Pharmaceutical Sciences, University of British Columbia, Canada, Vancouver BC Background: 281,550 new cases of invasive breast cancer will be diagnosed in US this year. 15% of these patients will be diagnosed with triple-negative breast cancers (TNBCs), which is the most aggressive subtype of breast cancer. Non-specific chemotherapy remains the current standard of care for TNBCs, due to the lack of targeted therapy. We have previously conducted a whole phosphatase RNA microarray analysis of TNBCs compared to estrogen receptor (ER)-positive breast cancers. These studies identified phosphatases that were either over-expressed or under-expressed in TNBCs as compared to ER-positive breast cancers. In this study, we investigated one of the highly expressed phosphatases NUDT5, which hydrolyzes 8-oxo-dGDP and ADP-ribose, as a potential new target for the treatment of TNBCs. Hypothesis: NUDT5 is a critical phosphatase that is necessary for the growth of triple-negative breast cancers. Methods: We obtained NUDT5 mRNA expression levels from publicly-available TCGA, METABRIC, and the CCLE datasets, and compared NUDT5 mRNA level in TNBCs versus ER-positive breast cancers. To demonstrate the effect of NUDT5 inhibition on cell growth, we used siRNA, shRNA, sgRNA, and the small molecule inhibitor TH5427 on various ER-positive cell lines and TNBC cell lines. Cell number was counted on Day 1, 3, 5 and 7. We then investigated the biological mechanisms of growth inhibition by Annexin V-PI, DRAQ7, and BrdU proliferation assays. We studied the effect of NUDT5 loss on oxidative stress and DNA damage pathways by measuring 8-oxoG level and γ H2AX positivity in the nucleus. Using nude mouse xenograft models, we also investigated the effect of TH5427 on TNBC growth in vivo. Results: NUDT5 mRNA was highly overexpressed in TNBCs as compared to ER-positive breast cancers in several publically-available datasets. NUDT5 loss significantly inhibited the growth of the TNBC cell lines MDAMB231 and MDAMB436, but not the ER-positive cell lines MCF7 and MDAMB361. NUDT5 inhibition via siRNA or TH5427 did not induce apoptosis or cell death, but did suppress growth as assessed by BrdU incorporation.. In the nucleus, loss of NUDT5 induces the accumulation of the oxidative DNA marker, 8-oxoG, and the DNA damage marker, γ H2AX, in TNBCs cells, indicating that loss of NUDT5 induces oxidative DNA damage response. In the MDAMB231 xenograft models, the inhibitor of NUDT5 suppressed TNBC tumor growth in mice. Conclusions: Our results showed NUDT5 is highly expressed in TNBCs as compared to ER-positive tumors. inhibition of NUDT5 suppresses the growth of TNBC but not of ER-positive breast cancer cells. NUDT5 loss also induces oxidative DNA damage, with increased 8-oxoG

and γ H2AX positivity. These results demonstrate that NUDT5 is essential for the growth of TNBC cells and suggest that NUDT5 is a promising new target for the treatment of these aggressive breast cancers. This work was supported by Charles Cain Endowment (PB).

BRCA2 is a well-established cancer driver in several human malignancies. While the remarkable success of PARP inhibitors proved the clinical potential of targeting BRCA deficiencies, the emergence of resistance mechanisms underscores the importance of seeking novel Synthetic Lethal (SL) targets for future drug development efforts. In this work, we performed a BRCA2-centric SL screen with a collection of plant-derived compounds from South America. We identified the steroidal alkaloid Solanocapsine as a selective SL inducer, and we were able to substantially increase its potency by deriving multiple analogs. The use of two complementary chemoproteomic approaches led to the identification of the nucleotide salvage pathway enzyme deoxycytidine kinase (dCK) as Solanocapsine's target responsible for its BRCA2-liked SL induction. Additional confirmatory evidence was obtained by using a highly specific dCK inhibitor (DI-87), which induces SL in multiple BRCA2-deficient and KO contexts. Interestingly, dCK-induced SL is mechanistically different from the one induced by PARP inhibitors. dCK inhibition generates substantially lower levels of DNA damage, and cytotoxic phenotypes are associated exclusively with mitosis, thus suggesting that the fine-tuning of nucleotide supply in mitosis is critical for the survival of BRCA2-deficient cells. Moreover, by using a xenograft model of contralateral tumors, we show that dCK impairment suffices to trigger SL in-vivo. Taken together, our findings unveil dCK as a promising new target for BRCA2-deficient cancers, which provides future therapeutic alternatives to PARP inhibitors.

Background: Triple-negative breast cancer (TNBC) is a highly aggressive breast cancer subtype with a high metastatic rate. Despite significant advances in breast cancer therapeutics, due to the lack of specific therapeutic targets in TNBC, cytotoxic chemotherapy is still the mainstay of treatment for this BC subtype. Preclinical studies have shown that the Receptor for Advanced Glycation End-products (RAGE) drives the progression and metastasis of aggressive cancer subtypes, including TNBC. RAGE plays a multifaceted role in driving tumorigenesis and metastasis through tumor cell-intrinsic mechanisms, such as cancer cell invasion, migration and epithelial-mesenchymal transition, and tumor cell-extrinsic mechanisms. This multifaceted role in cancer progression and metastasis makes RAGE a promising therapeutic target in the prevention and treatment of breast cancer. Here we tested the preclinical anti-metastatic efficacy of two small molecule RAGE inhibitors; TTP48 (Azeliragon) and FPS-ZM1. Importantly, TTP488 displays a high safety profile in human trials and has previously undergone Phase 3 clinical trials for Alzheimer's disease. While FPS-ZM1 is a well-known RAGE inhibitor in preclinical cancer models, TTP488 has not been tested for its anti-cancer activity in breast cancer. Methods: We tested the in vitro anti-metastatic effect of TTP488 and FPS-ZM1 on cancer cell migration and invasion in Boyden chamber assays with TNBC cell lines (MDA-MB-231 and 4T-1). We used the 4175 highly metastatic MDA-MB-231 variant in xenograft studies in

NSG mice to test the efficacy of the RAGE inhibitors in vivo on tumor progression and metastasis. Experimental metastasis assays were performed with tail-vein injection of 4T-1 cells into BALBc mice. We performed bulk RNA sequencing on the MDA-MB-231/4175/NSG tumors to unveil and compare the mechanism of action of the two small molecule RAGE inhibitors. Results: Our results showed that TTP488 and FPS-ZM1 impaired mechanisms of metastasis in vitro with both MDA-MB231/4175 and 4T-1 cells. TTP488 and FPS-ZM1 significantly inhibited MDA-MB231/4175 cell metastasis from the orthotopic site in NSG mice without displaying any deleterious effects on mouse health. In the syngeneic 4T-1/BALBc model, both TTP488 and FPS-ZM1 impaired metastasis in tail-vein injected experimental metastasis assays. Transcriptomic analysis of primary xenograft tumors from NSG mice revealed that TTP488 and FPS-ZM1 displayed high concordance in gene expression changes. Pathway enrichment analysis showed that both RAGE inhibitors affected metastatic pathways, including focal adhesion, ECM-receptor interaction, cell cycle, and DNA replication. Conclusions: These results show that TTP488 impairs metastasis of multiple highly aggressive TNBC models for the first time. Importantly, as TTP488 displays a high safety profile in human trials, this study provides the rationale for evaluating TTP488 in clinical trials to treat or prevent metastatic breast cancer.

Triple negative breast cancer (TNBC) is the most aggressive breast cancer subtype and has the highest rate of recurrence. The predominant standard of care for advanced TNBC is systemic chemotherapy with or without immunotherapy, however responses are typically short-lived. Thus, there is an urgent need to develop more effective treatments. PI3K pathway components represent plausible therapeutic targets, as approximately 40% of TNBCs have PIK3CA/AKT1/PTEN alterations. However, unlike hormone receptor-positive tumors, it is still unclear if or how PI3K pathway inhibitors will be effective in triple-negative disease. Here we identify a promising AKT inhibitor-based therapeutic combination for TNBC. Specifically, we show that AKT inhibitors potently synergize with agents that suppress the histone methyltransferase, EZH2, and promote robust tumor regression in multiple TNBC models in vivo. AKT and EZH2 inhibitors exert these effects by first cooperatively driving basal-like TNBC cells into a more differentiated, luminal-like state, which cannot be effectively induced by either agent alone. More importantly, once differentiated, these agents kill TNBCs by hijacking signals that normally drive mammary gland involution. Together these findings identify a promising therapeutic strategy for this highly aggressive tumor type and illustrate how deregulated epigenetic enzymes can insulate tumors from oncogenic vulnerabilities. These studies also reveal how developmental tissue-specific cell death pathways may be co-opted for therapeutic benefit.

Background: Cyclin E1 (CCNE1) plays a critical role in cell cycle regulation. CCNE1 overexpression and/or gene amplification (amp) have been associated with poor outcome in several tumors, including breast cancer (BC). CCNE1 amp has recently been identified as a potential therapeutic target for novel synthetic lethality-based therapies. Here we sought to define the clinical and genomic features of BCs carrying CCNE1 amp. Methods: Genomic and clinical data from all consecutive BCs, which had been subjected to targeted sequencing using the FDA-authorized MSK-IMPACT assay from April 2014 to December 2021, were retrieved. Allele-specific copy number and fraction genome altered (FGA) were assessed using FACETS. Whole genome doubling (WGD) status was inferred from MSK-IMPACT sequencing data. Samples were categorized as CCNE1 amp or non-amp based on copy number profile assessed by FACETS. Mutual exclusivity and co-occurrence analyses between CCNE1 amp and other genetic alterations were performed using CoMEt. Multiple testing correction using the Benjamini–Hochberg procedure was applied to control for the false discovery rate. Progression-free survival (PFS) was assessed by Kaplan Meier method and Cox proportional-hazards models. Survival analyses were restricted to only patients with available pre-treatment samples.

Results: Of 3,753 BCs with full clinical and genomic data, 125 (3.3%) harbored CCNE1 amp. A significant difference in the proportion of CCNE1 amp between treatment-naïve and post-treatment/metastatic samples was observed (2.4% vs 4%, $p=0.007$). CCNE1 amp was significantly less frequently detected in hormone receptor (HR)+/HER2- BCs than in HR-/HER2+ and HR-/HER2- subtypes (2% vs 7.6% and 7.2%, respectively, $p < 0.001$), and was particularly rare in invasive lobular BCs (1/452 cases). BCs with CCNE1 amp displayed a higher frequency of WGD ($p < 0.001$) and higher median FGA ($p < 0.001$) than non-amp tumors, overall and in different subtypes, suggesting increased genomic instability. No difference in tumor mutational burden (TMB) between CCNE1 amp and non-amp was found. In primary BC ($n=1,385$), a higher proportion of TP53 alterations was found in cases with CCNE1 amp (odds ratio [OR] 6.0, 95% confidence interval [CI] 2.5-16.6, $q < 0.001$). Conversely, CCNE1 amp was mutually exclusive with CDH1 alterations ($q < 0.001$). Comparable results were found in the analysis of post-treatment/metastatic samples ($n=2,368$). A subset analysis on HR+/HER2- BCs confirmed that TP53 (OR 4.2, 95%CI 2.28-8.11, $q < 0.001$) and CDH1 (OR 0.09, 95%CI 0.002-0.57, $q < 0.1$) alterations co-occurred and were mutually exclusive, respectively, with CCNE1 amp. ARID2 alterations were also enriched in HR+/HER2- tumors harboring CCNE1 amp (OR 10.6, 95%CI 2.54-33.93, $q < 0.1$). CCNE1 amp was significantly associated with reduced median PFS (8.8 vs 15.2 months in CCNE1 amp [$n=9$] vs CCNE1 non-amp [$n=402$]; hazard ratio [HR] 2.82, 95% CI 1.38-5.75, $p=0.004$) on first line treatment with CDK4/6 inhibitor plus endocrine therapy (ET) in HR+/HER2- metastatic BCs, regardless of the ET partner, FGA and TMB. CCNE1 amp was also associated with numerically inferior median PFS (7.3 vs 20.8 months in CCNE1 amp [$n=5$] vs CCNE1 non-amp [$n=106$]; HR 3.1, 95% CI 1.24-7.87, $p=0.01$) on first line trastuzumab/pertuzumab/taxane treatment in HER2+ metastatic BCs, with a trend toward significance after adjusting for FGA and TMB ($p=0.09$). Conclusions: CCNE1 amp is associated with specific clinicopathological and genomic features in BCs and linked to an increased genomic instability. CCNE1 amp defines a subset of metastatic BCs with marked poor clinical response to available standard-of-care treatments. Further studies testing novel therapeutic approaches, including synthetic lethality-based strategies targeting CCNE1 amp and CDK2-selective inhibition, are warranted.

Breast cancer is the major leading cause of cancer-related fatalities nationally and globally. There will be 287,850 new breast cancer cases and 43,250 breast cancer related deaths in the United States in 2022. The relapsed, treatment-resistant, undruggable, and incurable breast cancers are often associated with EGFR/HER2/K-RAS/SIAH pathway activation. The EGFR/HER2/K-RAS/SIAH pathway is a major tumor-driver whose hyperactivation is associated malignant tumor growth, multidrug-resistant phenotypes, early tumor relapse, and systematic metastasis. Seven-In-Absentia (SINA) homologues (SIAH) are extraordinarily evolutionarily-conserved E3 ubiquitin ligases that play a critical gatekeeper role downstream of the EGFR/HER2/K-RAS pathway. SIAH is a major tumor vulnerability that is ideally positioned to become an attractive target for innovative targeted therapy development against metastatic breast cancer (MBC). Prior studies have shown that tumor growth was abolished in malignant

tumor cell lines such as MDA-MB-231, MDA-MB-468, MiaPaCa, A459, and HeLa following SIAH inhibition in xenograft models; however, the underpinning molecular mechanisms that give rise to this striking anti-EGFR/K-RAS and anticancer phenotype remain unclear. Specific objectives: to delineate the molecular mechanism(s) of why anti-SIAH2PD targeted therapy is so effective in impeding and eradicating the stage IV and aggressive tumors, we conducted reverse phase protein array (RPPA)-based kinomic analysis to delineate how major cancer signaling pathways and EGFR/HER2/K-RAS/SIAH-dependent signaling networks are rewired and remodeled in response to anti-SIAH2 targeted therapy. Brief statement of methods: About 300 proteins/phosphoproteins were quantitatively measured by the RPPA platform to identify new tumor vulnerabilities and actionable targets, compensatory signaling network activation/inhibition in response to anti-SIAH targeted therapies in five highly malignant cancer cell lines. Doxycycline (DOX)-inducible Tet-ON MDA-MB-231, MDA-MB-468, MiaPaCa, HeLa and A459 cell lines were amplified from single cell and DOX-induced SIAH2PD expression was confirmed. Each of the cell lines was then subjected to one of four experimental conditions: Tet-ON control cells without DOX induction (group A), Tet-ON control cells with DOX induction (group B), Tet-ON-SIAH2PD cancer cells without DOX-induction (no SIAH2PD inhibitor) (group C), Tet-ON-SIAH2PD cancer cells with DOX-induction (SIAH2PD inhibitor) (group D). Reverse Phase Protein Array (RPPA) in conjunction with Principal Component Analysis (PCA) was conducted to quantify fold-changes of proteins/phosphoproteins in response to SIAH inhibition. The ratios of D/C/B/A, D/C, D/B, C/A, and B/A were calculated using GAPDH normalized data. Summary of results: Supported by statistical analyses, we identified 6 unique phospho-proteins that were either up- or down-regulated in response to SIAH Loss-of-function. Many have known roles in controlling and regulating cell growth, cell death, NFκB signaling, stress response, DNA damage, and cell attachment pathways, supporting a tumor eradication phenotype in the absence of SIAH function in these cancer cell lines. Conclusion: Cancer landscape (CScape) functional protein pathway mapping has categorized the synergistic feedforward, feedback, and compensatory signaling pathway activation/inactivation in response to SIAH blockade in these EGFR/HER2/K-RAS-driven malignant human cell lines. Further validation analysis will be conducted to gain better insight into the global cancer pathway alterations to reveal the molecular mechanism(s) of why SIAH inhibition works so effectively to shut down malignant tumor growth in the preclinical models.

Breast cancer liver metastasis (BCLM) is encountered in >50% of breast cancer patients with advanced disease and is associated with the poorest disease prognosis. Unlike primary tumors and metastatic lesions in other organs, BCLM growth relies heavily on the liver vasculature, leading to lesions that are hypo-vascularized. Consequently, most BCLM clinically appear as hypoattenuating spots. This under-vascularization prevents systemically administered agents from reaching all of the cells in these lesions, causing physiological, transport-related resistance to therapy. The liver is an organ enriched in macrophages, which play important roles by affecting tumor growth, angiogenesis, metastasis and chemoresistance. These phagocytic cells remain in close proximity to BCLM and have been clinically utilized for imaging with nanomaterials. We have previously shown (T. Tanei et al, *Cancer Res.* 2016) that drug transport barriers can be overcome using macrophages as carriers for nanotherapeutics, leading to an efficient therapy for BCLM. The prerequisite for this therapy is the ability of BCLM to attract macrophages from surrounding liver tissue. The drug-carrying macrophages can escape host defense mechanisms, hence extending the therapeutic agent half-life and releasing it in close proximity of tumor cells under-exposed to vascular-borne drugs. In the present study, we aimed to evaluate the ability of different breast cancer cells to attract macrophages, further exploiting these cells as a viable candidate for targeted delivery of lipid nanoparticles. For this purpose, we evaluated the transport phenomena of macrophages in the presence of a variety of human breast cancer cells, including, MCF7 (ER+, PR+/-, HER2-), T-47D (ER+, PR+/-, HER2-), MDA-MB-231 (TNBC), SUM-159 (TNBC). The studies were conducted in tumor cell-macrophage co-cultures in 2-dimensional (2D) and 3-dimensional (3D, hypovascularized model) settings. Human macrophages were derived from buffy coats from healthy donors and prelabelled for the co-culture experiments. The majority of macrophages were M0 phenotype. The following parameters were assessed for macrophage infiltration: a)

static (confocal) and kinetic (Incucyte) microscopy imaging of cell transport, b) cell counts for migration assay, c) immunofluorescence, d) directionality/path length. The datapoint towards the variability in behaviors of macrophage transport towards the tumor cells in both 2D and 3D settings. MDA-MB-231 (triple negative breast cancer cell line) was more prominent in recruiting macrophages, which can be clinically correlated to higher tumor grade and reduced overall and relapse-free survival. These findings were further utilized to mathematically model and experimentally evaluate BCLM therapeutic response to nanocarriers loaded with high molecular weight (HMW) therapeutics. Longer term, this work provides a methodology for macrophage-mediated targeting of particular patient hypo-vascularized BCLM. BACKGROUND HER2-negative (HER2-) breast cancer (BC) subtypes, such as luminal A and triple-negative breast cancer (TNBC), express human trophoblast cell-surface antigen 2 (Trop-2). A high level of Trop-2 expression is associated with a poor prognosis in solid tumors. Sacituzumab-govitecan (SG), a Trop-2-directed antibody conjugated with SN-38 (topoisomerase I inhibitor) significantly improves survival in patients with metastatic TNBC. Also, the IMMU-132-01 phase I / II study revealed that SG has antitumor activity in previously treated hormone receptor (HR)+/HER2- metastatic BC. In a phase III trial (TROPICS-02), SG demonstrated statistically significant progression-free survival in patients with heavily pre-treated HR+/HER2- endocrine-resistant metastatic BC. To augment the efficacy of SG, we sought to identify potential kinase targets whose inhibition enhances the antitumor efficacy of SG to formulate an SG-based combination therapy. MATERIALS AND METHODS

Fluorescence-activated cell sorting analysis and Western blotting were used to evaluate the expression of Trop-2 in 24 TNBC and 8 HR+ BC cell lines. Non-biased high-throughput kinome-wide RNAi screening was performed with BT-20 (TNBC) and T47D tamoxifen/abemaciclib double-resistant (HR+) cell lines to identify target kinases whose inhibition produces synergistic antitumor efficacy of SG. To validate the combination antitumor effect of SG and selected kinase target inhibitors, sulforhodamine B staining proliferation assays, cell cycle analysis, and caspase 3/7 activity assays were performed in Trop-2+ TNBC and HR+ BC cell lines, including cell lines resistant to tamoxifen and double-resistant to tamoxifen and CDK4/6 inhibitor (palbociclib or abemaciclib). RESULTS In vitro proliferation assays revealed that the half-maximal inhibitory concentration (IC50) of SG in tested TNBC cell lines ranged from 10 nM to 84 nM, and that of HR+ cell lines ranged from 12.5 nM to >250 nM. We identified 69 kinase targets in TNBC cell line BT-20 and 44 kinase targets in HR+ BC cell line T47D (tamoxifen/abemaciclib double-resistant) by the sensitivity index analysis (>0.15) of RNAi screening results, and further pathway analysis revealed DNA damage response (DDR), (drug: BAY1895344), PI3k/Akt/mTOR (drug: copanlisib), and MAPK (drug: trametinib) as potential target canonical pathways whose targeting enhanced the cytotoxic effect of SG in both TNBC and HR+ BC. Among these strategies, inhibition of the DDR pathway with ATR inhibitor (BAY1895344) yielded a synergistic antiproliferative effect in combination with SG compared to SG or BAY1895344 alone in all tested TNBC and HR+ BC cell lines. Growth inhibition by SG combined with BAY1895344 averaged 97.1% in TNBC cell lines and ranged from 30.7% to 81.3% in HR+ BC cell lines, with $P < 0.001$. Other combinations with SG showed partially synergistic antiproliferative effects (copanlisib: effective in 3 of 5 cell lines, trametinib: effective in 2 of 5 cell lines). CONCLUSIONS RNAi screening uncovered DDR, PI3k/Akt/mTOR, and MAPK pathways as potential targets for combination with SG. Among inhibitors of these targets, DDR pathway inhibitor BAY1895344 had the most robust synergy with SG, compared to two other target inhibitors, against Trop-2+ TNBC and HR+ BC cell lines. These in vitro data warrant future in vivo validation studies of the synergistic antitumor effect of SG and BAY1895344 in metastatic HER2- breast cancer.

Background: The Androgen Receptor (AR) is expressed in up to 90% of all ER+ breast cancers and has been associated with better patient outcome. While androgens were used at a high dose as an anticancer therapy historically, this was discontinued with the advent of Tamoxifen due to virilising effects. Non-steroidal, tissue selective AR modulators (SARMs) represent an attractive alternative, offering a targeted approach to AR activation. Recent compelling pre-clinical data has established that the AR is a tumour suppressor in ER+ breast cancers and that AR activation with a natural androgen or a SARM suppressed ER-driven tumour growth, in preclinical models of endocrine-sensitive and -resistant ER+ breast cancer. Here, we evaluate the efficacy of a SARM (enobosarm) and a natural AR ligand (dihydrotestosterone, DHT) in the context of metastatic, CDK4/6 inhibitor (CDK4/6i) resistant breast cancer. Methods: Enobosarm

and palbociclib treatments were evaluated in vitro by colony forming assays using CDK4/6i resistant (MCF7 PalbR) and both endocrine and CDK4/6i resistant (MCF7 cTamPalbR) cell lines. Next, enobosarm or DHT and palbociclib treatment were evaluated in vivo using endocrine and CDK4/6i resistant ER+ patient derived xenograft models (PDX) and cell line xenograft models. IHC, RNA and ChIP sequencing (AR, ER, H3K27ac) were subsequently performed on the harvested tumours. Results: While in vitro and in vivo growth of CDK4/6i resistant preclinical models was inhibited by treatment with a SARM or DHT alone, growth inhibition was more potent and durable in combination with a CDK4/6i. Gene set enrichment analysis of RNA-seq data integrated with ChIP-seq data revealed upregulation of an AR gene signature associated with a better prognosis following treatment with SARM. Co-treatment with a SARM and a CDK4/6i also enhanced AR signalling compared to SARM alone indicating an interaction of the two signalling pathways. Conclusion: Our data indicates that combination treatment with an AR agonist and a CDK4/6i represents a novel therapeutic strategy for CDK4/6i resistant ER+AR+ breast cancers

Background: The de novo drug development process is expensive and challenging, with a high risk of failure. Drug repurposing can ideally identify novel therapeutic indications for FDA-approved drugs with pre-existing pre-clinical and clinical evidence. Both aspirin and tamoxifen drugs are good examples of successful drug repurposing in oncology. Although proteasome inhibitors such as bortezomib and carfilzomib are currently only used to treat multiple myeloma and basal cell lymphoma, we and others have shown that triple-negative breast cancer (TNBC) is particularly sensitive to proteasome inhibition. TNBC is an aggressive form of breast cancer with an urgent need for novel treatment options. Here, we evaluate the potency of proteasome inhibitors and other clinically relevant chemotherapeutic agents on TNBC cell lines. Methods: We performed a high-throughput drug sensitivity screen with eight cell lines representing the four TNBC subtypes (basal-like 1: HCC70 and MDA-MB-468; basal-like 2: HCC1806 and MDA-MB-436; mesenchymal-like: BT-549 and HCC38; luminal androgen receptor: CAL-148 and MDA-MB-435) and MCF-7 as control (estrogen and progesterone receptor-positive) exposed to 18 drugs (11 proteasome inhibitors, 2 mitosis inhibitors, 2 topoisomerase inhibitors, and 3 platinum agents) for 24 hours. Drug potency was determined using the IC50, GR50, GRmax

drug metrics. IDACombo was then used to predict efficacious drug combinations, followed by calculation of synergistic drug combinations with SynergyFinder. Results: TNBC cell lines were generally more sensitive to proteasome inhibitors with significantly reduced cell viability than clinically relevant drugs, e.g. paclitaxel. Although the potency of different proteasome inhibitors varied, the most potent proteasome inhibitors included bortezomib, carfilzomib, delanzomib, epoxomicin, and MLN-2238. According to the GR50 values, HCC38 (range, 8.2-382.7 nM) and MDA-MB-468 (range, 10.8-110.6 nM) were most sensitive to proteasome inhibition, whereas the least sensitive TNBC cell lines were HCC1806 (range, 289.9-Inf nM) and BT-549 (range, 101.0-Inf nM). Using the drug sensitivity screening results for single drugs, IDACombo predicted potent drug combinations for different combinations of bortezomib, carboplatin, carfilzomib, delanzomib, docetaxel, doxorubicin, epirubicin, epoxomicin, MLN-2238, MLN-9708, and nedaplatin. Conclusions: In summary, some proteasome inhibitors (e.g. bortezomib) had a substantial impact on TNBC cell survival. These findings indicate that proteasome inhibitors, together with other forms of chemotherapy, may be further explored as a novel complement treatment for TNBC.

Engineered Toxin Bodies Specific for TROP2 Positive Cancers Authors: Garrett L. Cornelison, Ileana Pedraza, Kendra Garrison, Elizabeth M. Kapeel, Channing Pletka, Abdul Khan, Jessica Momb, Rebecca Martin, Adam Bartos, Joseph D. Dekker, Jay Zhao, John Majercak, Garrett L. Robinson Molecular Templates, Austin, TX Lanier Biotherapeutics, Bogart, GA Molecular Templates produces next generation immunotoxins called Engineered toxin bodies (ETBs). ETBs are comprised of a proprietarily engineered form of Shiga-like Toxin A subunit (SLT-A) genetically fused to antibody-like binding domains. ETBs work through novel mechanisms of action and are capable of forced internalization, undergoing retrograde translocation to the cytosol, and inducing potent cell-kill via the enzymatic and permanent inactivation of ribosomes resulting in the inhibition of protein synthesis and induction of apoptosis. In addition, Molecular Templates has expanded the ETB platform to include Antigen Seeding Technology (AST) to generate ETBs with the ability to deliver foreign protein antigen to targeted populations of tumor cells. This mechanism of action allows for the intracellular processing of antigen and subsequent surface MHC-I presentation required for activation of a re-directed T lymphocyte

response and the capacity to restore a functional immune clearance program against the tumor. Three ETBs are in clinical development (MT-5111 targeting HER2, MT-0169 targeting CD38, and AST enabled MT-6402 targeting PD-L1). The novel mechanisms of action have potential benefit in different indications including in the relapsed setting, when disease has progressed after chemotherapies and other targeted therapies, and additionally may be able to combine with standard of care. ETBs are being developed that target other cell surface receptors expressed on solid tumors including tumor-associated calcium signal transducer 2 (TROP2). TROP2 is a clinically validated target in metastatic triple-negative breast cancer (mTNBC) and other cancers such as metastatic urothelial carcinoma (mUC) using antibody drug conjugate (ADC) therapies such as sacituzumab govitecan (Trodelvy®). In vitro, ETBs targeting TROP2 specifically and directly kill tumor cells expressing TROP2 with picomolar activity. ETBs can bind to TROP2 in the presence of the Trodelvy parent monoclonal antibody, sacituzumab, and ETBs retain potency on TROP2 positive cell lines in the presence of clinically relevant concentrations of sacituzumab. AST enabled Trop2 targeted ETBs retain direct cell killing activity and can deliver multiple viral antigens to induce cytokine secretion and T-cell mediated killing in a co-culture assay of TROP2 target cells with antigen matched HLA type and antigen specific T-cells. In vivo, TROP2 targeted ETBs demonstrate good tolerability in a murine HCC1806 triple-negative breast cancer xenograft model and significantly reduce tumor burden relative to vehicle control. These pre-clinical in vitro and in vivo data suggest AST enabled Trop2 targeted ETBs have the potential to deplete Trop2 positive malignancies through multiple unique mechanisms of action.

Background: Inflammatory breast cancer (IBC) is a rare but aggressive tumor type accounting for up to 10% of breast cancer deaths. One-third of IBCs express high PD-L1 that can be targeted by atezolizumab (Az). MEK inhibitor cobimetinib (Co) not only inhibits the RAS-MAPK pathway but can further enhance immune-mediated killing. Thus, we hypothesize that Az+Co may enhance the efficacy of chemotherapy in metastatic IBC (mIBC). We opened a trial to test this hypothesis with a comprehensive multi-omics biomarker assessment. Patients and Methods: In a single-center, open-label phase II study, cohort 1 received one cycle of Az+ Co, followed by four cycles of Az+Co+eribulin (E) to induce a maximum clinical response, followed by Az+Co maintenance. Pre and Post one cycle of Az+Co tumors were collected for immunohistochemistry (IHC), multiplex immunofluorescence (mIF), whole-exome sequencing (WES), and RNA sequencing (RNAseq). Blood was collected for circulating tumor DNA (ctDNA). Results: Seventeen patients were enrolled in cohort 1. Seven had PR, and three had SD as the best responses. Fourteen had pre, and six had pre/post tumors. The levels of PD-L1 expression at pre/post were not associated with responses. WES revealed the median tumor mutation burden at pre- was 9mt/Mb. More than 50% had TP53 and PI3K pathway mutations at pre. RTK-RAS and Notch pathways were altered in 4/9 cases. PRDM9 and DPY19L2 single-gene mutations were commonly noted in pre. No cancer-associated gene aberration, including potential biomarkers of anti-PDL1 agent response was associated with clinical outcomes. Transcriptomic gene set enrichment analysis demonstrated a greater degree of TNF α and TGF β signaling, Oxphos, angiogenesis, and epithelial-to-mesenchymal transition (EMT) processes in tumors from patients with poor response. Immune profiling by RNAseq revealed two responders to have elevated effector memory T cells, NK T cells, myeloid dendritic cells, and M1 macrophage signatures in pre-samples, but post-samples were not available. mIF confirmed a higher frequency of NK-T cells. The ctDNA analysis from serially collected blood samples is ongoing. Discussion: In this comprehensive multi-omics analysis of pre-and-post-Az+Co, we observed several novel findings, while conventional biomarkers for Az and Co did not correlate with clinical responses. EMT, Oxphos, Notch, and chronic inflammation pathways, which are not previously well reported, were observed in this IBC cohort. These markers warrant further validation to see if they carry significance as therapeutic targets in IBC.

Centrosome amplification (CA) is a hallmark of cancer that is strongly associated with highly aggressive disease and worse clinical outcome. Enhanced mitotic progression via clustering of extra centrosomes is a major coping mechanism utilized by cancer cells with CA that would otherwise undergo mitotic cell death due to formation of multipolar spindles. However, the underlying molecular mechanisms have largely been unexplored. Furthermore, mitosis-targeting inhibitors have mostly been unsuccessful in clinical settings with poor efficacy and severe side effects. Therefore, there is a dire need to uncover novel molecular mechanisms of CA-driven tumor growth and identify therapeutic targets playing key roles not only in mitosis, but also in interphase of cancer cells with CA to achieve durable anti-tumor effect with minimal toxicity. Here, we identified Transforming Acidic Coiled-Coil Containing Protein 3 (TACC3) as a novel CA-directed dependency, driving highly aggressive cell growth by forming distinct functional interactomes during cell cycle progression. We demonstrated, for the first time, that TACC3 interacts with the Kinesin Family Member C1 (KIFC1) via its TACC domain in mitotic cells with CA to promote centrosome clustering (CC) and facilitate mitotic progression. On the other hand, TACC3 interacts with the members of the nucleosome remodeling and deacetylase (NuRD) complex (HDAC2 and MBD2) in the nucleus of interphase cells with CA, thereby suppressing the transcription of key tumor suppressors to facilitate G1/S progression and cell survival. Inhibiting TACC3 in mitotic cells blocks the formation of TACC3/KIFC1 complex, leading to formation of multipolar spindles and activation of spindle assembly checkpoint (SAC)/CDK1/p-Bcl2 axis that ultimately results in mitotic cell death; whereas TACC3 inhibition in interphase cells blocks TACC3/HDAC2/MBD2 complex, leading to enhanced transcription of cyclin-dependent kinase inhibitors (e.g., p21 and p16) and apoptosis regulators (e.g., APAF1), ultimately causing p53-independent G1 arrest and strong apoptosis. Notably, inducing CA by chemical (cytochalasin D) or genomic (PLK4 overexpression or p53 loss) modulations renders cancer cells highly sensitive to TACC3 inhibition, showing the dependency of cells with CA to TACC3. Targeting TACC3 by small molecule inhibitors or CrispR-CAS9-mediated knock-out significantly reduces colony formation ability, inhibits the growth of organoids of patient-derived xenografts (PDXs) with CA, and strongly inhibits tumor growth in breast cancer cell line xenografts and PDXs with CA. Notably, we demonstrated that high CA tumors express much higher levels of TACC3, and high TACC3 expression, in association with its downstream effectors, KIFC1, HDAC2 and MBD2, leads to drastically worse clinical outcome in cancer

patients with CA. Altogether, our results show, for the first time, that TACC3 is a multifunctional driver of the growth of the highly aggressive breast tumors with CA and that targeting TACC3 is a promising approach to tackle this aggressive disease.

Activation of the AKT/PI3K/mTOR signaling through genetic and epigenetic mechanisms is a frequent event in all subtypes of breast cancer, and it is associated with resistance to various therapies. Development of inhibitors targeting this pathway has been met with limited success so far, mainly due to various feedback and crosstalk mechanisms amongst different members of the pathway. Several therapies that target the PI3K pathway have also been associated with dose limiting toxicities such as hyperglycemia, hyperinsulinemia, skin rashes and infections, limiting their use. The SGK family of kinases has recently been implicated in the resistance to

AKT and PI3K inhibitors by promoting AKT-independent signaling to maintain the activation of the AKT/PI3K/mTOR pathway. The SGK and AKT families share similar domain structures as well as upstream activators such as PDK1 and mTORC2, and downstream effectors such as TSC2, FOXO3, and GSK3B, providing a strong rationale for the development of inhibitors targeting the SGK family. Here we present the development of novel small molecule ATP-competitive inhibitors of the SGK family. Several compounds displayed low nanomolar affinity towards SGK1 in whole cell assays, with IC50s ranging between 10-100 nM, which is 30-300 folds and 80-1000 folds higher than the previously characterized SGK1 inhibitors GSK650394 and EMD638683, respectively, as well as good selectivity against related AGC family kinases. Experiments in cells have shown a strong dose-dependent decrease in the phosphorylation of its downstream target NDRG1 at sub-micromolar concentrations, confirming selective targeting of SGK1 in whole cells. Single agent activity of SGK1 inhibition was modest in different cancer cell lines, with IC50 values for inhibition of their proliferation ranging from 1-10 μ M, in agreement with the role of the SGK family in regulation of stress-induced signaling and not normal cell proliferation. However, combinations of SGK with AKT inhibitors displayed strong synergies in different breast cancer cell lines, especially in cells with resistance to AKT/PI3K inhibitors. For example, strong Bliss synergy index scores > 18 were obtained with different SGK1 inhibitors when combined with either AKT inhibitors MK-2206, ipatasertib, or capivasertib, in the JIMT-1 breast cancer cell line, which is a model of resistance to AKT, PI3K, and HER2-directed therapies. These results suggest that the combination of SGK with AKT inhibitors could be an effective therapeutic strategy to alleviate toxicities associated with AKT/PI3K/mTOR inhibitors by lowering their required dose, while maintaining anti-tumor activity and delaying the development of resistance.

Expression of Dual Specific Phosphatase-7 (DUSP7/PYST2) and it's Connection with Salt Inducible Kinases (SIKs) and Downstream MKKs in breast cancer Wenxiao Ji¹, Emily Ling Xin^{1,2}, Lin Ye¹, Eleri Davies³, Wen G. Jiang¹, Tracey A. Martin¹ ¹CCMRC, Cardiff University School of Medicine, Cardiff, Wales, UK ²Breast Centre, Peking University First Hospital, Xicheng District, Beijing, China ³Wales Breast Centre, University Llandough Hospital, Cardiff CF64 2XX, UK Introduction. DUSP7 is a member of the large Dual specific phosphatase family, able to regulate the phosphorylation of both tyrosine and serine/threonine protein kinases. The role of DUSP7 in cancer is not clear, however, it has been identified as a possible target for therapy in cancers including breast cancer. It has also been reported as having value in prognosis of certain cancers, such as haematological malignancies, breast cancer and certain types of gynaecological cancer. The signalling network for DUSP7 is not fully established but is known to connect to ERKs and MAP2Ks. DUSP7 also appears to be linked with salt inducible kinases (SIKs), a small family of kinases linked with progression and response to therapies in breast cancer. Thus, DUSP7 and salt inducible kinases may interact with each other and with the downstream kinases including MAP2Ks and STK11 to influence the clinical course of breast cancer. The present study explored if the pattern of DUSP7 together with salt inducible kinases and the downstream MKKs in breast cancer. Methods. The expression of DUSP7 was quantified in a cohort of breast cancer tissues (both normal mammary tissues and breast cancer tissues). The expression of the potential downstream kinases including MKK1, MKK2, MKK3, MKK4 and STK11 was also quantified. The expression profile of these molecule, together with the salt inducible kinases reported to be aberrant in our previous studies, were analysed against clinical and outcome information. Results. Breast cancer tissues expressed high levels of DUSP7 compared with normal mammary tissues, although not statistically

significant. When we explored the relationship between DUSP7 and other potential related molecules in the database of the cohort, we found a highly significant correlation between DUSP7 and SIK1 ($r=0.385$, $p < 0.001$), SIK2 ($r=0.590$, $p < 0.001$), but not SIK3 ($r=0.158$, $p > 0.05$). Together with SIK1 and SIK2 (known to link to drug sensitivity), DUSP7, MKK1 (MAP2K1) and MKK3 (MAP2K3) appear to form a gene signature that is of significant value in predicting the overall survival of the patients (ROC 0.723, $p=0.001$). This allowed us to significantly distinguish between those with good OS and poor OS ($p < 0.001$, Hazard Ratio (HR) =1.443 (95%CI 1.154-1.804)). Multivariate analysis has shown that this signature is independent in predicting overall survival ($p=0.013$, HR=1.432). The signature is more significant in predicting OS in ER(-) tumours ($p < 0.001$) than ER(+) tumours ($p=0.61$). The same is seen when predicting OS with triple negative breast cancers (TNBC) ($p < 0.001$) than non-TNBC tumours ($p=0.044$). The gene signature also predicted disease free outcome ($p=0.007$, HR=1.266 (95% CI 1.065-1.504)). Conclusion. The dual specific phosphatase DUSP7 together with potentially correlated salt inducible kinases (SIK-1 and SIK-2) and downstream MKKs (MKK-1 and MKK3) have important clinical value in breast cancer. This provides support that DUSP7 may be a valuable therapeutic target in breast cancer.

Background: Triple-negative breast cancer (TNBC) is an aggressive and highly lethal disease in women, while the oncogenic mechanisms which contribute to TNBC development, progression,

and metastasis are poorly investigated and therefore warrant the critical need to identify novel oncogenic signalings and develop new therapeutic targets. Results: We show that Zinc Fingers and Homeoboxes 2 (ZHX2) is amplified or overexpressed in TNBC cell lines and patients. Functionally, depletion of ZHX2 inhibited TNBC cell growth and invasion in vitro, orthotopic tumor growth, and spontaneous lung metastasis in vivo. Mechanistically, ZHX2 bound with hypoxia-inducible factor (HIF) family members and positively regulated HIF1 α protein level and activity in TNBC. Integrated ChIP-seq and gene expression profiling demonstrated that ZHX2 co-occupied with HIF1 α on transcriptionally active promoters marked by H3K4me3 and H3K27ac, thereby promoting gene expression. Among the identified ZHX2 and HIF1 α coregulated genes, overexpression of AP2B1, COX20, KDM3A, or PTGES3L could partially rescue TNBC cell growth defect by ZHX2 depletion, suggesting that these downstream targets contribute to the oncogenic role of ZHX2 in an accumulative fashion. Furthermore, multiple residues (R491, R581, and R674) on ZHX2 are important in regulating its phenotype, which correspond with their roles in controlling ZHX2 transcriptional activity in TNBC cells. These studies establish that ZHX2 activates oncogenic HIF1 α signaling, therefore serving as a potential therapeutic target for TNBC. Conclusion: ZHX2 has been highlighted as one critical hypoxia-related factors regulator contributing to triple-negative breast cancer in this work, which has enriched the upstream regulatory network of HIF-1 α signaling. Moreover, identification of key residuals determining biological function of ZHX2 provides novel approaches for treating TNBC via targeting the hypoxia pathway.

Palmitoylation of Flotillin-1 contributes to Breast Cancer Metastasis

Presenting Author(s) and Co-Author(s):

Bryan McClellan, n/a, *Graduate Student - University of Texas at Austin*

Office Phone: (662) 295-2796

State: Texas

Country: United States

BACKGROUND Breast Cancer metastasis results in the majority of cancer-related mortality. Flotillin-1 is overexpressed in numerous solid tumors and has been demonstrated to contribute to invasion and metastasis in breast cancer. Though its expression alone has been associated with metastasis, there has yet to be any investigation as to how certain post-translational modifications can affect its metastatic capabilities. Flotillin-1 is modified through palmitoylation, a post-translational modification essential for protein stability, processing, and localization. By generating a palmitoylation defective mutant of flotillin-1, we have demonstrated that flotillin-1 palmitoylation contributes to its stability and metastatic capabilities in both 3D and in vivo models of invasion and metastasis. **MATERIALS AND METHODS** Flotillin-1 wild type or palmitoylation defective C-34-A mutants were expressed in stable flotillin-1 knockdown MDA-MB-231 and SUM-159 triple negative breast cancer cells. These cells were subjected to 2D invasion chambers and 3D collagen invasion assays. Further, both wild type and C34A expressing cells were used for experimental lung metastases in mice by tail vein injection. 2-bromopalmitate (50 μ M) was used as a chemical palmitoylation inhibitor and MG-132 (10 μ M) for proteasomal inhibition. **RESULTS** Invasion in stable knockdown cells was restored by re-expression of flotillin-1, but not by follitillin-1 C34A. We further observed a significant decrease in lung metastasis in flotillin-1 C34A cells compared to wild type flotillin-1. Flotillin-1 C34A expression led to a significant decrease in protein stability, which was restored by MG-132. **CONCLUSION** Flotillin-1 palmitoylation contributes to its stability and subsequent metastatic capabilities in breast cancer cells and experimental metastasis models. Thus, flotillin-1 palmitoylation could be a promising target for breast cancer metastasis.

Human endogenous retrovirus K (HERV-K) belongs to a family of endogenous retroviruses that are present in our genome with similarities to present day exogenous retroviruses. This virus can express several proteins but our knowledge of HERV-K expression in human cancers is mainly limited to the envelope (Env) protein. Elevated HERV-K env protein expression has been shown in breast cancer both in in vitro and in vivo studies. This project aimed to decipher mechanisms of HERV-K induction in triple negative breast cancer (TNBC), and the impact of HERV-K targeting shRNA mediated knockdown on TNBC characteristics including cell migration, invasion and proliferative capacity in 2D and 3D cell culture models. Our results show that a role for inducible nitric oxide synthase (iNOS) in the induction of HERV-K in TNBC cell lines. RNA seq and bioinformatics analysis was performed to identify key molecular processes regulated by HERV-K and nitric oxide (NO) in MDA-MB-231 TNBC cells. Reduced rates of migration, invasion and proliferation in HERV-K knockdowns points towards the essential role of HERV-K in tumorigenesis and metastasis. HERV-K knockdown also modulated key gene expression signatures traditionally associated with the basal and mesenchymal phenotypes in breast cancer, cellular senescence and MHC class gene regulation. The co-expression of iNOS and HERV-K was assessed in over 150 TNBC cases and the association with patient outcomes assessed. Taken together, our findings indicate that NO and HERV-K may be a useful molecular target for the treatment of TNBC.

Recent advancements in molecular profiling have revealed distinct breast cancer subtypes, but many clinical NGS assays rely on gene panels, such as PAM50, limiting their clinical utility. Basal-like breast cancer (BLBC), one of the most aggressive subtypes, has highly variable molecular and clinical characteristics. Now, the tumor microenvironment (TME) is recognized as a vital participant in tumor progression and therapeutic response. The development of more refined classifications based on the TME, capable of accounting for tissue heterogeneity, may improve NGS clinical utility for BLBC. Here, we apply our transcriptomic-based approach, recently described by Bagaev et. al., to classify the BLBC TME into discrete immune portraits, to potentially improve clinical outcomes and facilitate therapeutic decisions.

We collected a cohort of 1,708 BLBC samples based on the expression levels of 50 genes (PAM50) from 10 publicly available datasets, with clinical outcomes available (n = 819). Using methodology described by Bagaev et. al., 31 functional gene expression signatures (Fges)

were selected, and unsupervised dense Louvain clustering was performed to identify TME subtypes. A novel RNA-seq deconvolution algorithm was used to determine the cell types within the TME. Validation of the histological features, including stroma, tumor infiltrating lymphocytes (TILs), and tertiary lymphoid structures (TLS), relative to gene expression patterns in the TME subtypes was performed by automated and manual annotation of BLBC H&E slides (n = 146) from an independent TCGA cohort. Overall survival (OS) analysis was performed using Kaplan-Meier and Cox regression methods.

We revealed 5 BLBC subtypes with distinct expression patterns: immune-enriched, non-fibrotic (IE, 19%), B-cell-enriched, TLS-like (TLS, 25.5%), granulocyte-enriched (G, 12.8%), fibrotic (F, 28%), and immune desert (D, 17.7%) (Table). IE tumors featured an active immune TME, with high immune checkpoint expression and T cell activity. The TLS subtype also had an immune-rich TME, presenting high levels of B cells, T helper cells, and TLS ($p < 0.001$). The TLS subtype exhibited the highest number of stromal TILs on TCGA H&E slides. The G subtype was characterized by high expression of granulocytes and granulocyte traffic molecules. In accordance with our findings, deconvolution predicted the highest percent of neutrophils in the G subtype ($p < 0.001$). The F subtype demonstrated the highest levels of angiogenesis, stromal Fges, and VEGFR1-3, FGFR1, and EGFR expression. By histological evaluation, 84% of F subtype samples demonstrated a medium or high level of fibrosis. The D subtype showed a high proliferation rate and low stromal and immune Fges. Indicative of proliferation rate, CCNB1 and cyclin B1 were highest in G, D, and IE subtypes. OS analysis revealed a significant association between TME subtypes (TLS = baseline; log HR G = 0.87, $p < 0.05$; IE = 0.39, $p = 0.18$; F = 0.99, $p < 0.05$; D = 1.21, $p < 0.05$), and survival outcomes. The immune-enriched subtypes, IE and TLS, demonstrated good prognosis and higher expression of immune checkpoint genes, while immune desert D and granulocyte-enriched G subtypes exhibited the worst OS.

Using our transcriptomic-based approach, BLBC was classified into 5 distinct subtypes, each with unique therapeutic vulnerabilities. Further investigation of these TME subtypes may lead to potential clinical utility as a prognostic tool to improve clinical decision making.

Table. Characteristics of Basal-like breast cancer (BLBC) tumor microenvironment (TME) subtypes.

TME Subtypes	G	IE	TLS	F	D
<i>Fges, median z-score</i>					
Proliferation signature	0.33	0.56	-0.59	-0.52	0.57
T cells signature	-0.23	0.36	1	-0.29	-0.93
B cells signature	-0.24	0.1	1.36	-0.4	-0.53
TLS signature	-0.18	0.21	0.98	-0.25	-0.92
Granulocyte traffic signature	1.5	-0.11	-0.07	-0.12	-0.26
CAF signature	0	-0.67	0.02	0.84	-0.47
<i>Pathology analysis</i>					
Median lymphocyte immune infiltration area, mm²	6.24	5.32	7.06	2.37	2.32
Median TLS area, mm²	1.05	1.34	2.33	0.49	0.35
% of samples with high fibrosis, manual annotation	19%	20%	30%	42%	23%
<i>Samples with high RNA expression (high ≥ 0.83 quantile of the cohort)</i>					
CD274 expression	21%	28%	31%	4%	3%
CTLA4 expression	10%	21%	44%	4%	3%
PDGFRB expression	2%	0%	10%	49%	2%
VGFR2 expression	10%	6%	20%	30%	8%
<i>Overall survival (OS), 60 months</i>					
OS, %	71%	80%	85%	64%	60%
Log hazard ratio (p-value)	0.87 (<0.05)	0.39 (=0.18)	0	0.99 (<0.05)	1.21 (<0.05)

TLS - Tertiary lymphoid structures; CAF - cancer-associated fibroblasts

Survival differences between HER2-zero and HER2-low-expressing breast cancer—A meta-analysis of early breast cancer patient data from 12 studies including 39831 patients

Presenting Author(s) and Co-Author(s):

Xiaoqi Zhang, *n/a, Master - Guangdong Provincial People's Hospital*

State: Gansu

Country: China (People's Republic)

Ciqiu Yang, *Attending doctor, Doctor of Medicine - Guangdong Provincial People's Hospital*

State: Guangdong

Country: China (People's Republic)

Kun Wang, *n/a, Professor - Guangdong Provincial People's Hospital, Guangzhou, Guangdong, China*

State: Guangdong

Country: China (People's Republic)

Background:

HER2-low-expressing breast cancer takes up 40-50% in all breast cancer subtypes. Survival difference between HER2 low expression and HER2-zero breast cancer remains controversial. Therefore, the aim of this study was to compare the survival outcome of the two subtypes and to explore the impact of hormone receptor status.

Methods:

A comprehensive medical literature search was performed by PubMed, EMBASE, and the Cochrane Library through June 2022. We included observational studies reporting hazard ratios (HRs) with corresponding 95% confidence intervals (CIs). The results of individual studies were pooled by fixed-effects models. Twelve articles with a total of 39,831 breast cancer patients were included in the meta-analysis.

Results:

We observed a statistically significant association between low HER2 expression levels and better breast cancer survival outcomes (OS: HR: 0.82; 95% confidence interval: 0.77, 0.88; DFS/RFS: HR: 0.88; 95% confidence interval: 0.83, 0.93). In a subgroup analysis, we found that HER2-low patients had better survival outcomes among hormone receptor-positive breast cancer patients (OS: HR: 0.85; 95% confidence interval: 0.78, 0.92; DFS/RFS: HR: 0.90; 95% confidence interval: 0.84, 0.96). Similarly, in triple-negative breast cancer patients, we also observed a positive association between HER2 low expression and better survival (OS: HR: 0.78; 95% confidence interval: 0.69, 0.87; DFS/RFS: HR: 0.86; 95% confidence interval: 0.77, 0.94).

Conclusions:

Our study showed that HER2 low expressing breast cancer had better survival outcomes compared to HER2 negative breast cancer in patients with early stage breast cancer, regardless of hormone receptor status. The result has a positive effect on us to further explore the clinical features, molecular characteristics and better treatment strategies of HER2-low-expressing breast cancer.

Forest plot of HER2 low expression and overall survival in overall population

Forest plot of HER2 low expression and disease free survival or relapse free survival in overall population

Division of Breast Surgery, Brigham and Women's Hospital, Boston, MA 02215 Background Recently defined molecular subtypes of triple negative breast cancer (TNBC) show distinct clinical outcomes and suggest new therapeutic targets but have not been integrated into current pathologic classification

systems. Here, we describe the histopathologic features of TNBC according to four molecular subtypes: basal-like immune activated (BLIA), basal-like immune suppressed (BLIS), luminal androgen receptor (LAR) and mesenchymal (MES), classified using the NanoString BC360 gene expression assay. Methods Stage II and III invasive breast cancers were identified in the Kaiser Permanente (KP) clinical pathology archives (2005-2015) and triple negative status was determined from the KP Northern California Cancer Registry data on immunohistochemistry. Selected slides were reviewed by two pathologists who recorded key histopathologic features [histologic subtype, presence of apocrine, metaplastic or micropapillary features, nuclear grade, mitotic score, and Tumor Infiltrating Lymphocytes (TILs)] and marked the best tumor areas for molecular analysis. TILs were evaluated according to the guidelines of the International TILs Working Group. Cases were macrodissected and evaluated using the NanoString BC360 gene expression assay. Histologic features were then summarized according to molecular subtype. Results Of 72 TNBCs, 60 were classified as Basal-like (83.3%), 7 as HER2-enriched (9.7%) and 5 as Luminal A (6.9%). 41 cases were classified as BLIA (56.9%), 14 as BLIS (19.4%), 13 as LAR (18.0%) and 4 as MES (5.5%). Both BLIA and BLIS tumors showed uniformly high nuclear grade and high mitotic score but differed significantly in TILs (BLIA average 32% vs BLIS average 9%; p value< 0.001, t-test for mean difference in TILs). The majority of LAR cases (69%) showed apocrine differentiation, not present in any other molecular subtype (p value< 0.001, chi-square test for presence of apocrine differentiation). LAR cases showed high nuclear grade but a lower average mitotic score (average score of 2) compared with the basal-like subtypes. TILs in LAR tumors were intermediate (17%) between BLIA and BLIS tumors. Of the 4 MES cases, all showed high nuclear grade. TILs in the MES cases were also intermediate (14%) between BLIA and BLIS tumors. Other histologic features, including lobular subtype, metaplastic and micropapillary features were not associated with specific triple negative molecular subtypes. Conclusion TILs are high in the BLIA molecular subtype (average 32%), low in the BLIS subtype (average 9%) and intermediate in LAR (average 17%) and MES (average 14%) subtypes. Apocrine features, if present in a TNBC, are a strong predictor of LAR molecular subtype. The inclusion of TILs and apocrine features (both easily derived from H&E slides) in routine pathology reporting could improve the classification of TNBC and aid in the identification of patients more likely to respond to specific therapies for the BLIA, BLIS and LAR subtypes, especially in resource-limited settings.

Background: Tumor and microenvironment features, including luminal phenotype as well as metabolic, immune and stroma activation, impact prognosis and treatment response in HER2-positive breast cancer. Here, we aimed to identify subgroups depicting biological processes associated with prognosis in patients receiving adjuvant trastuzumab in the phase III ALTTO trial, and to validate their biological and prognostic characteristics in the phase III neoadjuvant NeoALTTO trial. Methods: By applying a case-control approach (1:2), we selected from the ALTTO trastuzumab arm 134 and 268 patients with and without a distant relapse respectively, matched for clinicopathological characteristics. In ALTTO, RNA was obtained from FFPE tumor cores from surgical samples. RNA sequencing (RNAseq) data available from 254 frozen pre-treatment samples were used for validation in patients receiving trastuzumab and/or lapatinib in NeoALTTO. The Absolute Intrinsic Molecular Subtyping (AIMS) was used to compute PAM50 subtypes. Prognostic genes were identified using a multivariable Cox proportional hazard model (controlling for clinicopathological characteristics and PAM50 HER2-enriched [HER2-E] vs others) for distant relapse-free survival (DRFS). Clusters were identified using non-negative matrix factorization (NMF) and k-means clustering, and characterized with gene expression profiling and Gene Set Variation Analysis (GSVA, hallmark gene sets from MSigDB). Aiming at identifying the subgroups in external cohorts, we identified relevant genes to develop group-specific signatures with LASSO regression, and used the derived scores to build a multinomial classifier. Results: The case-control cohort includes a high-risk population, with higher proportions of >2cm, node positive and G3 tumors compared to the whole ALTTO trastuzumab arm. RNAseq data were generated for 386/402 patients. NMF and k-means clustering performed on genes associated with DRFS (false discovery rate < 0.05) identified 4 groups with distinct biological characteristics and prognosis: immune-enriched (IM, N = 69), proliferative/metabolic (P/M, N = 87, characterized by glycolysis, cholesterol homeostasis and proliferation pathways), mesenchymal/stroma-enriched (M/S, N = 76, characterized by epithelial-mesenchymal transition, angiogenesis and TGF-beta signaling), and hormone receptor positive-enriched (N = 154), further divided into PAM50 HER2-E (N = 91) and non-HER2-E (N = 63, LUM, mainly luminal A/B tumors). The IM and LUM groups presented better DRFS (91% and 87% 5-year DRFS, respectively) compared to the others (5-year DRFS of

72%, 58% and 51% for HER2-E, M/S and P/M, respectively). The gene expression-based classifier identified the same 5 groups in NeoALTTO. GSVA analysis and comparisons among the 5 groups showed similar results in the two studies. Of interest, we observed significant differences in event-free survival in NeoALTTO ($P = 0.035$ and $P = 0.041$ in the whole population and in the subgroup with residual disease, respectively), with IM and LUM presenting better outcomes compared to the other groups. Sensitivity to neoadjuvant treatment as described by pathological complete response (pCR, ypT0/is ypN0) differed across the groups, with LUM presenting lower pCR rates (8%) compared to HER2-E (40%), IM (35%), P/M (32%), and M/S (32%). Conclusions: Five biologically-driven HER2-positive breast cancer subgroups were identified in ALTTO, highlighting the heterogeneity of this disease. Of note, their biological features and clinical behavior were validated in the NeoALTTO population, suggesting the robustness of our findings. IM and LUM tumors could be considered for treatment de-escalation approaches. Additional validation in cohorts receiving standard (neo)adjuvant therapies is warranted.

Background: Prior studies in breast cancer (BC) have demonstrated variability in the immune microenvironment of BCs across subtypes, with higher levels of immune infiltration observed in triple-negative (TN) BC. Clinical trials of immunotherapy in BC have largely targeted patients with TNBC, however many of these patients do not respond to treatment, suggesting heterogeneity across TN tumors. Further, immune infiltrated hormone receptor–positive, HER2-

negative (HR+/HER2-) tumors have been observed. Patients with these tumors may benefit from immune checkpoint blockade (ICB). Identification of patients with immunogenic tumors would be valuable for future patient selection and stratification in clinical trials. In this study, we conducted comprehensive molecular profiling of a set of commercially procured BC samples to characterize the tumor microenvironment (TME) of HR+/HER2- and TN tumors and to identify patient or tumor features associated with immune infiltration. Methods: 163 surgically resected BC samples were used for this study (93 HR+/HER2-, 70 TN). Clinically validated immunohistochemistry (IHC) assays were used to evaluate the expression of two immune checkpoint (IC) molecules, PD-L1 (by VENTANA PD-L1 (SP142) Assay and Agilent PD-L1 IHC 28-8 pharmDx) and LAG3 (antibody clone 17B4). The presence of CD8+ cells was measured by IHC (Dako/Agilent clone C8/144B) and used to derive the spatial location and density (topology) of CD8+ cells within the TME. RNA sequencing (RNA-seq) was used to construct gene expression signatures representative of immune cell types. Furthermore, RNAseq data was used to identify expressed somatic mutations and to calculate the total expressed tumor mutational burden ('eTMB'). Results: As previously reported, the prevalence of PD-L1 + tumors was higher in TN vs HR+/HER2- BC, however close to half (44.1% SP142 IC> 1%) of HR+/HER2- tumors showed some degree of PD-L1 expression. Similar patterns were observed for LAG3 IHC expression (32.3% and 64.7% of HR+ and TN tumors respectively with >1% expression). Concordant expression of the two markers (SP142 IC> 1% and LAG3 >=1% or < 1% and < 1%) was observed in approximately 80% of tumors in both subtypes. Less than 10% of tumors in both subtypes had high LAG3 (>1%) and low PD-L1(< 1%) expression. Most (82.4%) HR+/HER2- tumors in the dataset were deficient in CD8+ cells in both stroma and tumor parenchyma, however a subset (12.9%) were identified as having an 'excluded' CD8 pattern, and four (4.7%) were classified as 'inflamed'. The frequency of both the excluded and inflamed states was slightly higher among the TN tumors (20.6% and 15.9% respectively). Expression of PD-L1+ occurred more frequently among tumors with higher CD8 expression. Among both TN and HR+ tumors, most 'inflamed' tumors were grade 3. We also examined a range of gene expression signatures representative of various immune cell subpopulations, their distribution within each subtype, and relationships with other molecular data. For example, expression of a CXCL13+ T cell signature, a cell type that has been shown to be predictive of response to anti-PD-L1 + chemo combo therapy in TNBC, was significantly higher in TN vs HR+ tumors, however, a large subset of HR+ tumors had levels of expression of the signature above the median observed in TN tumors. In addition, we noted that eTMB, while low overall, was positively correlated with certain immune-related expression signatures across HR+/HER2- samples, including signatures previously associated with improved response to ICB, as well as PD-L1 positivity. Conclusions: We observed heterogeneity in the immune profile of the real-world HR+ and TN tumors in this cohort. A subset of tumors in both subtypes expressed markers or signatures previously reported to be associated with response to ICB. (1) Cancer Cell. 2021 Dec 13;39(12):1578-1593.e8.

Background: Morphological features of cancer cell nuclei are routinely used to assess disease severity and prognosis, and cancer nuclear morphology has been linked to genomic alterations. Quantitative analyses of the nuclear features of cancer cells and other tumor-resident cell types, such as cancer-associated fibroblasts (CAFs), may reveal novel biomarkers for prognosis and treatment response. Here, we applied a pan-cancer nucleus detection and segmentation algorithm and a cell classification model to hematoxylin and eosin (H&E)-stained whole slide images (WSIs) of breast cancer specimens, enabling the measurement of morphological features of nuclei of multiple cell types within a tumor. Methods: Convolutional Neural Network models for 1) nucleus detection and segmentation and 2) cell classification were deployed on H&E-stained WSIs from The Cancer Genome Atlas (TCGA) breast cancer dataset (primary surgical resections; N=890). Separate models were trained to segment regions of stromal subtypes, such as inflamed and fibroblastic stroma. Nuclear features (area, axis length, eccentricity, color, and texture) were computed and aggregated across each slide to summarize slide-level nuclear morphology for each cell type. Next-generation sequencing-based metrics of genomic instability (N=774) and gene expression (N=868) were acquired and paired with TCGA WSIs. Gene set enrichment analysis was performed using the Molecular

Signatures Database. Spearman correlation compared nuclear features to genomic instability metrics. Linear regression was used to assess the relationship between nuclear features and bulk gene expression. Multivariable Cox regression with age and ordinal tumor stage as covariates was used to find association between overall survival (OS) and nuclear features. All reported results were significant ($p < 0.05$) when adjusted for false discovery rate via the Benjamini-Hochberg procedure. Results: Variation in cancer cell nuclear area, a quantitative metric related to pathologist-assessed nuclear pleomorphism, was calculated by the standard deviation of the nuclear area of cancer cells across a WSI. This feature was associated with genomic instability, as measured by aneuploidy score ($r=0.448$) and homologous recombination deficiency score ($r=0.382$), and reduced OS. In contrast, the variability in fibroblast and lymphocyte nuclear areas did not correlate with either metric of genomic instability (all $r < 0.1$, $p > 0.05$). Furthermore, an association between variation in cancer cell nuclear area with the expression of cell cycle and proliferation pathway genes was observed, suggesting that increased nuclear size heterogeneity may indicate a more aggressive cancer phenotype. Features quantifying CAF nuclear morphology were also assessed, revealing that CAF nucleus shape (larger minor axis length) was associated with lower OS, as well as the expression of gene sets involved in extracellular matrix remodeling and degradation. Conclusions: The nuclear morphologies of breast cancer cells and CAFs reflect underlying genomic and transcriptomic properties of the tumor and correlates with patient outcome. The application of digital pathology analysis of breast cancer histopathology slides enables the integrative study of genomics, transcriptomics, tumor morphology, and overall survival to support research into disease biology research and biomarker discovery.

Background: Spatial transcriptomics and proteomics are cutting-edge techniques that allow for quantification of RNA and protein expression within separate cell populations or regions of interest in a tissue biopsy specimen. We aimed to independently characterize the tumor cells and immune infiltrate in metastatic site biopsy specimens from patients with somatic or germline BRCA1/2 mutations. Methods: We performed spatial transcriptomics and proteomics using the Nanostring GeoMx Digital Spatial Profiler (DSP) on 9 formalin-fixed paraffin-embedded (FFPE) tissue biopsy specimens from 5 patients with metastatic breast cancer and a known somatic or germline BRCA1/2 mutation. Each patient had 1-3 separate metastatic site tissue biopsy specimens. Cell populations of interest were delineated with fluorescently labeled antibodies to pan-cytokeratin on tumor cells, CD45 of immune cells, and a nuclear stain. On each sample, 4-5 regions of interest (ROIs) were selected near the interface of the metastatic tumor deposit and surrounding normal tissue. Each ROI was segmented into 3 areas of interest (AOIs): pan-cytokeratin-positive tumor cells, CD45-positive immune cells, and the remaining stromal cells negative for both pan-cytokeratin and CD45. Data was background corrected and normalized with internal negative and positive internal controls. Relative abundance of immune cell subtypes was derived from CD45+ cell gene expression data using the TIMER algorithm. Results: The expression of 57 proteins and 84 RNAs was quantified in each of the 396 AOIs. Separate analysis of CD45+ cells, pan-cytokeratin cells, and stromal cell populations confirmed

expected differential expression of immune, tumor and stromal markers, respectively. Protein expression of the estrogen receptor (ER) and progesterone receptor (PR) on pan-cytokeratin-positive tumor cells using the DSP correlated with pathologist reviewed immunohistochemistry (IHC) for ER and PR. Significant differential expression was found within each cell population between hormone receptor (HR) positive and negative cohorts, including enrichment for S100B in HR negative samples. Comparison will be shown for expression of 14 overlapping genes/proteins. Immune cell compartment gene expression deconvolution showed heterogeneity in the relative proportion of infiltrating immune cell subtypes between samples and also between ROIs within a sample. Changes in gene and protein expression from a patient with 3 serial biopsy specimens can be tracked with substantial heterogeneity across distinct AOIs within individual specimens and across metastatic sites.. Conclusions: Spatial transcriptomics and proteomics is feasible for concurrent, relative quantification of protein and gene expression in tumor, immune, and stromal cells in FFPE tissue biopsies from patients with metastatic breast cancer harboring germline or somatic BRCA1 or BRCA2 mutations. Heterogeneity within individual samples and across serial time points offers opportunity for methods development in the analyses and interpretation of spatial transcriptomic/proteomic data.

Background

CDK4/6 inhibitors are the latest and highly specific CDK inhibitors approved for metastatic and early estrogen receptor (ER)-positive breast cancer patients, improving the survival outcomes. Prior preclinical research has indicated various aberrations of cell cycle regulation and activated oncogenic signaling pathway as the mechanisms of resistance to CDK4/6 inhibitors. However, there is currently no available biomarker except ER and human epidermal growth factor receptor 2 (HER2) in clinical practice. The aim of our study is to elucidate diverse mechanisms of acquired resistance of ER-positive breast cancers to CDK4/6 inhibitors and develop personalized medicine in ER-positive breast cancer patients.

Materials and methods

To generate resistant lines, the ER-positive human breast cancer cell lines MCF7 and T47D were treated individually with increasing concentrations of the CDK4/6 inhibitors palbociclib and ribociclib until a target concentration of 3 μ M for six months. Cells were maintained in RPMI 1640 containing 10% fetal bovine serum, 100 U/ml penicillin/streptomycin at 37°C in a 5% CO₂ incubator. Western blot analysis was performed for whole cell extract proteins from resistant cells to CDK4/6 inhibitors and parental cells. Colony formation assay was done to observe cell viability.

Results

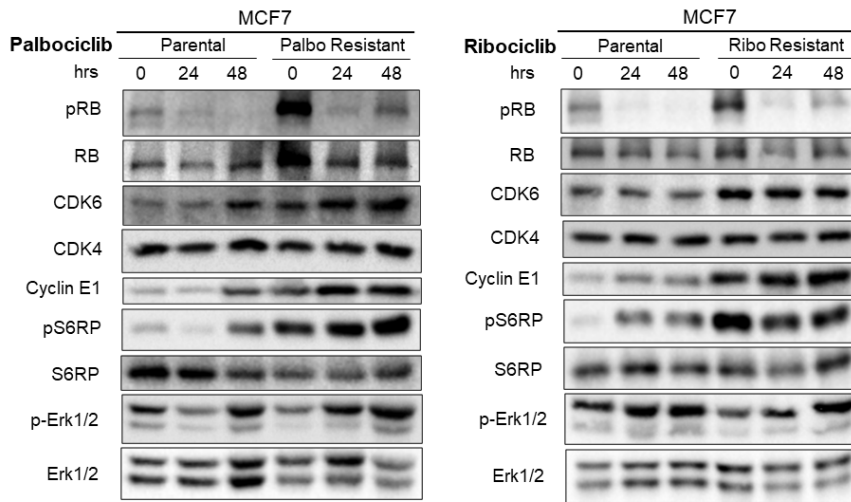

Western blot analysis showed elevated FGFR2, CDK6, pS6RP, and cyclin E1 in resistant cells

compared to parental cells. Specifically, cyclin E1 and pS6RP were increased in MCF7 palbociclib- and ribociclib-resistant cells, while FGFR2 and CDK6 in T47D palbociclib- and ribociclib-resistant cells. Notably, CDK6 was upregulated in MCF7 ribociclib-resistant cells, whereas increased cyclin E1 was detected in T47D palbociclib-resistant cells, respectively. Colony formation assay revealed acquired ability of resistance to CDK4/6 inhibitors in generated resistant cell lines.

Conclusions

The tumors harboring resistance to CDK4/6 inhibitors have heterogenous mechanisms of therapeutic resistance to these agents. The novel combination treatment of targeted molecular therapy and CDK4/6 inhibition will lead development of personalized medicine for ER-positive breast cancer based on elucidation of diverse resistant mechanisms to CDK4/6 inhibition.

Western blot analysis of lysates from MCF-7 cells treated for 24 to 48 hours with palbociclib (Palbo) and ribociclib (Ribo)

Cyclin E1 and pS6RP were increased in MCF7 palbociclib- and ribociclib-resistant cells, whereas CDK6 was upregulated especially in MCF7 ribociclib-resistant cells.

Western blot analysis of lysates from T47D cells treated for 24 to 48 hours with palbociclib (Palbo) and ribociclib (Ribo)

FGFR2 and CDK6 were increased in T47D palbociclib- and ribociclib-resistant cells, whereas increased cyclin E1 was detected especially in T47D palbociclib-resistant cells.

Viability in MCF7 ribociclib-resistant and parental cells by colony formation assay
Colony formation assay (Ribociclib)

Colony formation assay revealed acquired ability of resistance to CDK4/6 inhibitors in MCF7 resistant-cells.

Introduction: Phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha (PIK3CA) is mutated in ~40% of patients (pts) with hormone receptor-positive (HR+), human epidermal growth factor receptor 2-negative (HER2-) advanced breast cancer (ABC). PIK3CA mutations are associated with resistance to endocrine therapy (ET) and worse overall survival. Alpelisib (ALP), an α -selective PI3K inhibitor and degrader, is indicated in combination with fulvestrant (FUL) for pts with PIK3CA-mutated (mut) HR+, HER2- ABC following progression on/after ET-based treatments. In the Phase 2, open-label, 3-cohort, noncomparative BYLieve study, clinical benefit of ALP in combination with ET was observed in the post-cyclin-dependent kinase 4/6 inhibitor (CDK4/6i) setting in pts with PIK3CA-mut, HR+, HER2- ABC. Here we report the results of a biomarker analysis using paired baseline (Cycle 1 Day 1) and end-of-treatment (EOT) circulating tumor DNA (ctDNA) samples from pts in BYLieve Cohorts A and B.

Methods: In the BYLieve study, pts with PIK3CA-mut, HR+, HER2- ABC had CDK4/6i + aromatase inhibitor (Cohort A; N=127) or CDK4/6i + FUL (Cohort B; N=126) as treatment immediately prior to receiving ALP + FUL and ALP + letrozole, respectively. In this biomarker analysis, gene alterations were detected in ctDNA at baseline and EOT using next-generation sequencing (PanCancer V2 panel). Pts included in this interim analysis had confirmed PIK3CA mutations and matched baseline/EOT samples with enough sequencing coverage and ctDNA fraction to detect mutations at both time points. ctDNA fractions, tumor mutation burden (TMB) distributions, genomic landscapes, gain/loss of PIK3CA and estrogen receptor 1 (ESR1), chromosome 8/11 amplification profiles, and alterations in PI3K pathway and potential CDK4/6i resistance markers were assessed across time points. Sample sizes were small; results should thus be interpreted with caution.

Results: Forty-three pts were included in the Cohort A biomarker population and 40 pts were included in Cohort B. ctDNA fraction was numerically higher at EOT compared with baseline in both cohorts; further analyses will be presented. In Cohort A, no significant differences were observed in TMB at EOT compared with baseline ($P=0.21$). In Cohort B, TMB was higher at EOT compared with baseline ($P=0.053$). Chromosome 8/11 amplifications were consistent between baseline and EOT for both cohorts. Small variations were observed in ESR1/PIK3CA mutations between baseline and EOT on both cohorts (Table). The status of potential CDK4/6i resistance markers was relatively unchanged at EOT (Table). Loss-of-function mutations in PTEN, a known PI3K inhibitor resistance marker, increased from 9% at baseline to 14% at EOT in Cohort A and from 12% at baseline to 22% at EOT in Cohort B.

Conclusions: Between baseline and EOT, only small variations in gene alterations in PIK3CA-mutated HR+, HER2- ABC were observed in the post-CDK4/6i setting. As the disease progressed, increases in loss-of-function mutations in PTEN at EOT in both Cohorts A and B suggested loss of PTEN in PI3K pathway may drive resistance to ALP. Early intervention with ALP, when the tumor is particularly driven by PIK3CA oncogenic mutations and before it develops more genomic complexity, may potentially provide better clinical outcomes.

Table. Gene Alteration Gain/Loss at Baseline/EOT Across Cohorts A and B

Background: ESR1 hotspot mutations (HS) (i.e. 380, 536, 537, and 538) are important drivers of resistance to aromatase inhibitors, but the differential impact of genomic variants (HS vs non-HS) on response to endocrine therapies (ET) under clinical development, such as novel oral Selective Estrogen Receptor Degraders and Modulators (SERDs and SERMs), is not known. The aim of the study was to evaluate the impact of non-HS ESR1 mutations on the pharmacodynamics of SERDs and SERMs as an additional ET resistance mechanism. Materials and Methods: The study analyzed a multi-institutional cohort of 1008 patients with hormone receptor positive metastatic breast cancer characterized by circulating tumor DNA (ctDNA). Pathway classification was defined based on previous work (i.e. RTK, RAS, RAF, MEK, NRF2, ER, WNT, MYC, p53, Cell Cycle, Notch, PI3K). Single nucleotide variations (SNVs) were annotated through OncoKB; co-occurrence was tested by Fisher's exact test. A structure-based computational strategy was used to create 3D-models of ESR1 mutants and predict changes in binding affinity (dAff) across approved and experimental drugs. A positive dAff reflects a lower affinity of the drug for mutant ESR1 compared with wild type and thus a

potential for a reduced response. Results: Among the total 680 detected ESR1 mutations, 633 were missense, and 631 were gain-of-function. The most frequent mutations were in codon 537 (N=305), followed by 538 (N=224). No significant MAF differences were observed across ESR1 variants (P=0.0829). The L391F mutation resulted in an increased binding affinity for Lasofoxifene (LAS) (dAff -0.34), Giredestrant (GIR) (dAff -0.18), Elacestrant (ELA) (dAff -0.08) and Amcenestrant (AMC) (dAff -0.41), while a decreased binding affinity was observed for 4OH-Tamoxifen (TAM) (dAff 0.01), Imlunestrant (IML) (dAff 0.15), Fulvestrant (FUL) (dAff 0.43), and Camizestrant (CAM) (dAff 0.02). V392F decreased binding affinity for TAM (dAff 0.05), LAS (dAff 0.13), IML (dAff 0.11), GIR (dAff 0.11), FUL (dAff 0.04), CAM (dAff 0.05), AMC (dAff 0.06) but not for ELA (dAff -0.01). F404L decreased binding affinity for FUL (dAff 0.07), ELA (dAff 0.73), and CAM (dAff 0.26), while it increased binding affinity for TAM (dAff -0.27), LAS (dAff -0.02), IML (dAff -0.05), GIR (dAff -0.69), and AMC (dAff -2.01). G415E increased binding affinity for LAS, (dAff -0.15) GIR (dAff -0.02) and ELA (dAff -0.08), while it decreased binding affinity for TAM (dAff 0.11), IML (dAff 0.09), FUL (dAff 0.29), CAM (dAff 0.19) and AMC (dAff 0.10). Mutations in codon 537 did not affect dAff for TAM, GIR, and ELA; a significant decrease in binding affinity was observed for FUL and AMC, whereas it was increased for LAS. Mutational co-occurrence was tested between ESR1 mutations in FUL docking sites and oncogenic pathways. Significant associations were observed for cell cycle SNVs (P=0.047), Notch SNVs (P=0.020), and ER SNVs (P< 0.001). Within these pathways, significant single-gene associations were observed for FBXW7 SNVs (P=0.020), ESR1 SNVs (P< 0.001), and GATA3 SNVs (P= 0.016). Given the highly significant co-occurrence of non-HS with other ESR1 mutations, combined models were examined. The Y537/F404 combination resulted in decreased binding affinity for FUL and increased binding affinity for LAS, while L536/F404 decreased binding affinity for TAM and increased binding affinity for IML, ELA, and AMC. Notably, L540/F404 restored the FUL-ESR1 interaction resulting in an increased binding affinity (dAff -2.1). Conclusions: The study suggests that genomic variability in drug targets detectable through ctDNA may modulate therapeutic response. Preclinical models are under development to investigate the combined endocrine resistance mechanism suggested by the significant co-occurrence between ESR1 mutations in SERDs/SERMs docking sites and ESR1 hotspot mutations and provide valuable additional insights for drug development and future treatment algorithms.

Breast cancer is a leading cause of female mortality and despite advancements in diagnostics and personalized therapeutics, metastatic disease largely remains incurable due to drug resistance. The druggable estrogen receptor (ER, ESR1), overexpressed in two-thirds of all breast cancer, evolves in 30% of tumors exposed to endocrine therapy consequently resulting in treatment resistance. A more recently discovered mechanism of ER mediated endocrine resistance is ER fusion proteins. ER fusions, found predominately in metastatic endocrine resistant disease, harbor ESR1 exons 1-6 fused to an in-frame gene partner due to an ESR1 intron 6 translocation break. Our lab has demonstrated that ER fusion proteins, which lack the C-terminal ligand-binding domain (LBD), recapitulate phenotypes of ER proteins harboring endocrine-resistant point mutations occurring in the LBD. Our research goals aim to 1) determine fusion prevalence and emergence, 2) understand fusion mechanisms of resistance and 3) explore alternative treatment options for our patients. The promiscuous nature of fusion partners hinders fusion detection by traditional sequencing and thus our research team has developed a novel ER fusion detection method, EnRich. The EnRich probe set (4,324 probes in total) is composed of two separate probe pools targeting at 2x tiling intronic and exonic ESR1, the upstream promoter region and select oncogenic genes. To optimize the EnRich pipeline,

DNA was extracted from a frozen tumor sample and a PDX model harboring ESR1-DAB2 and ESR1-LPP fusions, respectively. ESR1-DAB2 and ESR1-LPP were accurately detected by quantifying discordant paired-end or split reads mapped to chromosome 6. In addition, liquid biopsies from 15 patients with ER positive advanced breast cancer were also assessed through EnRich to uncover unidentified ESR1 structural variants. Two patient samples were detected to harbor ESR1 fusions (ESR1-CCDC170, ESR1-AKAP12 and ESR1-YAP1) and were further validated in corresponding mRNA. These recurrent and novel fusions were supported with more than 10 reads each, indicating that the EnRich pipeline is an effective and accurate sequencing approach to understanding ER fusion prevalence. Our lab, furthermore, has studied ER fusion proteins mechanistically. We have stably overexpressed ER fusions in transgenic breast cancer cell lines engineered with shRNA targeting the endogenous wildtype ER (ESR1-WT). In this ESR1-WT depleted cellular context, we found that ER fusions (notably ESR1-SOX9 and ESR1-YAP1) demonstrate ER hyperactivation through an estrogen response element (ERE) assay compared to ESR1-WT and a truncated exon 1-6 ESR1 (ESR1 Δ CTD). Importantly, fusion ERE activity was robust in the absence of the ER ligand, estradiol, as well as in the presence of endocrine therapies, implying ER fusion proteins function in a ligand independent, endocrine resistant mechanism. ER fusion positive cell lines were also enriched in oncogenic phenotypes such as enhanced 3D growth, cell survival via colony formation, and migration in a wound scratch assay. These enhanced metastatic potentials of the ER fusions were observed in both invasive ductal and lobular carcinoma cell lines, albeit at varying magnitudes depending on the 3' fusion partner and phenotype being assessed. Although the ER fusions harbored unique characteristics due to the C-terminal partner, transcriptomic profiling revealed that enhanced EMT and KRAS signaling signatures were shared among all fusions when compared to the ESR1-WT and ESR1 Δ CTD cell lines, which may serve as future exploitable drug targets. Comprehensive detection and functional evaluation of ER fusion proteins will provide clinicians and patients with better understanding of tumor endocrine-resistant prevalence and discovery of more effective treatment options.

Background: Recent studies suggest that enhancer reprogramming underlies heterogeneity and disease progression in estrogen receptor-positive (ER+) BC. Cell-type/state specific transcription is governed by high-order assemblies of master transcription factors (TFs) and epigenetically defined regulatory regions including super-enhancers (SEs). We previously showed that aberrant activation of the pioneer TF FOXA1 promotes enhancer and transcriptional reprogramming in endocrine-resistant BC, involving the ER and the AP-1 FRA1 and c-JUN TFs. As SEs maintain a robust cell-type/state specific core transcriptional regulatory

circuitry (CRC) in developmental and tumorigenic processes, we sought to identify key additional TFs in SE/FOXA1-driven CRCs in endocrine resistance, which could serve as attractive therapeutic targets. Methods: TF binding motif at the shared SEs (mapped by H3K27ac ChIP-seq) between MCF7-parental (P) cells with ectopic FOXA1 overexpression (OE) and the endogenous FOXA1-amplified tamoxifen-resistant (TamR) cells was analyzed by HOMER. ER-bound SEs distinguishing TamR vs. P cells were defined by integrating the SEs with our prior ER ChIP-seq data (PMID 28507152). KLF4 motif within these ER-bound SEs was scanned using FIMO and linked to nearby genes by intersection with the previously defined promoter-tethered regions (PTRs) (PMID 24141950). Differential gene expression in MCF7-TamR cells upon KLF4 knockdown (KD) by 3 unique siRNAs was analyzed using limma from edgeR. The biological and clinical significance of the KLF4-dependent genes was analyzed using Gene Ontology and survival modeling with METABRIC and the ER+ metastatic BC cohort (SABCS19-GS2-02). Cell migration was assessed by the wound-healing assay. Results: We identified KLF4 among the top enriched TF binding motifs at the shared SEs in FOXA1-overexpressing MCF7-P cells and the FOXA1-amplified TamR cells. Analysis of our prior RNA-seq data of MCF7-P and TamR cells upon OE or siRNA KD of FOXA1, FRA1, or c-JUN (PMIDs 27791031, 31826955, 32424275, SABCS21-PD1-05) revealed KLF4, the Yamanaka factor for induced pluripotent stem cells, as a common target activated by the FOXA1/FRA1/c-JUN axis. We next identified 44 genes commonly down-regulated upon KLF4 KD in the MCF7-TamR cells. This KLF4-dependent 44-gene set was enriched in biological processes of embryonic development and tumor progression, preferentially dependent on ER in MCF7-TamR vs. P cells, highly elevated in ER+ metastases vs. primary tumors, and associated with poor outcome in ER+ BC treated with endocrine therapy. KLF4 KD, using the 2 siRNAs that generated similar pathway perturbations in MCF7-TamR cells, reduced TamR cell migration. Notably, among the genes co-dependent on KLF4 and ER in TamR cells, PYGB was the only gene with a PTR residing in an ER-bound SE established in TamR but not P cells. Glycogen phosphorylase B, encoded by PYGB, is the rate-limiting enzyme in glycogen degradation and plays a role in the progression of various tumors. Expression of KLF4, FOXA1, and FRA1 are commonly activated during the differentiation of human embryonic stem cells into foregut endoderm and in the inner core of fibroblasts of first-trimester human placenta villi, suggesting a unique role of KLF4 in mediating lineage-specific CRC, possibly by engaging PYGB and the glycogen metabolic pathway in advanced ER+ disease. Conclusions: Using SE-oriented integrative bioinformatics, we identified KLF4 as a potential novel target in the FOXA1/AP-1 transcriptional axis. As KLF4 binding motif resides in the unique ER-bound SEs of TamR cells, KLF4 likely forms an auto-regulated loop amplifying CRC in transcriptional reprogramming, among which the PYGB/glycogen metabolic pathway merits further investigation in endocrine-resistant ER+ disease.

Next-generation oral selective estrogen receptor degraders (ngSERDs) are aiming to become the backbone endocrine therapy (ET) for patients with estrogen receptor positive (ER+) breast cancer (BC) by achieving greater ER signaling blockade than current therapies and tackling key mechanisms of resistance. Camizestrant (AZD9833) is an ngSERD for the treatment of ER+ BC which has demonstrated selective ER α degradation, pure ER antagonism and significant anti-tumor activity in ESR1 wild-type (ESR1wt) and mutant (ESR1m) tumors, as well as encouraging clinical activity in early phase trials. ER+ BC is responsive to therapies targeting ER α and CDK4/6 signaling in the adjuvant and metastatic settings. To explore camizestrant combination potential as a backbone ET, camizestrant was partnered with either palbociclib or abemaciclib in CDK4/6 inhibitor (CDK4/6i) naïve and resistant in vitro and in vivo models. Combination benefit was observed in vitro in 3 parental ER+ BC cell lines, moreover camizestrant plus abemaciclib showed activity in palbociclib-resistant cell lines including lines harboring CCNE1amp and RB1 loss. In vivo, combination of camizestrant and either CDK4/6i was well tolerated with the combinations promoting improved efficacy in ESR1wt and ESR1m PDX tumor models compared to monotherapy arms. ER+ BC has a high prevalence of alterations in the PI3K/AKT/PTEN pathway which provides opportunities for treatment with PI3K/AKT pathway inhibitors. Camizestrant delivered enhanced efficacy when combined with mTORC1 inhibitor everolimus and AKT inhibitor capivasertib in CTC-174, an ESR1m and PI3KCAm tumor model. Additionally, combination with capivasertib was more efficacious than single treatments, at clinically relevant dose and schedules, in both PI3Kwt and mutated pathway in PDX models. These data demonstrate the interplay between PI3K/AKT/PTEN pathway inhibition and camizestrant mechanism of action. Finally, we explored a potential triple combination of camizestrant, capivasertib and palbociclib in Palbociclib-resistant models representative of PI3KCA/AKT/PTEN wt and altered tumors. This strategy delivered robust efficacy across these models comparing to single treatments and double combinations. The triplet led to durable regressions at clinically achievable doses of all compounds, irrespective of genetic background and aligned to biomarker modulation of the three signaling axis. These preclinical data demonstrate the potential of camizestrant to become the backbone ET, with high combinability in vivo with inhibitors of CDK4/6, mTOR and AKT. These combinations demonstrate the opportunity to impact care of patients with early and metastatic ER+BC, delivering benefit to broad patient populations including those with ESR1wt or ESR1m tumors, independent of PI3K/AKT/PTEN pathway mutation status, and in patients with both CDK4/6i sensitive and resistant tumors.

Therapeutic effect of tamoxifen (Tam) against ER+ breast cancer (BC) is known to be mediated by its binding to estrogen receptor-alpha (ER α /ESR1) and inhibiting estrogen signaling leading to altered gene expression. Besides this canonical mode of function, our pre-clinical studies had revealed a novel mechanism wherein ESR1 directly binds wild type p53 (wt TP53) resulting in repression of its tumor suppressor functions, and Tam blocks this inactivation of TP53. Although patients with Luminal Tumors expressing wt TP53 are known to be more responsive to tamoxifen therapy, the underlying mechanism in tumors has remained unknown. To test the hypothesis that abrogation of the ESR1-mediated functional inactivation of TP53 is one of the major mechanisms that underlie the early effects of Tam therapy, we conducted a window of opportunity clinical trial in newly diagnosed luminal breast cancer patients undergoing surgical therapy. Methods: 59 women with ER+ invasive BC were randomized to 20mg Tam daily for 28 days prior to surgery or standard of care (SOC). TP53 status was confirmed by massively parallel sequencing. ER+ wt TP53 tumors were included in the study. IHC was performed on FFPE tissue from tumors to compare expression of ESR1 and TP53 along with their selected downstream targets. ESR1-TP53 interaction in situ was determined by Proximity Ligation Assay (PLA). 17 β -estradiol and Tam metabolites were measured in the plasma, tumor, and surrounding normal tissue using LC-MS/MS. Global transcriptome analysis in tumors was conducted by RNA-seq. Proteome expression in resected tumors was analyzed by reverse phase protein array (RPPA) with 216 proteins. Findings: Importantly, IHC on tumor tissues showed that the levels of ESR1 and TP53 were not altered in response to Tam therapy, whereas ESR1-TP53 interaction was considerably disrupted by Tam (in situ PLA data). Differential gene expression (DGE) analysis using DESeq2 R package followed by GSEA pathway analysis showed that 307 genes were differentially expressed ($p < 0.05$) ($\log FC > 1.5$) in tumors from Tam-treated versus untreated patients in response to Tam therapy. Pathways

representing TP53 signaling, stem cells, and low-grade luminal breast cancer were upregulated in the Tam treated group while those representing adipogenesis, invasive breast cancer, estradiol response, ras signaling, and E2F targets were downregulated. “Master Regulators” identified by iRegulon included several p53 targets. Integration of RNA-seq and RPPA data revealed that DEGs fall into three categories: (i) regulated by TP53, (ii) regulated by ESR1, and (iii) regulated by both TP53 and ESR1. Together, the data demonstrated that in addition to its conventional effects mediated by its binding to ESR1 and inhibiting estrogen signaling leading to altered gene expression, Tam disrupted the ESR1–TP53 interaction leading to functional reactivation of TP53 and reprogramming of gene expression. Conclusions: Our data 1) support ESR1–TP53 crosstalk in tumors as a novel mechanism underlying endocrine therapy response of luminal BC patients, and 2) highlight the importance of factoring TP53 into therapeutic strategies for ER+ BC patients, and 3) have implications in stratifying ER+ BC patients to those who will or will not be responsive to Tam therapy.

Background: Endocrine therapy (ET) is the mainstay of ER+ BC treatment. However; up to 20% of ER+ BC tumors progress into metastatic disease and develop ET resistance, underscoring the need for combination therapies. Preclinical data suggest that combining phosphatidylinositol 3-kinase (PI3K) inhibitors with ET may overcome resistance. OPPORTUNE, a preoperative phase II window trial, evaluated whether the combination of the PI3K inhibitor pictilisib with

anastrozole (PIC+ANA) can increase the antitumor effect of ANA in newly diagnosed operable ER+ BC. Early results showed greater suppression of tumor Ki67 in patients treated with PIC+ANA versus ANA alone. Here, we present gene expression analysis from tumors collected pre- and post-treatment, and their associations with Ki67 outcomes. Methods: Postmenopausal women with newly diagnosed operable ER+/HER2-negative BC were randomly allocated (2:1, favoring the combination) to 2 weeks of preoperative treatment with ANA 1 mg once per day (n = 47) or the combination of ANA 1 mg with PIC 260 mg once per day (n = 89). The primary end point was inhibition of tumor cell proliferation measured by change in Ki67 protein expression via IHC between tumor samples taken pre- and post-treatment. Samples were analyzed by RNA-sequencing—ER pathway activity, PAM50 intrinsic subtypes, and pathway analyses were assessed by Ki67 outcomes. Elastic net regression analysis and transcription factor activity inference with Dorothea were performed to identify features strongly associated with Ki67 outcomes. Results: 124 patients (ANA, n=43; PIC+ANA, n=81) had paired tumor samples at baseline/week 2 that were evaluable for both Ki67 and RNA-seq. PIC+ANA showed improved suppression of Ki67 compared to ANA alone (-83.78% vs -73.85%, p=0.012) and a greater proportion of patients achieved complete cell cycle arrest (CCCA, as defined by Ki67< 2.7%) in the PIC+ANA arm (45.68% vs 36.59%). ER pathway activity suppression was comparable between treatments. PAM50 classification based on RNA-seq showed that 83.0% of tumors were luminal (Lum) A at baseline and 12.9% were LumB, with the remainder being classified as Normal-like. PIC+ANA showed greater suppression of Ki67 in LumB tumors compared to LumA (-92.29% vs -81.62%). This effect was much greater in the PIC+ANA arm compared to LumB tumors treated with ANA alone (-92.29% vs -37.87%); however, given the low number of LumB tumors in the ANA arm (n=3), we could not determine statistical significance. Bioinformatic analysis of RNA-seq from baseline specimens showed that MYBL2 activity was associated with resistance to ANA (as defined by Ki67≥7.5% at week2). Tumors in the top quartile of MYBL2 activity at baseline showed improved Ki67 outcomes in the PIC+ANA arm compared to ANA alone (-91.71% vs -51.44%), while no differences were observed between treatments for tumors with lower MYBL2 activity (-79.16% vs -76.72%). Single-nucleus (sn)-RNA-seq from untreated ER+ BC tumors showed that MYBL2 was enriched in a single cluster of tumor cells, which also had the highest expression of a subset of actionable targets (including CDK1, CDK2, CDK4, EZH2, and AKT1), as compared to other tumor cells. Expression data from DepMap and drug-sensitivity data from ER+ BC cell lines show a positive trend between high MYBL2 expression and sensitivity to the ER degrader, giredestrant. Conclusions: PIC exhibited greater antiproliferative effects in combination with ANA in ER+/HER2- early BC compared to ANA alone, particularly in LumB and MYBL2-high tumors. Furthermore, the transcriptional profile and in vitro response of tumor cells with high MYBL2 expression suggest potential sensitivity to other combination therapies.

Background: Aromatase inhibitors (AIs) are highly effective at reducing recurrences and mortality in postmenopausal patients with estrogen receptor positive breast cancer (ER+ BC). Poor anti-proliferative (Ki67) response or ER+ BCs to AIs after 2 weeks is associated with worse long-term outcomes. Factors that relate to the degree of the response may identify markers and/or mechanisms of resistance. Methods: The PeriOperative Endocrine Therapy for Individualizing Care (POETIC) trial randomized 4,480 with ER+ BC to 2 weeks' AI before surgery or no presurgical treatment. All patients within the bottom 15% of Ki67 responders to AI (poor responders [PRs]; n=177 with RNA extracted) were selected from and matched to good responders (GRs) within the 50% showing the best response (n=190). Matching was based on baseline Ki67 levels as measured by immunohistochemistry (IHC). Response to AI was measured by the percentage change in Ki67 after 2 weeks' treatment. PRs were further divided into groups expressing high ESR1 (PRs ESR1HIGH; n=119) and low ESR1 (PRs ESR1LOW; n=58) levels since there were very few GRs with low ESR1. RNAseq, targeted exome DNA sequencing of 87 BC/resistance related genes and measurement of plasma estradiol levels by mass spectrometry were performed to understand mechanisms of de novo resistance. Intrinsic subtypes were estimated from RNAseq data. Results: More than 90% of PRs ESR1LOW were non-luminal subtypes with low expression of estrogen-responsive genes. In contrast, 11% of PRs ESR1HIGH were non-luminal compared to 4% of GRs but only HER2-enriched subtypes were significantly higher in PR ESR1HIGH (p=0.05, Fisher exact). While AI treatment had limited impact on Ki67 IHC values in PRs ESR1HIGH, PGR expression was more than 2-fold lower after 2 weeks of AI. Gene-set enrichment analysis showed significantly lower expression of estrogen-response genes in PRs ESR1HIGH compared to GRs (FDR < 10⁻⁹) at baseline despite similar percentage of Luminal subtypes in PRs ESR1HIGH and GRs. Plasma estradiol levels were correlated with expression of estrogen-response genes (FDR=0.01) and levels were significantly lower in PRs ESR1HIGH compared to GRs (p=0.003, Mann Whitney). PRs ESR1HIGH had significantly more mutations in RB1, TP53, ARID1B and DNAAH11 genes (p < 0.05, Fisher exact). TP53 mutations were significantly enriched in Luminal-A PRs ESR1HIGH compared to GRs (22% and 3% respectively; p=0.003, Fisher exact), but not in Luminal-B tumors (23% and 15% mutated respectively). Discussion and conclusions: In approximately 33% of PRs, de novo AI resistance was associated with and most likely due to low expression of ER/ESR1 and estrogen-responsive genes in non-luminal tumors. In the remaining tumors, AI treatment still impacted some estrogen responsive genes but had limited downstream impact on suppressing proliferation. This might be due to mutations including in TP53 that limit suppression of proliferation downstream of estrogen signaling. The proportion of Luminal tumors in GRs and PRs ESR1HIGH was similar, suggesting better outcome of Luminal-A tumors on AI is likely due to their better intrinsic prognosis rather than better response to endocrine therapy.

Background: Aromatase inhibitors (AIs) are one of the main treatment strategies for the clinical management of estrogen receptor-positive (ER+) breast cancer (BC). Despite prolonged time to recurrence and initial clinical responses, >20% of patients eventually relapse, and previous studies have shown an association of poor anti-proliferative response to AIs and worse outcome. High immune activity in ER+ tumors may be associated with worse outcome, in contrast to ER-negative BC where immune infiltration is a feature associated with better outcome. Our work focused on understanding the correlations between immune cell infiltration and response to AI. Methods: All patients with ER+ HER2- tumors within the bottom 15% of Ki67 anti-proliferative responders to AIs (poor responders [PRs]; n=177) were selected from the PeriOperative Endocrine Therapy for Individualizing Care (POETIC) trial and matched on baseline Ki67 levels to good responders (GRs) within the 50% showing the best response (n=190). Response to AI was measured by the Ki67 percentage change after 2 weeks of treatment. PRs were further divided into groups expressing high ESR1 (PRs ESR1HIGH; n=119) and low ESR1 (PRs ESR1LOW; n=58) levels to represent PR subgroups that showed partial or no response to AIs. The percentage of stromal tumor-infiltrating lymphocytes (TILs) was assessed. Multiple immunofluorescence was performed for ER, CD3, CD20, CD68, FOXP3, and CD3/FOXP3 in 15 baseline samples from each of the GR, PR ESR1HIGH, and PR ESR1LOW populations and immune cell density in stromal or tumor compartments was estimated. Spearman correlations of TILs with Consensus tumor microenvironment (TME) deconvolution and Molecular Signatures Database hallmark gene sets were conducted. The relationship between the immune markers' density and genes, hallmark gene sets and Consensus TME was assessed. Results: The percentage of TILs was significantly higher in the PR ESR1HIGH and PR ESR1LOW compared to the GRs (adjusted $p < 0.05$). As expected, TILs were highly correlated with T cells (particularly T-regulatory cells) and immune hallmark gene sets. There was a tendency for higher density of each of the immune markers in PRs compared to GRs, with significant differences being observed in stromal B-cell marker CD20 density ($p < 0.05$). Analysis showed a significant correlation between TILs and stromal FOXP3 marker density (FDR < 0.05), and stromal biomarker density was highly correlated to the gene expression of the encoding genes of the same tumors (CD3/CD3D, FOXP3/FOXP3, and CD20/MS4A1) (FDRs < 0.05). There was also a strong and significant correlation between the stromal expression of CD20, CD3, FOXP3, and CD3/FOXP3 with the immune hallmark gene sets (FDRs < 0.05). Finally, the immune phenotyping showed the expected correlations with TME deconvolution, with particularly strong correlations of CD20 and CD3 with B- and T-cell gene signatures, respectively (FDRs < 0.05). Conclusions: Different immune features indicated a broad involvement of several immune cell types in PRs to AIs, suggesting that the immune system might be associated with resistance of ER+ breast tumors to AI treatment. Spatial gene

expression profiling is ongoing to characterize these tumors further and investigate potential mechanisms of AI resistance.

Background: 80% of all breast cancers (BCs) are ER-positive (ER+). Not all respond to adjuvant endocrine therapy (aET) and a significant number develop endocrine resistance and recur. The basis for primary and acquired endocrine resistance is poorly understood. A multiomics analysis of primary ER+ BCs matched with recurrences on or after completion of aET has been performed. Patients: A unique cohort of 520 women with matched primary and recurrent ER+, HER2-negative (HER2-) BC is being analysed. In the first subset of 75, all had surgery to clear margins, followed by aET. The endocrine therapy given was tamoxifen (66%), aromatase inhibitors (AI) (28%: 17% letrozole, 6% anastrozole, 2% exemestane, and 3% a succession of 2 different AIs), or a combination of tamoxifen and an AI (6%). aET duration was 5 years, unless the patient stopped treatment or developed a recurrence sooner. 16/75 patients (21%) had positive lymph nodes. All patients developed recurrences: local in 59/75, concurrent local and nodal in 13/75 and lymph node-only in 3/75. Median time to recurrence was 4.1 years (range: 0.7-29 years). 62% of patients were on aET at the time of recurrence. All patients have long-term follow-up. Methods: DNA and RNA were extracted from matched primary and recurrence BC tissue samples. Targeted DNA-exome and whole-genome expression analyses were performed. A custom targeted DNA panel was used to study genes implicated in endocrine therapy resistance (ETR): this included 73 different targets, selected based on our previous full-exome sequencing of sequential ET recurrences and those implicated in the literature and in curated somatic and cancer mutation databases. Somatic mutations and copy number alterations (CNA) were determined. Differential gene expression analysis was performed using two-class unpaired Significance Analysis of Microarrays (SAM). Validation of pathways implicated in ETR using NanoString GeoMx protein analysis is ongoing. Results: Targeted DNA-exome profiling identified 1 or 2 potential driver mutations in all but a few primary samples. Multiple aberrations and a highly diverse mutational landscape were observed in all the recurrences. Matched breast and lymph node samples from synchronous recurrences had very similar somatic profiles. Changes significantly enriched in recurrent samples included somatic aberrations in well-established drivers such as MAP3K1, PIK3CA,

TP53 and CDH1, as well as ESR1. Aberrations were also common in PTEN and in ER-associated factors FOXA1 and GATA3. Transcriptomic analysis revealed a number of pathways implicated in resistance, including ER, HER2, GATA3, AKT, RAS and p63 signalling. A panel-based, targeted DNA sequencing approach for mutational profiling allowed capture of relevant mutational profiles linked to ETR in a cost-effective manner compared with traditional whole-exome sequencing. Ongoing analysis has linked mutational profiles to specific endocrine agents and has allowed us to demonstrate significant differences between recurrences on aET compared with those after completion of aET. Multiomics profiling of the remaining samples in the cohort is underway. Discussion: This multiomics study provides the largest cohort to-date of matched early and recurrent ER+/HER2- BCs. It has shed new light on how different adjuvant endocrine agents can affect primary drivers and lead to complex somatic and transcriptomic changes in recurrent disease. This work confirms that the mechanisms of endocrine resistance are diverse and has already identified mechanisms underlying ETR and clinically meaningful biomarkers of ETR, including potentially actionable mutations and targets.

Background About 70% of breast cancer cases are hormone receptor positive, indicating that cancer cells exploit estrogens for their growth. Postmenopausal estrogen receptor positive breast cancer patients are currently often treated with aromatase inhibitors suppressing serum and tumor tissue estradiol levels by >90%. Two widely used aromatase inhibitors are letrozole, a nonsteroidal inhibitor and exemestane, a steroidal aromatase inactivator. While the mechanisms of action of these two drugs are well studied, their effects on the tumor immune

microenvironment and mechanisms of resistance to these drugs are still not sufficiently elucidated. Study design The NEOLETEXE trial¹ was a neoadjuvant, randomized, open-label, intra-patient, cross-over, single center clinical trial aiming at treating postmenopausal patients with locally advanced breast cancer defined primarily as large T3/T4 and or N2/N3. However, patients with large T2 tumors were also eligible. Patients were randomized to neoadjuvant therapy with either letrozole (2.5 mg daily) or exemestane 25 mg daily for about 3 months, followed by a cross-over to the alternative drug for another 3 months prior to surgery. 102 patients were enrolled in NEOLETEXE. Methods Pre-treatment, on-treatment (3 months) and end-of-treatment (6 months of therapy) biopsies were subjected to single-cell transcriptome, T cell receptor and B cell receptor profiling using the Chromium Single-Cell v2 5' Chemistry (10x Genomics). Libraries were paired-end sequenced on a NovaSeq6000. Single cell gene expression matrices were analyzed with the Seurat package (v4.0.2). After filtering out stressed / dying cells or cells with low quality sequencing, gene expression of the remaining good quality cells was normalized and scaled to construct principal components and further cluster cells. Results We clustered 362.762 cells from 26 pre-treatment, 20 on-treatment and 19 end-of-treatment biopsies and identified 8 main cell types to be present: T cells, B cells, epithelial cells, fibroblasts, endothelial cells, macrophages, mast cells and dendritic cells. To further identify specific and specialized cell subtypes, we clustered the cells belonging to the above-mentioned cell types independently and annotated the clusters obtained using validated marker genes. Finally, we use statistical methods and algorithms to characterize how the proportion of the different cell types changes in tumors under treatment pressure. Specifically, we show changes in the proportion of CD8 effector memory cells under treatment pressure, with a significant increase in cytotoxic T cell proportions after two months of treatment with aromatase inhibitor. Conclusions We use single cell profiling to obtain a high-resolution map of the cell types found in tumor biopsies of the NEOLETEXE trial to characterize the effects of aromatase inhibitors on the tumor microenvironment and to identify the cancer cell signatures during treatment with letrozole or exemestane. 1. Background: I-SPY2 is a multicenter, phase 2 trial using response-adaptive randomization within biomarker subtypes defined by hormone-receptor (HR), HER2, and MammaPrint (MP) status to evaluate novel agents as neoadjuvant therapy for high-risk breast cancer. The primary endpoint is pathologic complete response (pCR). Cemiplimab (Cemi) is a PD-1 inhibitor approved for the treatment of NSCLC, cutaneous basal, and squamous cell cancer. Here, we report current efficacy rates of Cemi in combination with paclitaxel followed by AC.

Methods: Women with tumors ≥ 2.5 cm were eligible for screening. Only HER2 negative (HER2-) patients were eligible for this treatment; HR positive (HR+) patients had to be MP high risk. Treatment included paclitaxel 80 mg/m² IV weekly x 12 and Cemi 350 mg IV given q3weeks x 4, followed by doxorubicin/cyclophosphamide (AC) every 2 weeks x 4. The control arm was weekly paclitaxel x 12 followed by AC every 2-3 weeks x 4. All patients undergo serial MRI imaging; and imaging response (at 3 weeks, 12 weeks and prior to surgery) were used along with accumulating pCR data to continuously update and estimate pCR rates for trial arms. Analysis was modified intent to treat. Patients who switched to non-protocol therapy count as non-pCR. The goal is to identify (graduate) regimens with $\geq 85\%$ Bayesian predictive probability of success (i.e. demonstrating superiority to control) in a future 300-patient phase 3 neoadjuvant trial with a pCR endpoint within responsive signatures. Cemi was eligible to graduate in 3 pre-defined signatures: HER2-, HR-HER2-, and HR+HER2-. To adapt to changing standard of care, we constructed “dynamic controls” comprising ‘best’ alternative therapies using I-SPY 2 and external data and estimated the probability of Cemi being superior to the dynamic control.

Results: 60 HER2- patients (28 HR+ and 32 HR-) received Cemi arm treatment. The control group included 357 patients with HER2- tumors (201 HR+ and 156 HR-) enrolled since March 2010. Cemi graduated in HR-/HER2- signature. Estimated pCR rates (as of June 2022) are summarized in the table.

Immune-related endocrine disorders include: hypothyroid (14.5%), adrenal insufficiency (10%), hyperthyroid (4.8%), and thyroiditis (3.2%). Only one grade 3 adrenal insufficiency was observed. All immune related AE's were manageable. Additional biomarker analyses are ongoing and will be presented at the meeting. Response predictive subtypes (Immune+ vs Immune-) and additional predictive biomarkers were assessed. Associations with pCR will be presented at SABCS.

Conclusion: The I-SPY 2 study aims to assess the probability that investigational regimens will be successful in a phase 3 neoadjuvant trial. Anti-PD-1 therapy with Cemi resulted in a higher predicted pCR rate in HR-/HER2- 55 rate% disease compared to control at 29%. Immune-mediated AE's were observed. This data is consistent with previously published data using check point inhibitors in early-stage HR-/HER2- breast cancer.

Signature	Estimated pCR rate		Probability Cemi Superior to Control	Predictive Probability of Success in Phase 3	Probability Cemi Superior to Dynamic Control
	Cemi	Control			
HER2-	0.321	0.211	0.985	0.555	
HR-/HER2-	0.548	0.291	0.999	0.931	0.419
HR+/HER2-	0.132	0.145	0.377	0.088	0.013

Estimated pCR rates

Background: The majority of breast cancers outside of the triple negative subtype are considered immunological quiescent and are therefore minimally responsive to immunotherapies. One potential method to combat this is through local therapies that induce cell death, thereby exposing tumor antigens, providing adjuvants for anti-tumor immune priming, and potentially increasing responsiveness to immunotherapies. We have conducted a randomized, Phase 2 presurgical Window-Of-Opportunity trial for intratumoral (IT) INT230-6 (comprising VINblastine (VIN) Cisplatin (VIN)) evaluating clinical and BioLogical Effects in patients with early-stage operable Breast Cancer (the INVINCIBLE trial- <https://clinicaltrials.gov/ct2/show/NCT04781725>). INT230-6 contains a dispersion enhancer molecule (SHAO) with the cytotoxic agents and is designed to cause tumor necrosis by dispersion throughout the tumor and diffusion into cancer cells. Previous in vitro studies have demonstrated that INT230-6 halts cancer cell replication and induces cell death recruiting dendritic cells and T-cells to the tumor microenvironment. In this trial, IT injections of INT230-6 are conducted to 1) exploit the potential of regional cytotoxic chemotherapy on breast cancer in vivo and 2) assess the immune response within the tumor, microenvironment and systemically in the host blood prior to surgical resection. **Methods:** Women with newly diagnosed and awaiting surgery for early-stage intermediate or high-grade T1-T2 invasive breast cancers were recruited to the trial. The study has two parts. Part I was a randomized (2:1) open label trial comparing 1-3 doses of INT230-6 injected weekly versus no treatment prior to surgery to evaluate safety, feasibility, and optimal drug dosing. Part II was a double-blinded randomized (2:1) trial where patients received one IT dose of INT230-6 vs saline injection. The primary objective was to estimate the proportion of patients with tumor necrosis and complete cell cycle arrest (CCCA) at the time of surgery compared to control. In addition, we performed targeted sequencing and proteomic profiling in tumour samples from the INT230-6 clinical trial. **Results:** The study recruited 90 patients with age ranges of 40-77 yrs (mean = 60 yrs) with tumors ranging from 1.5-4.3 cm (mean = 2.4cm). No surgeries were delayed or altered as a result of trial participation and the most common (>10%) AEs were injection site pain, injection site reaction and nausea/vomiting. Compared to the control group, up to 95% tumor necrosis was present in varying biologic subtypes and histologies, including invasive lobular carcinoma. Preliminary gene expression analysis showed significant differential gene expression between the baseline biopsy and surgical specimens. Pathway analysis identified genes associated with TCR signaling, B cells, T cells, chemokine signaling and NF- κ B signaling were significantly changed in the post treatment samples. There was a relative increase in CD4 and CD8 T cells and B and NK cells within the tumor and in the tumour microenvironment. **Conclusion:** Preliminary evidence shows that a single dose of INT230-6 can cause substantial tumor necrosis and stimulate an immune response in breast cancers prior to surgery with minimal adverse effects and good tolerability. This window of opportunity clinical trial demonstrates that INT230-6 injection is a novel and simple method to convert traditionally immune quiescent breast cancers into immunogenic tumors. This can open the door to future potential immunotherapeutic options in early stage breast cancer.

Introduction: Improvement of systemic treatment of TNBC represents an unmet medical need. Targeted therapy of regulatory immune pathways has become an important option in the treatment of many malignant diseases including breast cancer. Neoadjuvant trials combining chemotherapy and checkpoint inhibitors (KEYNOTE-522 and IMpassion031) have demonstrated a meaningful benefit regarding pathological complete remission (pCR) for the addition of PD-1- or PD-L1-inhibitors to chemotherapy in patients with TNBC. In the KEYNOTE-522 trial, the addition of an immune checkpoint inhibitor (ICI) to neoadjuvant chemotherapy also had a beneficial impact on event-free survival even in patients who did not achieve a pCR. Of note, in the neoadjuvant GeparNuevo trial only those patients with TNBC who received a 2-week checkpoint inhibitor monotherapy window before the start of neoadjuvant chemotherapy in combination with checkpoint inhibition, achieved a significant pCR benefit from the addition of the PD-1 inhibitor Durvalumab to neoadjuvant chemotherapy alone. Methods: NeoMono is a phase 2 randomized multicenter trial recruiting male and female patients with primary TNBC (defined as ER/PR < 10% and HER2 negative). Neoadjuvant treatment in Arm A and B consists of Atezolizumab 1200 mg every 3 weeks in addition to neoadjuvant chemotherapy (i.e., 12 x Carboplatin and Paclitaxel q1w followed by Epirubicin and Cyclophosphamide q3w). Combination therapy in arm A is preceded by an Atezolizumab monotherapy window (i.e., 840 mg Atezolizumab once two weeks prior to initiation of combination therapy). Study goals are to compare the efficacy of neoadjuvant chemotherapy with Atezolizumab with and without an Atezolizumab two-week monotherapy window (primary endpoint: pCR) and the identification of biomarkers predicting (early) response to or resistance against Atezolizumab. The extensive translational program of the neoMono trial aims at identifying these biomarkers on tumor and patient level through analysis of sequential tissue and liquid biopsies. The NeoMono statistical design adapts the idea of a proof-of-concept trial and uses Bayesian posterior and predictive probabilities for inference about the primary hypothesis. Up to four planned efficacy interim analyses provide decision points for early stopping for success or futility. The expected maximum number of patients to be recruited is 458. Results: The predefined number of 50 patients in each arm being evaluable for the primary endpoint pCR has been reached and the results of the first planned interim analysis will be presented at the meeting. Conclusion: The addition of an ICI to state of the art neoadjuvant chemotherapy has recently been established as a new standard of care in TNBC. NeoMono has the potential to answer the question if the beneficial effect of the ICI can be increased by a chemotherapy free ICI monotherapy window prior to a combination with neoadjuvant chemotherapy.

Background: Residual disease (RD) following neoadjuvant chemotherapy (NAC) in early HER2-negative breast cancer (BC) remains an unmet medical need. However, no therapies to date have tested their activity directly in chemo-resistant RD. Here, we hypothesized that combining an oncolytic virus such as T-VEC with atezolizumab may offer clinical benefit in patients (pts) with RD after standard NAC. To our knowledge, PROMETEO is the first trial that examines the activity of immunotherapy in pts with RD prior to surgery. Methods: PROMETEO (NCT03802604) is a single-arm, open-label, multicenter phase II trial. Women with triple-negative BC (TNBC) or hormone receptor-positive/HER2-negative (HR+/HER2-) BC with baseline (i.e., before NAC) ki67 \geq 20% were eligible. RD was confirmed with a magnetic resonance imaging (MRI) showing a tumor diameter \geq 10 mm and a core-biopsy detecting the presence of invasive cells. Before surgery, T-VEC was administered intratumorally on week 1 (106 pfu/mL), then in week 4 and every 2 weeks thereafter (108 pfu/mL) for 4 injections. Atezolizumab (840 mg) was administered intravenously every 2 weeks for 4 infusions, starting at week 4. Surgery was performed in $<$ 3 weeks after completing the treatment. The primary objective was to evaluate the efficacy of the combination, measured by the rate of residual cancer burden (RCB) class 0/1 at surgery. Tumor samples collected at 5 timepoints (before NAC, during screening period, after first dose of T-VEC, after first dose of T-VEC and atezolizumab and at surgery) were mandatory to assess gene expression, tumor-infiltrating lymphocytes (TILs), immune cells PD-L1 IHC (SP142), tumor mutational burden (TMB) by FoundationOne and other translational endpoints. Results: Between Dec 2018 to Feb 2022, 28 pts were enrolled: 20 pts with HR+/HER2- disease and 8 pts with TNBC. Median age was 47 (range 31-71) and 71% of pts were premenopausal. At diagnosis before NAC, clinical stage II disease represented 60.7%, cN+ 60.7%, median Ki-67 was 37.5% (range 20%-95%), high TILs (\geq 10%) 37%, median TMB was 3 (0-19) and only 1 of 27 pts (3.7%) had a PD-L1-positive

tumor. After NAC, mean tumor size by MRI was 28.3 mm (10-93). Two pts discontinued from the trial (1 withdrawal of consent and 1 COVID infection). The completion of 5 cycles of treatment was achieved by 73% of pts. The overall RCB-0/1 rate was 25% (7 of 28, 95% IC 10.7 – 44.9%), all with RCB 0 (pathologic complete response [pCR]). The pCR rate was 30% in HR+/HER2- disease and 12.5 % in TNBC. Radiological response by MRI was achieved by 3 of 28 pts (10.7%). Interestingly, none of the 7 pts with a pCR had radiological response (stable disease n=5, progressive disease [PD] n=2). Six pts (21.4%) had radiological PD and had RCB 2/3. Overall, 27 (96%) patients had at least one treatment-emergent adverse event (TEAE) of any grade. Most common grade 1 or 2 AEs were fever (11 pts, 39.3%), ALT increased (9 pts, 32.1%), AST increased (8 pts, 28.6%), arthralgia (6 pts, 21.4%) and anemia (6 pts, 21.4%). Grade 3 reversible neutropenia occurred in 1 patient. Across all pts, significant increases ($p < 0.001$) in TILs, immune genes and immune PDL1+ cells were observed after 1 dose of TVEC, 1 dose of the combination and at surgery. Intrinsic subtype changes at surgery occurred in 73.1% of cases, mostly (46.1%) Luminal A/B converting to Normal-like. At surgery, 19 of 26 (73.1%) of tumors were PDL1+. Conclusions: Two months of T-VEC in combination with atezolizumab induced a pCR in a subgroup of pts with chemoresistant HER2- breast cancer. This effect is probably related to the immune activation provoked by the combined treatment. Interestingly, a high discrepancy was observed between the pre-surgical radiological imaging and the actual surgical pathological report. Pre-operative window-of-opportunity trials in this context might provide important clues regarding the activity of novel treatment strategies.

Background: The gut microbiome modulates response and resistance to immune checkpoint inhibitors (ICI) across different cancer types. The objective of this study was to explore the association between fecal microbiome profiles and clinical outcomes in patients with hormone receptor-positive (HR+) metastatic breast cancer (MBC) treated with eribulin (E) + pembrolizumab (P) or E alone as part of a randomized phase II study (NCT03051659). **Patients and Methods:** Metagenomic shotgun sequencing was performed on fecal samples collected prior to randomization from a subset of 26 participating patients (E+P, n = 15; E, n = 11) collected prior to randomization. Sequencing data were processed with MetaPhlan3 to obtain diversity scores and taxonomic composition profiles. Associations between microbiome diversity, taxonomic composition, and clinical outcomes including survival metrics were assessed using Kaplan-Meier estimation methods and Cox proportional hazard models. **Results:** In this subset, median follow-up was 21.6 months and median overall survival (OS) was 17.9 months. OS was not statistically significant between two treatment arms as observed in the overall cohort. Metagenomic microbiome analysis revealed higher alpha diversity by inverse Simpson Index values associated with longer survival among all patients ($p = 0.004$), and in patients in the E + P arm ($p = 0.006$) but not in the E arm ($p = 0.2$). At the taxonomic level, longer OS among all patients was associated with a baseline lower relative abundance of *Blautia wexlerae* ($\leq 0.2\%$ vs $> 0.2\%$) (22.1 vs 16.6 months; $p = 0.01$) and a higher relative abundance of *Odoribacter splanchnicus*, a common short-chain fatty acid producing gut bacterium ($> 0.35\%$ vs $\leq 0.35\%$) (22.3 vs 11.3 months; $p < 0.0001$). These associations remained significant after controlling for age, ECOG-PS status, and use or not of prior lines of chemotherapy in the metastatic setting. **Conclusions:** These results suggest high diversity and composition of the gut microbiome are associated with prolonged OS in HR+ MBC pts receiving eribulin with pembrolizumab. Additional and larger clinical studies are needed to validate these findings and preclinical models are needed to interrogate the mechanisms by which gut microbiome diversity and composition may impact therapeutic response and clinical outcomes in this patient population.

Background. Patients (pts) with early triple negative breast cancer (eTNBC) are at increased risk of breast cancer recurrence and death. Recent studies have focused on escalation of therapy, with current treatment standard of at least five drugs – and associated toxicities - for eTNBC. Though presence of residual disease after neoadjuvant therapy (NAT) as measured by

residual cancer burden (RCB) helps guide addition of adjuvant treatment, more effective tools to tailor therapy are limited. Persistence of circulating tumor DNA (ctDNA) in the setting of residual disease is associated with high risk of distant recurrence. However, more sensitive minimal residual disease (MRD) assays are needed to potentially guide optimization of systemic therapy.

Methods. TBCRC 030 is a phase II randomized study of 12 weeks of NAT single agent cisplatin or paclitaxel for stage II-III TNBC, followed by surgery. The primary objective of the parent study was to correlate baseline biomarker for homologous recombination deficiency and RCB by study arm. From this group, responders (RCB 0/1) and non-responders (RCB 2/3) from both study arms who did not receive additional NAT prior to surgery were selected for analysis from the study cohort, matched on baseline nodal status and tumor size. As a post hoc study amendment, available pts were followed for event free survival (EFS). Plasma samples were collected prior to treatment initiation (W0), at three weeks (W3), and at twelve weeks, prior to surgery (W12). Whole genome sequencing (WGS) was performed on primary tumor tissue to identify somatic mutations and design for each pt a tumor-informed, ctDNA assay tracking up to 1000 mutations to detect MRD. Detection limit was computed for each tested sample as previously described. For each sample assayed, we report tumor fraction (TFx) when MRD was detected and the detection limit at 90% power when MRD was not detected.

Results. Of 139 study pts, 68 had complete tissue and plasma samples and no receipt of additional NAT. Of these, 22 were responders. These responders, and 22 matched non-responders were identified for analysis. Data from 22 pts – 11 responders, 11 non-responders - are described here; full analysis on all 44 pts will be presented at the meeting. Personalized ctDNA assays were designed targeting 434 to 1000 variants (median 1000) and applied to 66 plasma samples. At W0, 100% (22/22) were positive for ctDNA; 73% (16/22) and 55% (12/22) were positive at W3, and W12, respectively. In pts with T1-T2 tumors median TFx was $4.1e-3$ ($7.8e-6$, $3.4e-2$) and $4.7e-1$ ($4.3e-2$, $9.0e-1$) in pts with T3-T4 tumors. TFx decreased from W0 to W3 and from W0 to W12 in responders (Table 1). By W12, ctDNA had cleared in 7/8 pts with RCB 0, 1/3 with RCB 1, 2/8 with RCB 2, and 0/3 with RCB 3. Overall, ctDNA levels were broad with median TFx of $1.5e-3$ (range $2.9e-6$ to 0.90). Detection limit at 90% power for all tested samples was a median of $8.8e-6$ (range $9.9e-7$ to $6.8e-3$).

To investigate whether ctDNA persistence after NAT was associated with BC recurrence, we analyzed a separate group of all 8 pts with known recurrence and with complete data and samples. All pts had persistent ctDNA at W12 (median TFx $6.8e-3$, [$2.9e-6$ to $6.6e-2$]).

Conclusions. After 3 weeks of NAT for eTNBC, ctDNA TFx decreased, with a 3900-fold change in responders and 18-fold change in non-responders. By W3, TFx for most pts with RCB 0/1 were below the 1 in 10,000 limit of detection for many currently available assays, emphasizing the need for sensitive tests to potentially guide therapy. Additional studies will determine if ctDNA-guided approaches in eTNBC can improve pt outcomes.

Table 1: Tumor Fraction and Tumor Fraction Fold Change by Response to Neoadjuvant Therapy

	Responders (N=11)	Non-Responders (N=11)
TFx		
Median (Min, Max)		
W0	7.0e-3 (2.4e-4, 9.0e-1)	3.0e-3 (7.8e-06, 4.3e-2)
W3	3.6e-6 (0, 1.1e-3)	2.0e-4 (0, 9.8e-3)
W12	0 (0, 1.2e-4)	2.4e-4 (0, 9.1e-3)
TFx Fold Change		
Median (Min, Max)		
From W0 to W3	3.9e-3 (3.2e-6, 6.6e-1)	1.8e-1 (3.0e-4, 7.2e-1)
From W0 to W12	1.0e-3 (7.5e-6, 7.8e-2)	2.9e-1 (4.1e-4, 1.7)

Introduction: The TNBC-DX risk score includes the 14-gene immunoglobulin (IGG) immune signature, tumor size, and nodal status and has shown prognostic value for survival in early-stage TNBC (B. Conte et al., ESMO Breast 2021). However, currently unknown are the value of the TNBC-DX risk score and IGG immune signature in 1) predicting pathologic complete response (pCR) following neoadjuvant therapy, and 2) predicting outcomes in the context of neoadjuvant anti-PD1 treatment. Here, we assessed the IGG immune signature and the TNBC-DX risk score in patients with TNBC treated with neoadjuvant chemoimmunotherapy (NeoPACT; NCT03639948) and neoadjuvant chemotherapy without immunotherapy (NeoSTOP; NCT02413320). **Methods:** NeoPACT trial enrolled 120 patients with stage I-III TNBC who received carboplatin (AUC 6) + docetaxel (75 mg/m²) + pembrolizumab (200 mg) every 21 days x 6 cycles. NeoSTOP randomized 100 patients with stage I-III TNBC to two chemotherapy regimens; Arm B of NeoSTOP was included in this correlative study as the chemotherapy regimen was identical to NeoPACT. RNA isolated from pretreatment tumor tissue was subjected to next-generation sequencing. The 14-gene IGG immune signature and TNBC-DX risk score were calculated *in silico* as previously described. Evaluation of stromal tumor-infiltrating lymphocytes (sTILs) was performed as previously described. Markers were tested for prediction of pCR. Logistic regression analysis was used to examine the effect of multiple variables. Event-free survival (EFS) curves were assessed by the Kaplan-Meier method and groups compared by the log-rank test, followed by Cox regression analysis. **Results:** In this analysis, 112 patients were treated with chemoimmunotherapy on NeoPACT (node-positive = 38%, pCR rate = 58%). In the NeoPACT trial, the 14-gene IGG immune signature (as a continuous variable) was significantly associated with improved pCR (odds ratio [OR]=1.105, 95% CI 1.019-1.197, P=0.015 for every 0.2 increment). The pCR rates in IGG-high (\geq median) and IGG-low (< median) groups were 71% and 44%, respectively (OR=3.152, 95% CI 1.420-6.996, P=0.005). In terms of EFS, the 14-gene IGG immune signature was not prognostic (hazard ratio [HR]=0.507, 95% CI 0.148-1.735, p=0.269). In contrast, TNBC-DX risk score was strongly associated with EFS (HR=5.684, 95% CI 1.226-26.356, P=0.012), even when adjusted for sTILs and pCR status (HR=8.415, 95% CI 1.054-67.169, P=0.044). Estimated 3-year EFS rates in TNBC-DX high and low risk groups (above and below median) were 77% and 89%, respectively (P=0.012). In 43 NeoSTOP patients treated with neoadjuvant chemotherapy only (node-positive = 33%, pCR rate = 53%), no association of IGG immune signature with pCR or TNBC-DX score with EFS was observed. Finally, we observed a moderate correlation between IGG immune signature and sTILs in both trial datasets combined (r=0.642, P< 0.001). **Conclusions:** High expression of the 14-gene IGG immune signature in baseline pretreatment tumor samples in early-stage TNBC is significantly associated with pCR following pembrolizumab-based neoadjuvant chemotherapy. The combination of this signature with tumor burden as assessed by TNBC-DX is prognostic for long-term outcomes. Availability of biomarkers that can predict both pathological response and survival with chemoimmunotherapy can optimize this therapy, and evaluation of this biomarker in larger studies is warranted.

Background: Patients with HR- advanced/metastatic breast cancer (a/mBC) with a low level of HER2 (immunohistochemistry [IHC] score 1+ or IHC 2+ and negative in situ hybridization [ISH]) have poor prognosis. Combining 1L chemotherapy with immune checkpoint inhibitors can modestly improve outcomes vs chemotherapy alone, but treatment benefit is largely seen in patients with PD-L1+ disease. BEGONIA (NCT03742102) is an ongoing 2-part, open-label platform study, evaluating safety and efficacy of D, an anti-PD-L1 antibody, combined with other novel therapies in 1L triple-negative a/mBC, including HR-, HER2-low disease. T-DXd is a trastuzumab-topoisomerase I inhibitor antibody-drug conjugate that improves survival in patients with previously treated HR-, HER2-low mBC (NCT03734029; Modi NEJM 2022). Here, we report updated results of the T-DXd + D combination from BEGONIA. Methods: Patients with unresectable HR-, HER2-low (per local testing, IHC 2+/ISH-, IHC 1+/ISH-, or IHC 1+/ISH untested) a/mBC were enrolled in the T-DXd + D arm. Patients eligible for 1L treatment, regardless of PD-L1 status, received intravenous T-DXd 5.4 mg/kg + D 1120 mg every 3 weeks until progression or unacceptable toxicity. PD-L1, assessed using the VENTANA PD-L1 (SP263) Assay, was defined as high if $\geq 5\%$ of the tumor area was populated by PD-L1-expressing tumor or immune cells. Primary endpoints were safety and tolerability. Secondary endpoints included investigator-assessed objective response rate (ORR; RECIST v1.1); progression-free survival [PFS]; and response duration. Patients included in the efficacy analysis had ≥ 2 on-treatment disease assessments, progressed, died, or withdrew from the study. Results: As of April 8, 2022, 56 patients received T-DXd + D (34 ongoing) and 46 were included in the efficacy analysis. Median (range) follow-up was 10.1 (0–22) months. Median age was 53.5 years, 71% had received prior treatment for early stage BC, and 64% had visceral metastases at baseline. Confirmed ORR was 26/46 (57%; 95% CI, 41–71) and unconfirmed ORR was 33/54 (61%; 95% CI, 47–74); 1/46 patients (2%) had complete and 25/46 (54%) had partial responses. Confirmed response occurred irrespective of PD-L1 expression (PD-L1 high ORR, 5/7 [71%]; PD-L1 low, 13/21 [62%]; PD-L1 missing, 8/18 [44%]). Median duration of response was not reached; however, 64% of patients remained in response at 12 month follow-up and 73% had an ongoing response at data cutoff. Median PFS was 12.6 months (95% CI, 8–not reached). Adverse events (AEs) were consistent with the agents' known safety, with treatment-related AEs occurring in 49 patients (88%), any Grade 3/4 AEs in 18 patients (32%), and any serious AEs in 10 patients (18%). The most common all-Grade AEs were nausea (41 [73%]), fatigue (26 [46%]), and vomiting (17 [30%]). Adjudicated treatment-related interstitial lung disease/pneumonitis occurred for 5 patients (9%), which were mostly Grade 1 or 2 and 1 case of Grade 5 associated with COVID pneumonia. Seven patients (13%) and 21 patients (38%) had T-DXd dose reduction and dose delay, respectively; 22 (39%) had D dose delay. Seven patients (13%) discontinued treatment due to AEs. Conclusions: For patients with HR-, HER2-low a/mBC, T-DXd in combination with D in the 1L setting shows manageable safety and promising efficacy including durable responses and an encouraging PFS. Although subgroups were small, responses were observed irrespective of PD-L1 expression. Analysis of additional translational data is ongoing. Funding: AstraZeneca/Daiichi Sankyo

Background: Patients with a/mTNBC have limited treatment options and a poor prognosis (objective response rate [ORR] of 37%, median duration of response 6.5 months, median overall survival 15.5 months for 1L chemotherapy [Rugo, et al. Ann Oncol. 2021 LBA16]). Combining checkpoint inhibitors with 1L chemotherapy modestly improves outcomes but only in PD-L1–positive a/mTNBC, emphasizing a critical unmet need for patients with PD-L1–negative disease and for further improving outcomes in PD-L1–positive disease. BEGONIA (NCT03742102) is an ongoing 2-part, open-label platform study, evaluating safety and efficacy of D, an anti–PD-L1 antibody, combined with other novel therapies in 1L a/mTNBC, including Dato-DXd, an antibody-drug conjugate consisting of a humanized anti-TROP2 antibody covalently linked to a highly potent topoisomerase I inhibitor payload via a stable, tumor-selective, tetrapeptide-based cleavable linker. Early data from BEGONIA of D in combination with Dato-DXd showed promising responses. Here, we report updated results of Dato-DXd + D. Methods: Patients with unresectable a/mTNBC eligible for 1L treatment were enrolled, regardless of PD-L1 or TROP2 status, and received intravenous Dato-DXd 6 mg/kg + D 1120 mg every 3 weeks until progression or unacceptable toxicity. PD-L1, assessed using the VENTANA PD-L1 (SP263) Assay, was defined as high if $\geq 5\%$ of the tumor area was populated by PD-L1–expressing tumor or immune cells. Primary endpoints were safety and tolerability. Secondary endpoints included investigator-assessed ORR (RECIST v1.1) and duration of response. Patients included in the efficacy analysis had ≥ 2 on-treatment disease assessments, progressed, died, or withdrew from the study. Results: As of April 8, 2022, 47 patients received Dato-DXd + D (39 ongoing) and 33 of those were included in the efficacy analysis. Median (range) follow-up was 7.5 (0–11) months. Patient age was a median of 51 years, 57% received prior treatment for early stage TNBC, and 60% had visceral metastases at baseline. Confirmed ORR was 26/33 (79%; 95% CI, 61–91); 2/33 patients (6%) had a complete response and 24/33 (73%) had a partial response. Confirmed response was irrespective of PD-L1 expression (PD-L1 high ORR, 4/5 [80%]; PD-L1 low, 16/21 [76%]; PD-L1 missing, 6/7 [86%] patients). Median duration of response was not reached; 100% of patients with a complete or partial response remained in response at 6 month follow-up, and 96% had an ongoing response at data cutoff. Adverse events (AEs) were manageable and consistent with the known safety profiles of each agent, with treatment-related AEs occurring in 41 patients (87%), any Grade 3/4 AEs in 17 patients (36%), and any serious AEs in 7 patients (15%). The most common all-Grade AEs were gastrointestinal (nausea in 26 patients [55%] and stomatitis in 24 patients [51%]). A low rate of diarrhea was reported (6 patients [13%], all Grade 1 or 2); 4 patients had anemia and 1

had neutropenia. There were no cases of interstitial lung disease/pneumonitis or thrombocytopenia. Nine patients (19%) and 11 patients (23%) underwent Dato-DXd dose reduction and delay, respectively; 14 (30%) had D dose delay. Treatment was discontinued due to an AE for 3 patients (6%). There were no deaths due to treatment-related AEs. Conclusions: In this updated analysis with additional patients and longer follow-up, the combination of Dato-DXd + D in 1L a/mTNBC demonstrated a manageable safety profile and compelling high response rates with promising durability. Although subgroups were small, responses occurred irrespective of PD-L1 expression. Further investigation of this treatment combination is warranted. Analysis of translational data is ongoing. Funding: AstraZeneca/Daiichi Sankyo

Background: Despite recent FDA approval of immune checkpoint inhibitor pembrolizumab and drug-antibody conjugate in the treatment of mTNBC, the overall survival benefit of these patients remains modest. We conducted a phase 2 study to assess the efficacy and safety of

anti-PD-L1/CTLA-4 bispecific antibody KN046 in combination with nab-paclitaxel in mTNBC patients (pts) regardless of PD-L1 status. Preliminary results have been delivered in 2021 AACR[1], here we reported the final results of the progression-free survival (PFS) and overall survival (OS) analysis. Methods: This study enrolled pts with treatment-naïve locally advanced inoperable or metastatic TNBC. Eligible pts received nab-paclitaxel plus KN046 at two dose levels (DL1: KN046 3 mg/kg Q2W or DL2: KN046 5 mg/kg Q2W). Tumor response was evaluated Q8W per RECIST 1.1. The primary endpoint included objective response (ORR) and duration of response (DoR), secondary included disease control rate (DCR), clinical benefit rate (CBR), PFS, 1-year/2-year OS rate and safety/tolerability. Results: As of May 9, 2022 (cut-off date), 27 pts were enrolled into DL1 (n=16) and DL2 (n=11). Median patient age in the study was 50 years (range, 33-70 years). At baseline, 52% and 48% of patients had ECOG PS of 0 and 1, respectively. By the cut-off date, there are 1 pts under treatment and 16pts alive. The median study follow-up time was 26.3 months (95% CI, 20.7 - 29.8). Based on the intent-to-treatment (ITT) population, the confirmed ORR was 33.3% (95% CI, 16.5% - 54.0%), DCR was 88.9% (95% CI, 70.8% - 97.7%), and CBR was 48.1% (95% CI, 28.7% - 68.1%), which remained stable compared with last reported in 2021 [1]. The DoR was 11.9 (95% CI, 5.6 - NR) months. The median PFS was 7.3 (95% CI, 3.7 - 13.7) months. The median OS is immature, the preliminary result is 27.7 (95% CI, 14.8 - NR) months, and the 2-year OS rate was 60.1% (95%CI, 37.2% - 76.9%). Among the 11 pts with PD-L1 positive ($\geq 1\%$ IC), confirmed ORR was 45.5% (95%CI, 16.7% - 76.6%) and mPFS was 8.61 (95%CI, 1.6 - 13.8) months. Both PD-L1 positive and negative pts derived OS benefit from the combination treatment, with the 2-year OS rate of 57.14% (95%CI, 25.4% - 79.6%) and 62.5% (95%CI, 22.9% - 86.1%) respectively. Patients tolerated well to combination therapy in this trial. The most common reported treatment related adverse event (TRAEs) were ALT elevation (13 pts, 48%), AST elevation (12 pts, 44%), pyrexia (9 pts, 33%), neutropenia (8 pts, 30%), and anemia (7 pts, 26%). Grade ≥ 3 TRAEs ($\geq 10\%$) were neutropenia (7 pts, 26%), leukopenia (6 pts, 22%) and AST elevation (5 pts, 15%). 13 pts (48%) experienced immune related adverse events (irAEs), and only 3 irAEs (11%) were grade 3. The incidence of SAE was 33%, with no TRAE leading to death. Conclusions: The combination therapy of KN046 plus nab-paclitaxel has shown favorable clinical efficacy in mTNBC, especially in PD-L1 positive patients. By the cut-off date, the mOS is not mature and there is still more than half of pts alive, which demonstrated an encouraging 2-year OS rate. Pts in this trial tolerated well to the combination therapy and safety profile was manageable. Clinical trial information: NCT03872791 Reference 1. Cancer Res (2021) 81 (13_Supplement): 1660.

Background: Immune checkpoint inhibitors (CPI) have shown efficacy against metastatic triple negative breast cancer (mTNBC), but only for PD-L1 positive tumors. It is not known if so-called

immunogenic chemotherapies may yield clinical relevant synergies with CPI. We addressed these issues, by conducting a trial evaluating atezolizumab (anti-PD-L1) in combination with doxorubicin, which has been reported to provoke immunogenic cell death, and low-dose metronomic cyclophosphamide, which has been reported to counter immunosuppressive cells. The pegylated liposomal form of doxorubicin (PLD) was selected to avoid steroids and allow for long term therapy in responders. To our knowledge, this is the first randomized trial reporting on the concomitant addition of CPI to anticyclines in mTNBC. Methods: The trial enrolled patients with mTNBC and maximum one previous line of chemotherapy in the metastatic setting. Patients were randomized 2:3 into arm A (n=28), receiving chemotherapy alone, or arm B (n=40), receiving chemotherapy in combination with atezolizumab (840 mg every 2nd week). The chemotherapy consisted of PLD (20mg/m² every 2nd week) + oral cyclophosphamide (cyclo; 50mg/day, 2/4 weeks) in both arms. The per protocol (PP) population was defined as patients receiving > 3 doses of atezolizumab and >2 doses of PLD. The primary efficacy endpoint was progression-free survival (PFS) in the PP population. The protocol power analysis focused on durable response, as measured by 15 months PFS. Safety, a co-primary endpoint, was evaluated in all patients that started therapy (Full Analysis Set; FAS). Secondary endpoints included PFS in FAS, objective response rate (ORR), clinical benefit rate (CBR), durable response rate (>6 months; DRR), overall survival (OS) and biomarkers. PD-L1 status was determined retrospectively by the Ventana SP142 assay, as tumor-infiltrating immune cells with cut-off $\geq 1\%$. Efficacy data are given in the PP population unless stated otherwise. Hazard ratios (HR) are given with 95% confidence intervals (CI). Results: A total of 68 patients started therapy (FAS), of which 59 were in the PP population and 57% had not received previous chemotherapy in the metastatic setting. PFS was significantly improved in arm B compared to arm A in both the PP population (HR 0.57; CI 0.33-0.99; p=0.0477) and in the FAS (HR 0.56; CI 0.33-0.95; p=0.0326). Median PFS was 4.3 months in arm B versus 3.5 months in arm A. The progression-free proportion after 15 months was 14.7% (CI 6.4-30.1%) in arm B versus 0% in arm A. The ORR was 30.6%/21.7%, CBR was 52.8%/43.5% and DRR was 13.9%/4.3% in arm B/A. The PFS advantage was observed for both PD-L1+ (n=27; HR 0.58) and PD-L1- subjects (n=31; HR 0.66). All five patients without progression after 15 months belonged to arm B, and three out of these patients were PD-L1 negative. Serious adverse events occurred for 48% in arm B and 29% in arm A (FAS). The most common immune related adverse events of any grade in arm B/A were hypothyroidism (10.0%/7.1%), pneumonitis (10.0%/3.6%), hyperthyroidism (5.0%/7.1%) and rash (7.5%/3.6%). Further biomarker analyses and assessments of immunological changes during therapy are ongoing. Conclusions: The addition of atezolizumab to PLD and low-dose metronomic cyclophosphamide significantly improved PFS. A benefit was indicated also in patients with PD-L1 negative disease. The combination regimen was well tolerated with no new safety signals. Results from the ongoing analyses of consecutive tumor and blood samples will be important to assess the hypothesized immunological effects of the chemotherapy and to investigate biomarkers associated with the response to the combined treatment.

Introduction: A significant proportion of aTNBC patients carry homologous recombination defects associated with platinum sensitivity. Olaparib is an approved PARP inhibitor (PARPi) for germline BRCA (gBRCA) associated early and metastatic breast cancer as well as maintenance therapy in platinum-sensitive ovarian cancer irrespective of gBRCA status. PARPi enhances immune response via cGAS/STING activation and is synergistic with anti-PD-1 blockade in preclinical models without overlapping toxicities. Here, the efficacy of maintenance olaparib (O) +/- durvalumab (D) in aTNBC patients following clinical benefit from platinum chemotherapy is investigated (NCT03167619). Methods: Eligible pts had aTNBC with investigator-assessed clinical benefit (SD, PR, CR) after a minimum of 3 q3-weekly or 6 q1-weekly cycles of platinum-based chemotherapy in the 1st or 2nd line treatment setting. Patients were randomized 1:1 to receive O 300 mg BID daily or O 300mg BID daily + D 1.5g IV q4 wks. The study was a non-comparator trial; randomization aimed to reduce bias. Tumors were evaluated by RECIST1.1 at baseline and q8 wks. Known gBRCA carriers were limited to 10. The primary endpoint was progression-free survival (PFS). Secondary endpoints were disease control rate (DCR), clinical benefit rate (CBR), and overall survival (OS). Results: From 2/4/2019-12/24/2020, 45 pts were randomized (23 pts in O arm; 22 in O+D arm). 82.2%

received platinum as 1st line therapy and 82% received a platinum-doublet. As of data cutoff (6/30/2021), median follow-up of 9.8m (7.2-15.1), the median PFS was 3.95m (p= 0.0023; 95% CI 2.55-6.13) with O monotherapy. The median PFS was 6.1 mos (p= <.0001; 95% CI 3.68-10.11) in the O+D arm. CBR (CR, PR or SD ≥ 24 wks) was 39.1% (19.7%-61.5%) and 36.4% (17.2%-59.3%) in the O and O+D arms, respectively. DCR was 52.2% (30.6%, 73.2%) and 68.2% (45.1%, 86.1%) in the O and O + D arms, respectively. Currently, 7 pts (15.6%) remain on study treatment, only 2 have gBRCA alterations. No new safety signals were reported. Correlative analysis including germline/somatic BRCA, HRR genes, BRCA methylation, TMB and PDL-1 in association with clinical outcomes will be presented. Conclusions: A subset of non-gBRCA altered aTNBC pts who derived clinical benefit from platinum-based chemotherapy had a durable disease control with a chemotherapy-free maintenance strategy of olaparib +/- durvalumab.

Background: The association between obesity and breast cancer risk is well documented, but fewer studies have explored the impact of post diagnosis weight changes on survival especially in more contemporary contexts. The existing evidence has mainly focused on weight gain, been limited by small sample sizes and has evaluated prospective cohorts with restrictive eligibility criteria rather than population-based samples. Our study uniquely contributes to the literature by using a population-based approach and recent clinically measured weight data from the electronic health record (EHR) to explore the impact of weight change following a breast cancer diagnosis on survival. Methods: EHR weight measurements were extracted for women diagnosed with stages I-IV breast cancer at CT's Smilow Cancer Hospital and Care Network between 2013-2019 (N=6,934). During the follow-up period through April 26, 2020 (mean=3.2

years, standard deviation=1.8), there were 497 deaths. We used multivariable Cox regression models, adjusting for age at diagnosis, race/ethnicity, chemotherapy, radiation therapy, ER/PR subtype, to estimate the association between body mass index (BMI) at diagnosis and all-cause mortality from time since first post-diagnosis clinic visit (within 6 months of diagnosis). Percent weight change at 1-year post-diagnosis was categorized as a 5-level variable (weight stable – change within 5% of weight at diagnosis, moderate weight loss – 5% to < 10% change, large weight loss – ≥10% change, moderate weight gain – 5% to < 10% change, and large weight gain – ≥10% change) and evaluated in relation to all-cause mortality. A non-linear relationship between percent weight change at 1-year post-diagnosis and mortality was evaluated by comparing linear and cubic spline models. Results: Among these 6,934 breast cancer cases, the mean age was 61±13 years, BMI at diagnosis was 29±7 kg/m² and weight change from diagnosis to 1-year post-diagnosis was -0.47±5.4 kg. Being underweight (BMI< 18.5) or having class II obesity (BMI>35) at diagnosis were statistically significantly independently associated with higher all-cause mortality compared with normal BMI (Hazard Ratio [HR]=1.43, 95% Confidence Interval [CI]=1.11-1.85 and HR=3.32, 95% CI=1.90-5.80, respectively). At 1-year post-diagnosis, 64% of women remained weight stable since diagnosis, 12% gained moderate body weight, 5% had large weight gain, 12% lost moderate weight and 7% experienced a large weight loss. Compared with the weight stable group, there was a positive, non-significant association between moderate weight gain at 1-year post-diagnosis and overall mortality (HR=1.24, 95% CI=0.84-1.81). Greater than 10% weight loss at 1-year post-diagnosis was statistically significantly associated with higher mortality (HR=2.87, 95% CI=2.13-3.87). The test for curvature suggested a non-linear relationship between percent weight change at 1-year and mortality (p< 0.001). Conclusion: In this contemporary, population-based study of women with breast cancer from one large academic medical center, underweight and obesity at diagnosis were associated with poorer survival. Weight loss during the first-year post-diagnosis was also strongly associated with an increased risk of mortality. To further inform weight management strategies and future interventions for breast cancer survivors, we need to better understand changes in body composition in the post-diagnosis period.

Purpose: To examine the association between obesity and breast cancer outcomes and to describe socioeconomic position (SEP) in patients enrolled in the Malmö Diet and Cancer Study (MDCS) according to anthropometric measures. Patients and methods: The MDCS is a prospective cohort study that enrolled 17,035 female individuals in Malmö, Sweden from 1991 to 1996. The primary objective of the MDCS was to investigate associations between dietary patterns and cancer risk. Body mass index (BMI) and waist circumferences were measured upon enrollment, in the MDCS cohort. We identified all female MDCS participants with incident invasive breast cancer diagnosed between 1991 and 2014. The primary endpoint was breast cancer recurrence, defined as the time from breast cancer diagnosis until the earliest occurrence of invasive loco-regional recurrence or distant metastases. Follow-up time began at breast cancer diagnosis and continued until the first of breast cancer recurrence, death, emigration, or end of follow-up (June 8, 2020). BMI and waist circumference were categorized according to the World Health Organization guidelines as healthy weight (18.5-24.9 kg/m² or waist < 81 cm), overweight (25.0-29.9 kg/m² or waist 81-85 cm), and obese (≥ 30.0 kg/m² or waist > 85 cm). Consistent with the Swedish socioeconomic classification, we categorized labor status into two groups—manual labor and non-manual labor. We categorized socioeconomic position (SEP) as low if patients had unskilled manual labor with < 2 years post-high school education, low-middle if skilled manual labor with > 2 years of post-high school education, high-middle if assistant non-manual labor with < 3 years of post-high school education, and high if non-manual labor with > 3 years of post-high school education. We fit Cox regression models to compute crude and adjusted hazard ratios (HRs) with 95% confidence intervals (95% CI) of breast cancer recurrence as well as all-cause mortality according to BMI and waist circumference. To evaluate effect measure modification, we stratified the Cox models by labor

status, SEP, and smoking. Results: Among 1,099 breast cancer patients, 263 breast cancer recurrences were diagnosed over 12,810 person-years with a median follow-up of 11.1 years (interquartile range [IQR] was 6.6-16.2). The cohort consisted of 556 patients with healthy weight, 384 patients with overweight, and 159 patients with obesity. The median age at breast cancer diagnosis was 66.3 years (IQR: 61.2-72.8), and patients with obesity were older than patients with healthy weight (69.2 vs 64.9 years). In multivariable analyses, having obesity according to BMI was associated with increased rate of recurrence (HR= 1.44 [95% CI: 1.00-2.07]) and all-cause mortality (HR= 1.50 [95% CI: 1.13-1.98]) in comparison to having healthy weight. Similarly, having obesity according to waist circumference was associated with higher risk of recurrence (HR= 1.31 [95% CI: 0.98-1.77]) and all-cause mortality (HR= 1.72 [95% CI: 1.39-2.13]) in comparison to having healthy weight. When evaluating effect measure modification, we observed that obesity was associated with breast cancer recurrence in obese non-smoking women (HR= 1.66 [95% CI: 1.01-2.73]), in obese women with manual labor (HR= 2.45 [95% CI: 1.22-4.93]), and obese women with low SEP (HR= 2.55 [95% CI: 1.08-6.02]). We observed little evidence of an association between obesity and breast cancer recurrence among smokers (HR= 1.12 [95% CI: 0.43-2.92]), among patients with non-manual labor (HR= 0.94 [95% CI: 0.44-2.00]), or among patients with high SEP (HR= 1.47 [95% CI: 0.58-3.75]). Conclusion: Obesity defined by pre-diagnostic levels of BMI and waist circumference was associated with an increased risk of recurrence and all-cause mortality among breast cancer patients. The association between obesity and breast cancer recurrence seems dependent on patient characteristics such as labor status, socioeconomic position, and smoking.

Background

Breast cancer (BC) is the most common cancer among women and the second most common cause of cancer-related mortality among women. Much attention has been paid to factors that increase the risk of developing BC. Among these are weight, typically defined by body mass index (BMI), and race. Elevated BMI has not only been shown to increase the risk of BC in some patients but has also been associated with increased rates of hormone receptor (HR) positive BC, particularly among postmenopausal patients. In premenopausal patients, an inverse relationship has been established between obesity and BC. In fact, a 2008 meta-analysis of obesity and malignancy evaluated almost 8,000 cases of premenopausal BC and showed a BC risk reduction of 8% for every 5 kg/m². However, this study was not inclusive of African American (AA) patients. AA women are more likely to be obese than any other racial group in the US. They are also at higher risk of aggressive breast cancers, and at an earlier age. We sought to evaluate the relative risk of breast cancer diagnosis among obese vs nonobese patients of different races, as well as the rate of HR positivity in patients diagnosed with BC.

Methods

BMI, age, and self-declared race were collected from the electronic health record for all female patients presenting to our health system located in Louisiana and Mississippi between 2012 and 2022. This same data was collected for female patients who were diagnosed with BC in the same time period (n=9123), as well as HR positivity vs HR negativity. Patients less than 50 years old were considered premenopausal, and patients greater than 50 years old were considered postmenopausal. BMI greater than 30 was used to define obesity. The relative risk of BC was calculated for demographic groups according to premenopausal or postmenopausal status, White or Black/African American race, and BMI less than or greater than 30. The relative risk of HR positive BC was calculated among the same demographic groups.

Discussion

Data collected across the largest health system in Louisiana and Mississippi shows that a higher BMI is linked to an increased risk of BC, regardless of age or race. This was seen across both stratifications and was statistically significant except in postmenopausal AA women. This is contrary to what is frequently published in the literature that premenopausal obesity is protective against BC. Additionally, this data demonstrates that there is not a link between obesity and HR+ BC. This data did show that obesity in younger white patients may be protective against HR+ BC, which is aligned with prior research.

Conclusion

The association between obesity and BC incidence has been well-described in the literature, primarily in the postmenopausal setting. This large, retrospective analysis confirms that association, but also shows a strong association in premenopausal patients. Unlike other studies, this review did not show an association between obesity and HR positivity, and additionally did not show significant differences between AA patients and White patients. This provides needed insight into the inequities faced by AA women with BC. Further studies should be done to evaluate the association of socioeconomic status with BC subtypes.

Breast cancer cases (5/1/2012-5/1/2022) among women by BMI, age group, and race

Table 1: Breast cancer cases (5/1/2012-5/1/2022) among women, by BMI, age group, and race

Breast Cancer Age	Race	Number of cases (n=9123)	Standardized Risk Estimates		Risk Ratio (95% CL RR)
			BMI > 30	BMI ≤ 30

Background: Obesity is an important risk factor for breast cancer and women with metabolic syndrome may be at the highest risk. Infiltration of CD8 T-cells into fat is an early event in obesity. Type I cytokines secreted by CD8 T-cells upregulate costimulatory molecules on enlarged adipocytes. The adipocytes, now antigen presenting cells, further stimulate Type I T-cell activation. The resulting T-cells compete for glucose and fatty acids which leads to metabolic dysfunction in both the adipose tissue and the T-cells themselves. The T-cells are not able to maintain tumor immune surveillance and secretion of adipokines promotes malignant transformation. Immunologic memory prevents inflammation from resolving even if an individual becomes normal weight. Strategies to increase Type II (anti-inflammatory) T-cells in inflamed adipose could have clinical benefit. Methods: We developed a method of CD4 epitope identification that includes functional screening for Th1 or Th2 epitopes. We use a multi-algorithm approach to ensure responsiveness across diverse HLA alleles. We identified Th2 selective epitopes associated with high IL-10 secretion for 6 adipocyte associated antigens that become overexpressed in inflamed adipocytes (IGF-IR, HIF-1a, DUSP1, FABP4, PAI-1 and ATGL). The epitopes were highly homologous between mouse and man (median 100% (range-82-100%). When the epitopes were used to immunize mice, all antigens generated a significant IL-10 response compared to control ($p < 0.05$). We questioned whether our "adipocyte directed" vaccine (ADVac) could prevent the development of breast cancer in obese mice. Results: First, C57BL/6 mice were fed a high fat high sucrose (HFHS) diet or normal chow. When mice became obese, vaccination with ADVac or adjuvant alone (Alum) was initiated. Four weeks after the final vaccine, visceral adipose tissue showed significantly fewer CD8 T-cells in the obese mice immunized with ADVac as compared to the control, $p=0.0011$. The decrease in CD8 T-cells was specific for adipose tissue as no change was observed in matched spleen. There was a significant increase in T-regulatory cells in the adipose tissue of mice immunized with ADVac as compared to control, $p=0.031$. Two weeks after the final vaccine, a glucose tolerance test (GTT) and insulin tolerance (ITT) showed blood glucose concentrations were significantly lower at all time points for the ADVac-immunized obese mice as compared to the control obese mice ($p < 0.01$ for all). TgMMTV-neu develop aggressive breast cancer when made obese. Ten-week old TgMMTV-neu mice were fed a HFHS diet for 4 weeks, then randomized into 2 cohorts when obese, one cohort receiving the adjuvant only (Alum) and one receiving ADVac. Mice were sacrificed at 31 weeks of age when all controls had developed

tumor. ITT showed the glucose levels in the blood were significantly lower in the ADVac group as compared to control ($p < 0.0001$). Fewer CD8 T-cells were observed in mammary adipose tissue of AdVac immunized mice compared to control ($p = 0.001$). There was significantly less leptin detected in the serum of ADVac vaccinated mice compared to Alum immunized, $p = 0.024$. The median age of tumor development was 25 weeks in controls and 29 weeks in the immunized group ($p = 0.009$). Sixty percent (9/15) of the vaccinated mice were tumor free at study termination, whereas 100% of the control mice had developed tumor. Conclusions: ADVac represents the first vaccine to lower breast cancer risk in obesity. Vaccination corrected metabolic dysfunction as evidenced by reversal of diabetes and prevented breast cancer in the majority of obese ADVac immunized mice. Further studies are ongoing evaluating the systemic distribution of ADVac specific T-cells and the safety of the approach.

PD12-06 Longitudinal analysis of breast density change assessed by digital mammogram is associated with breast cancer

Mammographic breast density is a well-established and strong risk factor for breast cancer. Widespread use of digital mammography has opened new potential for assessment of density changes over time. The underlying premise is that changes in breast tissue due to evolving structures that support cancer development should translate to quantifiable differences between the two breasts over time. To address this hypothesis, we draw on extensive digital mammography data and bring repeated measures over up to 10 years to evaluate the association between change in mammographic breast density and risk of breast cancer. Women were recruited from November 2008 to April 2012 through the mammography service at the Joanne Knight Breast Health Center at Washington University in St Louis. Baseline questionnaire risk factors and screening mammograms were collected from 12,153 women. Of these, 1,672 were excluded for prior history of any cancer (except non-melanoma skin) or diagnosis of breast cancer within 6 months of registration for the study, for a total of 10,481 women. Follow-up is through linking to electronic health records, tumor registry and death register. Routine screening mammograms are collected every 1 to 2 years. Follow-up of cohort participants through December 2020 was: 78% seen in 2019 or 2020; a further 4.4% seen most recently in 2018 and a further 2.4% in 2017 giving over 80% active follow-up for women seen within the last 36 months. The median number of mammograms is 5 (min = 1, max = 10; sd = 2.43). The average person-years of follow-up through most recent contact is 9.2 person-years. We have excluded women who are diagnosed within the first 6 month of baseline mammogram date in all analyses, leaving 259 cases and 695 controls with a total number of 8,966 craniocaudal (CC) view mammograms for analysis. For these 954 women, the mean number of years between mammograms is 1.3 (10th percentile: 1.0, 90th percentile: 2.0). For the cases, the mean number of years from last mammogram date to diagnosis date was 2.0 years (10th percentile: 1.0, 90th percentile: 3.9) after excluding mammograms that are within 6 months of diagnosis. The percentage volumetric density (MD) within each digital CC-view mammogram is estimated with an automated pixel-thresholding algorithm ADAPT implemented within the Division of Public Health at WashU. The skin around the breast is automatically removed using a boundary detection algorithm prior to estimating the dense areas. The percent density (MD) is then estimated using the dense area divided by the total breast area which normalizes the difference in breast size across women. The correlation between average MD generated from our automated algorithm with Volpara is 0.82. Initial analyses use linear mixed effects with average density between breasts (fitted with R package lmer). We performed test of assumptions for all linear mixed effects models, including the normality of residuals, linearity, and homogeneity of residual variance. Assessing the averaging density between 2 breasts

controlling for age, BMI, histology confirmed benign breast disease, family history, parity, and alcohol, MD decreases significantly over follow-up (time in years) ($P < 0.01$). At baseline, postmenopausal women had lower density than premenopausal women after controlling for the same set of risk factors. The average MD over all time points was significantly different for the case vs. control women ($P < 0.01$). For overweight women, the trajectory of MD over time was significantly different for the case vs. control women ($P < 0.01$). Drawing on over 10 years of follow-up we observe, for the first time, a dynamic effect for breast density such that divergence in density over time is related to risk for breast cancer.

Background: Neoadjuvant systemic therapy is increasingly applied in breast cancer patients to improve surgical and oncological outcomes. There is only limited data from clinical practice on the relevance of body mass index (BMI) on the pathologic complete response (pCR) rate following neoadjuvant systemic treatment (NST). We aimed to retrospectively analyze the impact of BMI on pCR after NST for Dutch breast cancer patients.

Methods: Patients diagnosed with invasive breast cancer between 2019 and 2021 who were treated with NST followed by a surgical procedure, were selected from the Netherlands Cancer Registry (NCR). Patients were divided into three groups based on BMI: patients with underweight/normal weight (BMI < 25 kg/m²), patients with overweight (BMI 25-29.9 kg/m²) and patients with obesity (BMI > 30 kg/m²). Patients with unknown BMI, ER/PR/HER2 or pCR status were excluded for analysis. The primary outcome was pCR after NST. The association between BMI and pCR was estimated using logistic regression models with the expression of odds ratios (ORs).

Results: After applying in- and exclusion criteria, 4430 patients were included for analysis, stratified into four molecular breast cancer subtypes; HR+/HER2- (n=2256), HR+/HER2+ (n=722), HR-/HER2+ (n=405) and HR-/HER2- (n=1047). The predictors age, differentiation grade, histological type, clinical tumor (cT) and nodal (cN) stage and molecular breast cancer subtype were found significant for achieving pCR after NST. Multivariable regression analysis identified differentiation grade, cT and cN stage and molecular subtype as independent

predictors for pCR after NST. There was no association between pCR and (continuous or categorical) BMI. Above mentioned analyses performed by stratification according to molecular breast cancer subtype, also showed no statistically meaningful association between BMI and pCR.

Conclusion: In this nationwide retrospective cohort study, evaluating 3340 patients with invasive breast cancer, we found no evidence of BMI being a predictive factor for achieving pCR following NST in neither the whole cohort, nor stratified according to molecular breast cancer subtype.

Background: Neoadjuvant chemotherapy is available to women with locally advanced breast cancer where chemotherapy is given prior to surgery. By examining resected tissue following neoadjuvant chemotherapy pathological complete response (pCR) can be determined. pCR is a favorable prognostic factor associated with longer survival compared to residual disease after neoadjuvant chemotherapy. Physical activity and diet may improve some side effects during treatment, but less is known about their effect on chemotherapy completion and more specifically on pCR in the neoadjuvant setting. Utilizing data from a randomized trial of diet and physical activity with a primary endpoint of chemotherapy completion in women with newly diagnosed breast cancer initiating chemotherapy, we evaluated the effect of a lifestyle intervention on pCR among the subset of women in the trial who received neoadjuvant chemotherapy. Methods: The Lifestyle, Exercise and Nutrition Early after Diagnosis (LEANer) Study enrolled 173 women with Stage I-III breast cancer who were randomized to usual care (n = 86) or a yearlong, 16-session, in-person or telephone-administered diet and physical activity intervention (n = 87) delivered by registered dietitians. Among study participants, 73 women received neoadjuvant chemotherapy and of these, 72 (98.6%) had complete follow-up pCR data (intervention = 40; usual care = 32). pCR, dates, doses and reason for dose-adjustments/delays of chemotherapy were abstracted from electronic medical records and confirmed with treating oncologists. A Chi-square test was used to examine the effect of the intervention versus usual care on pCR. Results: The 72 women receiving neoadjuvant chemotherapy with complete follow-up pCR data in LEANer were 49.4±11.6 years old, had a body mass index of 30.0±6.7 kg/m², and 37.0% and 49.3% had stage I or II breast cancer, respectively. Just over half (52.1%) of women had ER/PR positive cancers and 32.9% of tumors were HER2 positive, with no statistically significant differences in tumor type by study arm. 92.7% of the women randomized to intervention adhered to all of the counseling sessions during their neoadjuvant chemotherapy and had statistically significant improvements in mean physical activity (161 minute increase versus 40 minute increase, p-value = < 0.001) and fiber intake (0.21 gram/day increase versus -5.17 g/day decrease, p-value = 0.020), as well as median fruit and vegetable intake (0.6 serving/day increase versus -0.5 serving/day decrease, p-value = 0.041) compared to usual care. There was a benefit of the intervention on pCR compared to usual care (52.5% with pCR in the intervention arm versus 28.1% with pCR in the usual care arm, p-value = 0.037). The intervention effect on pCR did not appear to be impacted

by chemotherapy completion (relative dose intensity of 92% in intervention versus 90% in usual care) or chemotherapy dose delays as these were similar in the two study arms. In mediation analyses, results suggested that the changes in physical activity mediated, at least partially, the intervention effect on pCR. Conclusions: A primarily telephone-based diet and physical activity intervention led to improved pCR compared to usual care among the subset of women with breast cancer in the LEANer Study who received neoadjuvant chemotherapy. As pCR is an important prognostic factor for breast cancer, additional lifestyle interventions focusing on the neoadjuvant treatment setting with pCR as the primary outcome are necessary to confirm the potential benefits of lifestyle changes on pCR.

Background: Tumor characteristics such as grade, stage and receptor status are associated with breast cancer (BC) prognosis. Less is known about modifiable factors and BC prognosis. Advanced glycation end-products (AGEs) are reactive metabolites produced as a by-product of sugar metabolism, generated in conditions of increased oxidative stress. AGEs irreversibly accumulate in our tissues over time with pathogenic effects on genetic fidelity, protein function, cell signaling pathways, and chronic inflammatory diseases. The total body AGE pool is composed of endogenous AGEs and exogenous AGEs (consumed mainly through processed foods and those cooked at high temperatures). Serum AGE (sAGE) levels, a reflection of total body AGE, are higher in people with poor diet quality, lower levels of physical activity, and in women with BC compared to healthy controls. AGEs promote growth, migration and invasion in BC cell lines and activate prognostic inflammatory mediators such as interleukin-6 and C-reactive protein. Dietary AGEs have been associated with increased BC risk and increased mortality after BC diagnosis whereas lifestyle interventions can lower dietary and sAGE levels. The impact of sAGE levels, a better estimate of total body AGE than dietary AGE, on BC prognosis has not been previously evaluated. Methods: The Women's Healthy Eating and Living (WHEL) study randomized 3088 BC patients stage I-III who completed their primary therapy to a high-vegetable, low-fat diet or control and followed for a median of 7.3 years. Main

outcomes were invasive BC events (recurrence or new primary N=518), death due to BC (N=262) and deaths from any cause (N=315). sAGE was measured as the AGE metabolite carboxymethyllysine (ug/ml) from WHEL fasting blood specimens at study entry. sAGE was logged and corrected for plate batch effect via linear regression and analyzed in continuous scale and in quintiles. The Kaplan-Meier method and Cox regression model were performed for risk impact of sAGE on overall survival (OS), recurrence free survival (RFS), breast cancer specific survival (BCSS) and distant metastasis free survival (DMFS). We additionally adjusted in Cox models for potential confounding variables (age, race, BMI, smoking, alcohol use, physical activity, tumor characteristics). Results: 2564 participants had sAGE available. After excluding samples for excessive variabilities, 2315 samples were analyzed. Raw corrected sAGE ranged from 0.0-48.15 ug/ml (median 7.39); logged and corrected range -5.04-1.67. sAGE was positively associated with BMI ($p < .0001$, r_s 0.10) and negatively associated with physical activity ($p < .001$, r_s -.006). sAGE was not significantly associated with tumor stage, grade, receptor status, or race or menopausal status. Comparing the highest quintile (logged and corrected range=0.33~1.67) to the lowest quintile (range=-5.04~-0.30), sAGE was significantly associated with all survival outcomes (Table 1). As a continuous variable, AGE was associated with worse OS (HR 1.38, $P = .031$, β .32) and RFS (HR 1.29, $P = .028$, β .25) with a trend towards worse DMFS (HR 1.28, $P = .067$, β .25) and BCSS (HR 1.36, $P = .06$, β .31). Conclusions: Higher sAGEs are associated with worse survival outcomes in BC and may represent a novel, lifestyle-linked, modifiable prognostic biomarker in BC. Interventions aimed at lowering sAGE levels should be tested for their impact on known prognostic biomarkers as well as clinical outcomes. Individualized cancer-specific lifestyle recommendations are a crucial but currently lacking component of personalized cancer medicine.

Background: In patients (pts) with ER+/HER2- metastatic breast cancer (MBC) following progression on prior endocrine and CDK4/6i therapy, the EMERALD trial demonstrated significantly prolonged progression-free survival (PFS) and a manageable safety profile for elacestrant versus standard of care endocrine therapy (SoC). Benefit was observed in all pts and in pts with ESR1 mutant MBC (ESR1-mut). EMERALD is the only oral SERD monotherapy

pivotal trial where all pts were pretreated with CDK4/6 inhibitor (CDK 4/6i). Here, we examine the impact of duration of prior CDK4/6i on PFS.

Methods: EMERALD (NCT03778931) is a randomized, open-label, phase 3 trial that enrolled pts with ER+/HER2- MBC who previously had 1-2 lines of endocrine therapy, mandatory CDK4/6i, and ≤ 1 chemotherapy; prior treatment with fulvestrant was allowed. Patients were randomized 1:1 to elacestrant (400 mg orally daily) or SoC (investigator's choice of aromatase inhibitor or fulvestrant). If randomized to the control arm, patients who received prior fulvestrant were to receive an aromatase inhibitor, and vice versa. If two CDK4/6i were used in the metastatic setting (n=40), the cumulative duration was calculated.

Results: A total of 478 pts were randomized (228 with ESR1-mut) between Feb 2019 – Oct 2020 (n=239, elacestrant; n=239, SoC). Overall survival was not yet mature, as of September 2nd 2022. Updated PFS results show statistically significant results in favor of elacestrant, both in all pts and in pts with ESR1-mut. The duration of prior CDK4/6i in the metastatic setting was positively associated with PFS, the longer the duration of prior CDK4/6i in the metastatic setting (n=465), the longer the PFS on elacestrant versus SoC (Table 1).

Table 1: PFS estimates in the elacestrant and SoC arms based on different cut-off points for the duration of prior CDK4/6i.

Updated safety data were consistent with previously reported results. Most of the adverse events (AEs), including nausea, were grade 1 and 2, and only 3.4% and 0.9% of the pts discontinued trial therapy because of an AE on elacestrant and SoC, respectively. A low percentage of pts received an antiemetic; 8.0%, 3.7%, and 10.3%, on elacestrant, fulvestrant, and AI, respectively. No hematological safety signal was observed and none of the patients in either of the two treatment arms had sinus bradycardia.

Conclusions: EMERALD is the first phase 3 trial to demonstrate a significant PFS improvement versus SoC in all pts and in the subgroup with ESR1 mutations in pts with ER-positive/HER2-negative MBC with 1-2 prior lines of endocrine treatment \pm one line of chemotherapy. Elacestrant demonstrated longer PFS versus SoC that was positively associated with the duration of prior treatment with CDK4/6i, which was more pronounced in pts with ESR1-mut MBC. In this 2nd and 3rd line setting, elacestrant was well tolerated with significantly longer PFS versus SoC, highlighting its potential role as a therapeutic option for pts with ER+/HER2-MBC.

Table 1: PFS estimates in the elacestrant and SoC arms based on different cut-off points for the duration of prior CDK4/6i.

Duration on CDK4/6i in the metastatic setting	≥6.0 months		≥12.0 months		≥18 months

Background: ARV-471 is a selective, orally administered PROteolysis TArgeting Chimera (PROTAC®) protein degrader that targets wild-type and mutant ER. ARV-471 is being evaluated in patients with ER+/HER2- locally advanced or metastatic breast cancer in a first-in-human phase 1/2 study (NCT04072952). In the phase 1 dose escalation, ARV-471 monotherapy (dose range: 30–700 mg total daily dose) showed a manageable safety profile in patients who had previously received endocrine therapy and a cyclin-dependent kinase (CDK) 4/6 inhibitor. The clinical benefit rate (CBR; rate of confirmed complete or partial response or stable disease ≥ 24 weeks) was 40% (95% CI: 26–56) in 47 evaluable patients. The phase 2 expansion portion of the study (VERITAC) evaluated 2 doses of ARV-471. Methods: In VERITAC, ARV-471 monotherapy was administered at doses of 200 mg once daily (QD) or 500 mg QD to patients with ER+/HER2- locally advanced/metastatic breast cancer who had received ≥ 1 prior endocrine therapy for ≥ 6 months, ≥ 1 CDK4/6 inhibitor, and ≤ 1 chemotherapy regimen. The primary endpoint of CBR was evaluated in patients enrolled ≥ 24 weeks prior to the data cutoff. Results: As of June 6, 2022, 71 patients received ARV-471 (200 mg QD [n=35]; 500 mg QD [n=36]) in VERITAC. Across all treated patients, 69 (97.2%) were female and median age was 60 y (range: 41–86). Patients had received a median of 4 prior regimens in all settings (range: 1–10); 100% had prior CDK4/6 inhibitors, 78.9% had prior fulvestrant, and 73.2% had prior chemotherapy. ARV-471 was well tolerated at both doses, with most treatment-related adverse events (TRAEs) grade 1/2; the most common TRAEs were fatigue and nausea (Table). In all, 3 patients (1 in the 200 mg QD cohort and 2 in the 500 mg QD cohort) discontinued ARV-471 due to treatment-emergent adverse events (TEAEs); 3 patients had ARV-471 dose reductions due to TEAEs (all from 500 mg QD to 400 mg QD). CBR was 37.1% (95% CI: 21–55) in 35 evaluable patients treated at 200 mg QD and 38.9% (95% CI: 23–57) in 36 evaluable patients treated at 500 mg QD. CBR in evaluable patients with mutant ESR1 in the 200 mg QD (n=19) and 500 mg QD (n=22) cohorts was 47.4% (95% CI: 24–71) and 54.5% (95% CI: 32–76), respectively. Conclusions: In the phase 2 VERITAC expansion cohorts of patients with ER+/HER2- locally advanced/metastatic breast cancer and prior CDK4/6 inhibitor treatment, ARV-471 monotherapy showed evidence of clinical activity based on CBR, which was further enhanced in the subgroup with ESR1 mutations. The manageable AE profile observed in the phase 1 portion of the study was maintained during cohort expansion at doses of 200 mg QD and 500 mg QD. Additional analyses are ongoing. Table. TRAEs reported in $\geq 10\%$ of patients overall ^aNo grade 3/4 TRAE occurred in >1 patient.

AST=aspartate aminotransferase

Background: AKT pathway activation has been implicated in the development of endocrine therapy resistance in hormone receptor-positive/human epidermal growth factor receptor 2-negative (HR+/HER2-) advanced breast cancer (ABC). In the Phase II, placebo (PBO)-controlled FAKTION trial, the addition of the pan-AKT inhibitor capivasertib to fulvestrant significantly improved progression-free survival (PFS) and overall survival in postmenopausal women with aromatase inhibitor (AI)-resistant HR+/HER2- ABC. The Phase III, randomized, double-blind, PBO-controlled CAPItello-291 trial (NCT04305496) investigated the efficacy and safety of capivasertib + fulvestrant in patients with AI-resistant HR+/HER2- ABC. Methods: Eligible pre/peri or postmenopausal women or men with HR+/HER2- ABC that had recurred or progressed on or after AI therapy with or without a cyclin-dependent kinase 4 and 6 (CDK4/6) inhibitor were randomized 1:1 to receive fulvestrant (per standard dosing schedule) with either PBO or capivasertib (400 mg twice daily; 4 days on, 3 days off). Randomization was stratified by the presence of liver metastases, prior use of CDK4/6 inhibitors, and geographic location. AKT pathway alteration status (at least one qualifying PIK3CA, AKT1, or PTEN alteration) was determined using next-generation sequencing in tumor tissue. The dual primary endpoint was investigator-assessed PFS in the overall population and in patients with AKT pathway-altered tumors. **Results:** A total of 708 patients were randomized: 355 to capivasertib + fulvestrant and 353 to PBO + fulvestrant. Overall, 41% of patients had AKT pathway-altered tumors (48% [n=289/602] of patients with tumor sequencing results), 22% were pre/perimenopausal and 77% postmenopausal, with 1% male. Prior therapy for advanced disease included: 87% of patients with ≥1 line of prior treatment, 69% with a prior CDK4/6 inhibitor, and 18% with prior chemotherapy. Demographic and baseline characteristics were broadly balanced between the overall and altered populations and by treatment groups. At primary analysis (data cut-off Aug 15, 2022), 551 and 236 PFS events had occurred in the overall and pathway-altered

populations, respectively. Overall, the median PFS was 7.2 months with capivasertib + fulvestrant and 3.6 months with PBO + fulvestrant (hazard ratio [HR] 0.60; 95% confidence interval [CI] 0.51–0.71; $p < 0.001$). In patients with AKT pathway-altered tumors, median PFS was 7.3 months with capivasertib + fulvestrant and 3.1 months with PBO + fulvestrant (HR 0.50; 95% CI 0.38–0.65; $p < 0.001$). The objective response rate in patients with measurable disease was 22.9% for capivasertib + fulvestrant vs 12.2% for PBO + fulvestrant overall and 28.8% vs 9.7% in the AKT pathway-altered population. The most frequent all-grade adverse events (AEs) with capivasertib + fulvestrant were diarrhea (72.4% vs 20.0% PBO + fulvestrant arm), rash (group term of rash, rash macular, rash maculo-papular, rash papular, rash pruritic; 38.0% vs 7.1%) and nausea (34.6% vs 15.4%). The most frequently reported grade ≥ 3 AEs were rash (group term; 12.1% vs 0.3%), diarrhea (9.3% vs 0.3%), and hyperglycemia (2.3% vs 0.3%); grade ≥ 3 stomatitis was 2.0% vs 0%. AEs leading to discontinuation of capivasertib/placebo were reported in 13.0% and 2.3% of patients, respectively. **Conclusions:** Capivasertib + fulvestrant significantly improved PFS compared to fulvestrant alone in the overall population, and in patients with AKT pathway-altered tumors, and may become a future treatment option in this setting. The safety profile of capivasertib + fulvestrant was generally manageable and consistent with prior data. **Funding:** CAPItello-291 is sponsored by AstraZeneca. **Editorial acknowledgment:** AstraZeneca-funded medical writing support was provided by Suzanne Patel, Ph.D., from BOLDSCIENCE Inc. Capivasertib was discovered by AstraZeneca subsequent to a collaboration with Astex Therapeutics (and its collaboration with the Institute of Cancer Research and Cancer Research Technology Limited).

Background CDK4/6 inhibitors (CDK4/6i) in combination with endocrine therapy (ET) have a well-established role in the management of hormone receptor-positive (HR+)/HER2- metastatic

breast cancer (MBC). The benefit of continuing CDK4/6i beyond progression in combination with a different ET has not been confirmed. Preclinical data suggest synergy between CDK4/6i and PD-L1 inhibition. The PACE trial prospectively evaluates whether continuation of the CDK4/6i palbociclib beyond progression on prior CDK4/6i and aromatase inhibitor (AI), with a change in ET to fulvestrant, improves outcomes beyond change to fulvestrant alone, as well as explores the activity of the palbociclib, fulvestrant, and avelumab triplet. Methods PACE is a multicenter randomized open-label investigator-initiated phase II trial, open at 11 U.S. sites. Eligible patients (pts) had HR+/HER2- evaluable MBC with prior progression on AI and any CDK4/6i after > 6 months (mo) of therapy in the MBC setting, or during/within 12 mo in the adjuvant setting, with no more than 1 prior line of chemotherapy for MBC. Pts were randomized 1:2:1 to fulvestrant alone (F); fulvestrant and palbociclib (F+P); or fulvestrant, palbociclib, avelumab (F+P+A), with tumor assessments every 8 weeks. Blood for circulating tumor DNA (ctDNA) analysis was collected at baseline, at times of tumor assessments, and at progression. The primary objective was to evaluate progression-free survival (PFS) with F+P vs F; secondary objectives included PFS with F+P+A vs F, objective response rate (ORR) in all arms, and safety. A sample size of 220 patients was planned to provide 80% power to detect an improvement in PFS with HR 0.6154 with F+P vs F (6.5 vs 4 mo; $\alpha(1)=0.05$). Results A total of 220 pts were randomized from 9/2017-2/2022 (F: n=55, F+P: n=111, F+P+A: n=54); median age 57 years (range 25-83), 85% non-Hispanic (7.7% non-Hispanic black), 8.6% Hispanic, 6.4% unknown. 40% had de novo MBC, 60% had visceral disease, and 14% bone-only disease. 16% had 1 prior line of chemotherapy for MBC, 90% had received prior palbociclib, 4.5% ribociclib, 4.1% abemaciclib, 1.4% palbociclib and ribociclib. Pts entered the trial after a median 19 mo of prior CDK4/6i plus AI (interquartile range 12-31 mo). A total of 10 (5%) pts received protocol therapy as first line ET for MBC, 169 (77%) as second line, and 41 (17%) as beyond second line. 88% entered the trial directly after progression on CDK4/6i. After a median follow-up of 24 mo, 18 pts remained on protocol treatment. PFS was not improved with F+P vs F (median 4.6 vs 4.8 mo; HR=1.11, 90% CI 0.79-1.55; 2-sided p=0.62). Median PFS was 8.1 mo with F+P+A (HR=0.75 vs F, 90% CI 0.50-1.12; 2-sided p=0.23). ORR was 7.3% (90%CI 1.5-13.0) with F, 9.0% F+P (4.5-13.5%) and 13.0% F+P+A (5.4-20.5%). No new safety signals have been observed. Analysis of ctDNA panel sequencing encompassing 70 genes from 184 baseline samples, including correlation with known and hypothesized resistance genes, will be presented. Conclusions For ER+/HER2- breast cancer, combining palbociclib with fulvestrant beyond progression on prior CDK4/6i and AI did not significantly improve PFS compared with using fulvestrant alone. The observed longer PFS when a PD-L1 inhibitor was added to fulvestrant plus palbociclib is an intriguing signal in this ER+ population. Translational studies of blood and tumor tissue are ongoing and will be presented.

Background Despite the remarkable activity of CDK4/6 inhibitors (CDK4/6i) in the treatment of estrogen receptor positive (ER+) metastatic breast cancer (BC), most patients eventually develop resistance to these drugs. The ctDNA analysis of the PALOMA-3 trial showed that the estrogen receptor (ER) mutation Y537S is a potential mechanism of acquired resistance to the combination of endocrine therapy (ET) with CDK4/6i. To date, the role of the ER mutations in the clonal evolution and the mechanisms of acquired resistance to CDK4/6i is unknown. Moreover, it is not known if the development of resistance to CDK4/6i in the presence or absence of ER mutations is due to the expansion of pre-existing resistant clones or to the de novo acquisition of resistance mechanisms. **Methods** To explore the clonal evolution and the mechanisms of resistance to CDK4/6i in ER-wild type (ER-WT) and ER-mutant (ER-Mut) BC, we transduced doxycycline (DOX)-inducible Y537S ER-Mut MCF7 cells with the ClonTracer library, a high-complexity DNA barcode library, and cultured the barcoded cells without DOX (MCF7), or with DOX to induce the expression of the Y537S ER mutation (MCF7-YS). To develop Palbociclib (Palbo)-resistant (PDR) and Abemaciclib (Abema)-resistant (ABR) cell models, the barcoded MCF7 and MCF7-YS cells were passaged in culture with increasing concentrations of Palbo and Abema until the acquisition of resistance. The clonal dynamics and the molecular characteristics of the PDR and ABR models were investigated by barcode sequencing, whole-exome sequencing (WES), bulk and single cell RNA sequencing (RNAseq) and protein analyses. Finally, using an ER-Mut barcoded mice model, we compared the in vitro clonal evolution of ER-Mut CDK4/6i-resistant cells with the in vivo clonal evolution of ER-Mut metastases. **Results** The analysis of the barcodes revealed that during the acquisition of resistance to either Palbo or Abema there is a strong clonal selection of pre-existing resistant clones. The PDR clones were different in the presence of the Y537S mutation versus WT-ER. In contrast, the clones enriched in the ABR cells were comparable between WT and mutant ER. Furthermore, the ER mutations led to decreased diversity of the enriched clones in the PDR but not in the ABR cells. Interestingly, the barcodes enriched in the PDR and ABR models did not overlap. Unsupervised analyses showed that the samples clustering based on the barcodes fractions and the mutations were similar, suggesting that the clonal selection was driven by cellular populations with specific mutational landscapes. All the ER-WT and ER-Mut resistant models had different transcriptional profiles and by single-cell RNAseq showed various degrees of intra-sample heterogeneity. At the protein level, the PDR and the ABR cells displayed downregulation of ER, Rb and p27 and upregulation of p21. In the ER-Mut conditions Cyclin D1 was upregulated in the PDR cells, while Cyclin E was upregulated in the ABR cells. Finally, the barcode sequencing of the mice metastases revealed that the clonal selection in ER-Mut metastases and in ER-Mut CDK4/6i-resistant cells is different. **Conclusion** Our study suggests that the development of resistance to CDK4/6i is due to the selection of pre-existing resistant

clones. We also demonstrate that the expression of the Y537S ER mutation impacts the clonal evolution and the mechanisms of acquired resistance to Palbo but not to Abema. Finally, we show that the clonal evolution and mechanisms are disparate in Palbo and Abema resistance. These results support the addition of a third drug to CDK4/6i and ET, early in treatment, to delay the selection of pre-existing resistant clones and prolong the response to treatment and highlight differences between Palbo and Abema.

Adjuvant endocrine therapy for premenopausal ER+breast cancer had a relatively challenging initial pathway. The earliest trials testing adjuvant ovarian ablation in premenopausal breast cancer were hampered by the lack of ability to test for the relevant target, namely the estrogen receptor (ER). Therefore, trials testing adjuvant ovarian ablation and subsequently ovarian suppression with gonadotropin releasing hormone agonists (GnRHa) were diluted by the inclusion of women with estrogen receptor negative tumors. The subsequent demonstration of the effectiveness of adjuvant chemotherapy, initially with the CMF regimen, diverted some attention away from adjuvant endocrine therapy in premenopausal women, notwithstanding the fact that CMF, initially given for 12 months, resulted in permanent ovarian function suppression in many premenopausal women. Use of adjuvant CMF made it even more challenging to discern the added value of ovarian ablation or suppression. Oral adjuvant endocrine therapy with the selective estrogen receptor modulator tamoxifen became recommended for postmenopausal women, subsequently refined to only those with ER+ breast cancer, but the value of tamoxifen in premenopausal women was initially considered uncertain. Eventually, 5 years of adjuvant tamoxifen became a standard recommendation for premenopausal ER+ early breast cancer, although it took some time for evidence to emerge on the value of adding tamoxifen in women who received chemotherapy. The value of extending adjuvant endocrine therapy beyond 5 years was subsequently studied. More recent randomized premenopausal adjuvant endocrine therapy trials have focused on delineating the value of ovarian function suppression (OFS) added to tamoxifen or to an aromatase inhibitor. There are now a range of options for adjuvant endocrine therapy for premenopausal ER+ breast cancer, and identifying the clinical-pathologic features most appropriate for intensification of adjuvant endocrine therapy can assist with optimizing recommendations for an individual patient.
