Background: The results of the Early Breast Cancer Trialist Group (EBCTCG) meta-analysis (Lancet 2015) led to the widespread adoption of bisphosphonates as adjuvant therapy for postmenopausal early-stage breast cancer (EBC). Despite evaluating multiple bisphosphonate agents and regimens, there was no signal of varying efficacy with different agents, routes of administration or dose / dose intensity. We evaluated the question of treatment de-escalation using long-term outcome data from the prospective randomized ABCSG-12 trial.

Patients and methods: Between 1999 and 2006, ABCSG-12 accrued 1803 patients with hormone-receptor positive EBC on ovarian function suppression for three years that were randomized to receive 4 mg zoledronic acid 6-monthly or not (and tamoxifen or anastrozole, in a 2:2 factorial design). In the current retrospective study, we evaluated whether the number of zoledronate infusions actually received had an impact on breast cancer-specific and fragility fracture outcomes. Based on the results of the EBCTCG meta-analysis, we hypothesized that amongst patients who receive less infusions than the planned seven zoledronate infusion in this trial, the number of infusions has no differential effect on these outcomes. Time to event endpoints were analyzed with Cox models and Kaplan Meier curves starting from a 3-year landmark. BMD subset analyses were restricted to patients who participated in the BMD sub-study with available BMD data.

Results: 725 patients who received at least one zoledronate infusion were included in the time-to-event-analysis. There was no statistically significant difference in disease-free survival (adjusted HR 0.83, 95% CI 0.48–1.44, p=0.51) or overall survival (HR 0.97, 95% 0.30-3.11, p=0.96) in patients who received ≤6 zoledronate infusions (n=170) compared to those who received ≥7 zoledronate infusions (n=555) (adjusted HR 0.83, 95% CI 0.48 – 1.44, p=0.51). Both subgroups show stable lumbar spine and total hip BMD measurements across the five years.

Conclusions: Comparable to the metastatic bone disease and fragility fracture settings, there was no evidence observed to indicate that a reduced number of zoledronate infusions is associated with reduced adjuvant efficacy. Further studies to define optimal regimens of adjuvant bone-targeted therapies (prospective evaluation of “how-low-can-you-go”) are required.

Table 1: Multivariate Cox Regression: DFS and OS

Table 1: Multivariate Cox Regression: DFS and OS

Covariate		Outcome=DFS		Outcome=OS	
		HR (95% CI)	P-value	HR (95% CI)	P-value
Number of ZOL infusions	≤6 infusions vs. ≥7 infusions	0.83 (0.48, 1.44)	0.51	0.97 (0.30, 3.11)	0.96
Endocrine Therapy	Tamoxifen vs. Anastrozole	0.77 (0.49, 1.21)	0.26	0.85 (0.31, 2.37)	0.76
pT-Stage	pT2/pT3 vs. pT1	2.36 (1.47, 3.78)	<0.001	4.36 (1.54, 12.30)	0.006
pN-Stage	Positive vs. Negative	1.34 (0.84, 2.13)	0.22	0.80 (0.27, 2.42)	0.70

Background: The bone modifying agents (BMAs), bisphosphonates, reduce risk of cancer recurrence after diagnosis of early-stage breast cancer (EBC), particularly in postmenopausal women, while another BMA, denosumab, has not been shown to improve EBC outcomes. The 2017 American Society of Clinical Oncology (ASCO) and Cancer Care Ontario (CCO) clinical guidelines recommended consideration of adjuvant bisphosphonates for postmenopausal women with EBC who are candidates for adjuvant systemic therapy. Despite this, small survey-based studies suggest that their prescribing is variable. The goal of this study was to evaluate prescribing of adjuvant BMAs in the United States before and after publication of the 2017 ASCO/CCO guidelines (ACGD).

Methods: This retrospective cohort study used the nationwide Flatiron Health electronic health record (EHR)-derived de-identified database and included 11,740 patients diagnosed with stage I-III breast cancer from 2012 to 2019. We analyzed data on use of BMAs (bisphosphonates or denosumab) in the adjuvant setting, defined as receiving first dose of BMA within 24 months of breast cancer diagnosis and before diagnosis of metastatic disease. Any episodes of BMA use after a metastatic recurrence were excluded. We used Chi-squared test to compare the proportion of patients receiving adjuvant BMAs pre- and post-ACGD. We used univariable and multivariable logistic regression analyses with list-wise missing value deletions to identify predictors of adjuvant BMA prescribing.

Results: Of 11,740 patients, 7,391 were diagnosed pre-ACGD and 4,349 post-ACGD. Of the pre-ACGD patients, 545 (7.4%) patients received adjuvant BMAs, and of the post-ACGD patients, 390 (9.0%) patients received adjuvant BMAs. Patients diagnosed post-ACGD were more likely to receive adjuvant BMAs compared with patients diagnosed pre-ACGD (OR 1.23; 95% confidence interval (CI) 1.08-1.42; p=0.002). Of patients age \geq 50 (n=9,654), 522 of 6,027

(8.7%) and 360 of 3,627 (9.9%) received adjuvant BMAs pre- and post-ACGD, respectively (OR 1.146; 95% CI 0.996-1.319; p=0.0572). In multivariable analysis, age \geq 50 years at diagnosis, post-menopausal status, having T2 or higher stage at diagnosis, adjuvant endocrine therapy, and coexisting bone loss diagnosis were significantly associated with receipt of adjuvant BMAs (Table 1). Of the 935 patients who received adjuvant BMAs, 615 (65.8%) had denosumab only, 305 (32.6%) had a bisphosphonate only, and 13 (1.4%) received both a bisphosphonate and denosumab during the course of adjuvant treatment. Two patients received an adjuvant BMA as part of a clinical trial.

Conclusions: Adjuvant BMA prescribing in our cohort was overall low; there was a modest increase in uptake in patients with EBC diagnosed after the publication of the 2017 ACGD. Older age, higher T stage, endocrine therapy, and coexisting bone loss diagnoses were significantly associated with receipt of adjuvant BMAs. Despite the recommendations for bisphosphonates in the adjuvant setting in EBC, the majority of patients received denosumab only. Considering these findings, further research is required to determine barriers to BMA prescribing and factors that influence physician and patient decisions. There continues to be a need for improved implementation and dissemination of recent guidelines, including the updated 2021 ASCO/CCO recommendations which continue to endorse bisphosphonate use in the adjuvant setting.

Univariable and multivariable logistic regression analyses to identify predictors of receiving adjuvant BMAs

Table 1. Univariable and multivariable logistic regression analyses to identify predictors of receiving adjuvant BMAs

Variables	Univariate analysis		Multivariate analysis	
	OR (95% CI)	P-value	OR (95% CI)	P-value
Age at Diagnosis (\geq 50 versus <50 years)	3.86 (2.91-5.11)	<0.001*	1.61 (1.03-2.52)	0.038*

Background. Adjuvant denosumab treatment improved bone-health related outcomes in early breast cancer (BC) patients with discordant survival results. We undertook a systematic review and meta-analysis of randomized controlled trials (RCTs) to assess efficacy and safety of adjuvant denosumab in addition to standard anticancer therapy. **Methods.** PubMed, CENTRAL, Scopus, Embase, clinicaltrials.gov and key oncological meetings websites were screened to identify potentially eligible RCTs based on the PICO model: P) Participant: pre and postmenopausal early BC patients; I) Intervention: adjuvant denosumab; C) Comparator: placebo; O) Outcomes: Disease-free survival (DFS), Bone Metastasis-free survival (BMFS), Overall Survival (OS), fracture incidence and time to first fracture were adopted as survival endpoints, and Adverse Events, Serious Adverse Events, Osteonecrosis of the Jaw (ONJ) and Atypical Femur Fractures (AFF) as safety endpoints; S) Study design: phase III RCTs. Risk of bias was assessed with Cochrane Collaboration Risk of Bias Tool. Pooled hazard ratios (HR), risk ratios (RR), risk differences (RD) and respective confidence intervals (CI) were computed using both a fixed and a random effect model. Subgroup analyses based on menopausal status, hormone receptor and HER2 status and immunophenotype were performed. **Results.** Two phase III RCTs were included (ABCSG-18, D-CARE), for an overall population of 7929 early BC patients receiving denosumab or placebo. Denosumab addition to standard of care anticancer treatment showed no difference in DFS (HR 0.93; 95% CI 0.75-1.16, p=0.53), BMFS (HR 0.90; 95% CI 0.75-1.07, p=0.23) and OS (HR 0.92; 95% CI 0.72-1.17, p=0.49). In hormone receptor-positive/HER2 negative patients, denosumab significantly prolonged both DFS (HR 0.88; 95% CI 0.78-0.99, p=0.04) and BMFS (HR 0.83; 95% CI 0.71-0.97, p=0.02). No interaction was found between denosumab addition and menopausal status. Fracture incidence (RR 0.79; 95% CI 0.70-0.89, p< 0.01) and time to first fracture (HR 0.76; 95% CI 0.66-0.87, p< 0.01) were also improved with denosumab. No association between denosumab addition and overall toxicity was seen and no difference was observed in terms of ONJ and AFF between the 60mg every 6 months schedule and placebo (RD 0.001, 95% CI from -0.001 to 0.002, p=0.48) **Conclusions.** Findings from this meta-analysis validate the role of denosumab as a highly effective anti-resorptive agent. We provide robust evidence that its addition to standard anticancer treatment significantly improves survival outcomes in hormone receptor-positive/HER2 negative early BC patients, suggesting that the implementation of denosumab use in combination with endocrine therapy in this patient population should be reconsidered. Background :

Everolimus (EVE) addition to adjuvant hormonotherapy (HT) for high-risk early breast cancer (BC) did not improve 3-year disease-free survival (DFS) compared with ET alone in the randomized UNIRAD trial (NCT01805271) (1). Most patients (pts) withdrew from EVE for adverse events nearly midway before the expected treatment duration of 2 years. The main EVE target involves m-TOR-induced S6 protein phosphorylation, which is controlled by the molecular circadian clock in mice and cells. Toward the analysis of possible circadian time-dependencies in EVE toxicities and efficacy, we first determine the actual distribution of the daily times chosen by the patients for both oral EVE and HT intakes.

Patients and methods:

The registered pts were asked to record the clock hours they chose for both HT and EVE or placebo (PLAC) intakes within four possible daily 6-h slots, i.e. from 06:00 to 11:59 (morning), 12:00 to 17:59 (midtime), 18:00 to 23:59 (evening), or 24:00 to 05:59, (night) in a daily diary throughout their participation in the trial. Modifications in times of drugs intake were reported. Comparisons between groups involved Kruskal-Wallis sum test and Pearson's Chi-squared and Fisher's exact tests.

Results:

Out of 1,278 randomized patients, 1063 (83,1 %) recorded the times of EVE or PLAC intakes, 852 recorded those for HT intakes. Only 10 pts reported night EVE/PLAC intakes and were not considered here. Of the 1053 evaluated pts; 549 pts took EVE/PLAC in the morning, 82 pts at midtime and 422 in the evening. As compared with evening intakes, morning or midtime intakes of EVE or PLAC were significantly associated with an older age, and post-menopausal status, whilst younger and premenopausal women preferentially chose evening intakes ($p < 0.001$ for both). Consistently, HT with aromatase inhibitors (AI) were mostly taken in the morning or at midtime, whereas tamoxifene (TAM) was mostly taken the evening ($p = 0.001$). Tumor size, lymph nodes involvement, histological grade, hormonal receptors status, and EVE initial dose

were similarly distributed among the three time slots (Table 1). A similar distribution of oral intake times as in the whole timing study population was found according to age, menopausal status and HT type in the EVE arm (N=508 pts), and in the HT population (+/- EVE or PLAC) (N=852 pts). Initial oral timing intake was modified for EVE by 50 of 508 pts (10%) and for HT by 10 of 852 pts (1%).

Conclusion:

To the best of our knowledge, it is the first time that the patients' spontaneous selection of daily times for oral intakes of a targeted agent (EVE) and HT is reported in a large series of early breast cancer pts. Age and menopausal status were important determinants of patient-selected daily timing intakes of both EVE and HT, as well as HT types. These findings will be carefully considered in the analyses of possible EVE and HT timing effects on adverse events and efficacy of the current adjuvant regimens.

Sarcopenia on baseline imaging is associated with toxicity-related discontinuation of endocrine therapy in women with early-stage hormone-positive breast cancer

Background Adjuvant endocrine therapy (ET) is standard of care in women with hormone receptor-positive (HR+) breast cancer (BC) with the goal to reduce recurrence. However, early discontinuation of ET occurs in 30-40% of women, largely attributable to toxicity, and leads to increased recurrence risk. There is considerable overlap in risk factors that predict toxicity from ET and chemotherapy, including age, co-morbidities, and geriatric conditions. Baseline low skeletal muscle area (SMA) on chest computed tomography (CT) is a surrogate marker for sarcopenia and predicts for significant toxicity and intolerance to chemotherapy in women with BC. No study has assessed the association of sarcopenia with toxicity-related discontinuation of ET in women with early-stage HR+ BC. Methods This single center retrospective cohort study included consecutive women with Stage 0-II HR+ BC who received ET and adjuvant radiotherapy (RT) from 01/2011-12/2017. Inclusion required a minimum of 5-year clinical follow-up after diagnosis. We used a validated deep learning pipeline to quantify SMA (cm²) at the tenth thoracic (T10) vertebral body on existing RT planning CT. The skeletal muscle index (SMI [cm²/m²] = SMA / (patient height (m))²) was calculated to adjust for patient height. Sarcopenia was defined as SMI < 32.3 cm²/m², based on a previously validated independent cohort of young healthy women. The primary endpoint was toxicity-related discontinuation of ET less than 60 months after initiation of ET. Secondary endpoints included any NCI CTCAE v5.0 Grade 3-5 toxicity from ET and ipsilateral breast tumor recurrence. We assessed associations

between ET discontinuation and SMI (continuous), as well as thoracic sarcopenia (dichotomous), using logistic regression adjusting for baseline characteristics. We used cox proportional hazards regression to assess disease-free survival (DFS), defined as ipsilateral breast tumor recurrence, locoregional recurrence, or distant metastasis adjusting for baseline and treatment characteristics. Results A total of 265 women (median age 67 years) met inclusion criteria. The majority of women had a comorbidity index of 0-1 (89%) and were Caucasian (89%). The median follow-up was 82 months, 5-year overall survival was 96% and 5-year DFS was 94%. Diagnoses included DCIS (12%), IDC (76%), or ILC (12%); most were T1 (69%) or T2 (18%) and N0 (85%), ER-positive (100%), PR-positive (85%), or HER2-negative (9%). Most common ET type was anastrozole (63%), letrozole (16%), and tamoxifen (17%). SMI (continuous) was not associated with older age, Charlson Comorbidity Index (CCI), race, or tumor stage. A total of 64 (24%) women experienced toxicity-related early discontinuation of ET. On multivariate analysis (MVA), lower SMI was associated with increased toxicity-related early discontinuation of ET (Odds Ratio [OR] 0.89 per 1 cm²/m² SMI, p=0.001) independent of age, CCI, ET type, or receipt of adjuvant chemotherapy. Lower SMI was associated with higher risk of grade 3-5 toxicity from ET (OR 0.89 per 1 unit SMI, p=0.001) independent of age, CCI, ET type, or receipt of adjuvant chemotherapy. On MVA, sarcopenia was associated with higher risk of toxicity-related early discontinuation of ET (OR 2.43, p=0.019). DFS was associated with toxicity-related early discontinuation of ET (HR 8.06, p=0.005), grade 3 histology (HR 1.42, p=0.042), and multifocal disease (HR 2.55, p=0.040), but not age, histology, stage, or lymphovascular invasion (p>.05 for all). Conclusion Low baseline thoracic skeletal muscle is associated with toxicity-related early ET discontinuation in women with early-stage HR+ BC. Further studies should attempt to generalize this association to all HR+ BC who are candidates for ET. High-risk patients may be candidates for aggressive symptom management or alternative adjuvant therapies.

Background: The Breast Cancer Index (BCI) is a validated gene expression assay that provides a quantitative individualized risk of late recurrence and predicts the likelihood of benefit from extended endocrine therapy (EET) in HR+ early-stage breast cancer. The objective of this analysis was to assess the impact of BCI on clinical decision-making regarding EET in the BCI Registry Study. Methods: The BCI Registry Study is an ongoing, prospective, large-scale study to investigate the long-term clinical outcome, decision impact, and medication adherence in

HR+ early-stage breast cancer patients receiving BCI testing as part of routine clinical care. Per protocol, physicians and patients completed pre- and post-BCI test questionnaires to assess the following: physician decision-making regarding EET; physician confidence with decision-making; patient preferences for EET; patient concerns about the cost, side effects, drug safety and benefit of EET; and patient satisfaction regarding treatment recommendation. Pre- and post-BCI responses were compared using McNemar's test and Wilcoxon signed rank test. Results: Pre- and post-BCI test physician and patient questionnaires were completed for 843 and 823 patients, respectively. For the patients included in this analysis, mean age at enrollment was 65y and 88.4% of patients were postmenopausal. 74.7% of tumors were T1, 53.4% were G2, 75.3% N0, and 13.8% HER2-positive. Following BCI testing, physicians changed treatment recommendations for EET in 40.1% (338/843) of patients ($p < 0.0001$). In cases in which physicians recommended EET prior to BCI testing, 44.7% (214/479) changed their recommendation not to extend endocrine therapy. Of these cases, 98.1% (210/214) were BCI Prognostic low risk and/or BCI (H/I) Predictive low likelihood of benefit from EET. In cases in which physicians did not recommend EET prior to BCI testing, 34.6% (124/358) changed their recommendation in favor of EET. In such cases, 87.1% (108/124) of cases were BCI Prognostic high risk and/or BCI (H/I) Predictive high likelihood of benefit from EET. Further, following BCI testing, 38.8% (327/843) of physicians felt more confident in their recommendation ($p < 0.0001$). The percentage of physicians having high confidence levels (confident or strongly confident) increased from 58.1% (490/843) before BCI testing to 80.5% (679/843) after BCI testing. The percentage of physicians having low confidence levels (not at all confident, not confident, or ambivalent) decreased from 39.1% (330/843) before BCI testing to 18.7% (158/843) after BCI testing. In addition, 40.5% (341/843) of patients felt more comfortable with their EET decision ($p < 0.0001$) following BCI testing. Notably, changes in patient preferences for EET correlated with BCI test results. In BCI (H/I)-Low patients, 46.9% (241/514) showed a decreased preference for EET ($p < 0.0001$) while in BCI (H/I)-High patients, 28.2% (87/309) showed an increased preference for EET ($p < 0.0001$). Compared with baseline, after BCI testing, significantly more patients were less concerned about cost (20.9%, $p < 0.0001$), drug safety (25.4%, $p = 0.0014$), and the benefits of EET (29.3%, $p = 0.0002$). No significant change in concern regarding side-effects was observed ($p = 0.1486$). Conclusions: This first analysis in a large patient cohort of the BCI Registry confirms previous findings on the significant clinical decision-making impact of BCI for extending adjuvant endocrine therapy. Incorporating BCI into clinical practice resulted in changes in physician recommendations for EET in over 40% of cases, while at the same time increasing physician confidence in their recommendations. Knowledge of the BCI result also improved patient satisfaction and reduced patient concerns regarding cost, drug safety and benefit of EET.

Background: Cyclin-dependent kinase (CDK) 4/6 inhibitors combined with endocrine therapies (ET) have become the mainstay treatment for patients with hormone receptor (HR)-positive, HER2-negative advanced-stage breast cancer. However, there is no established prognostic markers to predict its efficacy to better guide its utilization. Neutrophil-to-lymphocyte ratio (NLR), an indicator of the host systemic inflammatory/immune response, is widely studied marker in various settings in different cancer sites with variable but promising results. In this study, we evaluate the impact of NLR, as a prognostic biomarker, at baseline and prior to the third and fourth cycles of ET/ribociclib in patient with advanced-stage breast cancer. Methods: Data on consecutive patients with HR-positive/HER2-negative advanced-stage disease treated with ribociclib and an aromatase inhibitor or fulvestrant, were retrospectively reviewed from our institutional cancer registry and patients' electronic medical records. NLR was calculated from blood counts performed at base line prior to commencing the first cycle of ribociclib, then prior to the third and fourth cycles, too, and was considered high if ≥ 2 . Ribociclib was given at the usual dose and schedule; 600 mg daily for 3 weeks on and one week off. Progression-free survival (PFS) was defined as the time from the initiation of CDK4/6 inhibitor to the date of radiological or clinical progression or death. Multivariate analysis for PFS was performed using Cox's proportional hazards regression model, covariates included age at diagnosis, ECOG performance status (≥ 1 vs. 0), body mass index (BMI) (≥ 25 vs. < 25), ribociclib beyond first line vs. first line, type of ET (aromatase inhibitors vs. fulvestrant), visceral metastasis, postmenopausal vs. premenopausal, smoking status and de novo metastasis vs. recurrent disease and histopathology. Results: Between June 2017 and May 2020, a total of 257 patients were included, median age was 48 (22-87) years. Majority (n=163, 63.3%) received ribociclib as a first-line, 211 (82.4%) had invasive ductal carcinoma, 137 (53.3%) patients had de novo metastasis and 122 (47.7%) were premenopausal. Progression-free survival was significantly lower among patients with high NLR (n=143, 55.6%) at baseline; 17.8 vs. 22.9 months, P=

0.028. A similar trend for lower PFS was also noted for high NLR measured prior to the third (20.6 vs. 18.6 months) and the fourth cycles (21.6 vs. 18.2 months), however both were not statistically significant; $P=0.154$ and 0.09 , respectively. Multivariate analysis confirmed an independent association between high NLR and lower PFS (adjusted HR 1.46, 95% CI 1.03-2.06, $P=0.032$). Visceral metastasis (aHR 1.57, 95% CI 1.11-2.23, $P=0.012$) and receiving ribociclib beyond the first line (aHR 1.96, 95% CI 1.38-2.77, $P<0.001$), were also independent factors predicting inferior PFS. Conclusions: To the best of our knowledge this is the largest study to show a significant association between high NLR at baseline and lower PFS in patients with HR+ advanced-stage breast cancer treated with ribociclib and ET. If confirmed, NLR at base line may provide reliable, accessible, and widely available prognostic marker that can be used easily in routine clinical practice.

Background:

The risk for patients with estrogen receptor (ER)-positive breast cancer remains stable decades after primary diagnosis, with a large proportion of distant metastatic events occurring late. Thus, long-term follow-up studies are essential to understand true treatment benefit. Tamoxifen (TAM) therapy is a fundamental endocrine treatment for ER-positive breast cancer. We have

previously shown a long-term tamoxifen therapy benefit for patients with less aggressive tumor characteristics in ER-positive/HER2-negative patients. However, ER-positive breast cancer is highly heterogeneous and can be separated into different molecular subpopulations that behave differently during extended follow-up. The long-term tamoxifen benefit by molecular subtype is largely unexplored. We therefore aimed to investigate the long-term benefit from tamoxifen by clinically used tumor characteristics in Luminal A vs Luminal B patients in the Stockholm tamoxifen (STO)-trials with complete 20-years follow-up.

Methods:

Secondary analysis of ER-positive/HER2-negative patients with Luminal A or B molecular subtype (n=952) from the STO-trials (1976-1997) randomized to TAM (40 mg) vs no endocrine therapy (control). Gene expression data was generated using custom designed Agilent arrays from FFPE breast cancer tumor tissue and was used to define PAM50 molecular subtypes. The clinically used markers were reannotated in 2014 and 2020. Complete 20-year follow-up was obtained from Swedish high-quality registries. The long-term distant recurrence-free interval (DRFI) was assessed by Kaplan-Meier, multivariable Cox proportional hazard regression and time-varying analysis, using flexible parametric modelling.

Results:

Multivariable analysis showed significantly improved long-term DRFI from TAM vs control for both Luminal A (HR=0.59; 95% CI, 0.44-0.81) and Luminal B (HR=0.67; 95% CI, 0.46-0.99) patients. Time-varying analysis showed that patients with Luminal A subtype significantly benefitted from TAM for 15 years (HR=0.60, 95% CI, 0.39-0.94 at year 15), whereas patients with Luminal B subtype had a significant TAM benefit for 5 years (HR=0.64, 95% CI, 0.42-0.98 at year 5), see Table.

Furthermore, a significant long-term TAM benefit for patients with large tumor size (pT>20mm: HR=0.46; 95% CI, 0.25-0.84), tumor grade 1-2 (HR=0.55; 95% CI, 0.40-0.77), lymph node-negative (HR=0.51, 95% CI, 0.34-0.78), PR-positive (HR=0.57, 95% CI, 0.40-0.81) and Ki-67-low tumors (HR=0.55, 95% CI, 0.39-0.77) was seen for Luminal A patients.

In Luminal B patients, significantly improved long-term DRFI from TAM vs control was seen for small tumor size (pT≤20mm: HR=0.44; 95% CI, 0.24-0.80), tumor grade 1-2 (HR=0.51; 95% CI, 0.29-0.90), lymph node-negative (HR=0.40, 95% CI, 0.19-0.83), PR-positive (HR=0.59, 95% CI, 0.38-0.93) and Ki-67-low tumors (HR=0.45, 95% CI, 0.25-0.84).

Conclusions:

This study suggests a 15 years tamoxifen benefit for patients with Luminal A subtype tumors, whereas the benefit for patients with Luminal B tumors is up to five years after diagnosis. Furthermore, our study suggests a long-term tamoxifen benefit for patients with less aggressive tumor characteristics regardless of tumor subtype, except for tumor size in Luminal A patients. ER-positive breast cancer is a heterogeneous disease and long-term follow-up studies in molecular subtypes are essential to understand differences in treatment benefit.

Table. Time-varying analysis of long-term tamoxifen therapy benefit by PAM50 molecular subtype.

ER-positive/HER2-negative patients		Years since randomization	Risk of distant recurrence HR (95% CI)
Luminal A (n=651)	Tamoxifen vs. Control	5	0.55 (0.40-0.77)*
		10	0.58 (0.41-0.83)*
		15	0.60 (0.39-0.94)*
		20	0.62 (0.37-1.03)
Luminal B (n=254)	Tamoxifen vs. Control	5	0.64 (0.42-0.98)*
		10	0.60 (0.33-1.07)
		15	0.57 (0.29-1.15)
		20	0.56 (0.26-1.20)

Time-varying analysis of distant recurrence-free interval (DRFI) to assess how tamoxifen benefit varied over the 20 year of follow-up using flexible parametric survival modelling. Patients included in analyses with no missing values. Estimated hazard ratios (HR) at year 5, 10, 15 and 20 for patients with Luminal A or Luminal B molecular subtype tumors randomized to tamoxifen therapy, as compared with patients randomized to no endocrine therapy (control). Adjusted for age, period of primary breast cancer diagnosis, tumor size, tumor grade, lymph node status, PR status, Ki-67 status, chemotherapy, radiotherapy, type of surgery, and menopausal status. *indicates significant findings P<0.05

HOXB13/IL17RB-low breast cancers are predicted to respond to PIK3CA inhibitors independent of PIK3CA mutational status

Background: The Breast Cancer Index is a gene expression-based signature comprising two functional biomarker panels, the Molecular Grade Index (MGI) and the two-gene ratio, HOXB13/IL17BR (H/I). MGI measures tumor proliferation, while H/I measures estrogen signaling. Integration of MGI and H/I provides a single score that quantifies the risk distant recurrence, while H/I alone predicts benefit from extended endocrine therapy (EET). In multiple EET trials, we have shown that hormone receptor-positive (HR+) breast cancer (BC) patients with H/I-high biomarker expression benefit from EET, while those with H/I-low expression do not benefit from such therapy. Previous protein-protein interaction (PPI) dysregulation (dysreg) analysis of H/I-low BC tumors with drug-response-associated dysreg in BC cell lines revealed a significant correlation with response to two PIK3CA inhibitors, suggesting that PIK3CA pathway may represent an exploitable therapeutic vulnerability for H/I-low BC patients. However, given that PIK3CA is frequently mutated in ER+ tumors, the PPI dysreg analysis may merely reflect enrichment of PIK3CA genomic alterations within the H/I-Low BCs. Thus, to determine if a genetic abnormality within the H/I-low BCs accounts for the correlation with PIK3CA inhibitor drug response in BC cell lines, we performed targeted DNA sequencing of H/I-high and H/I-low BC tumors. Methods: DNA was extracted from 44 H/I-high and 30-H/I-low BC samples using a Qiaqen DNeasy Blood & Tissue Kit. Samples were then prepared using the Archer VariantPlex kits according to a modified protocol and sequenced in batches on the Illumina NextSeq platform. To determine if a genetic abnormality within H/I-low BCs accounts for the PPI dysreg correlation with PIK3CA drug response, the magnitude of the sample's drug associated PPI dysregs was compared to its mutational status. Geneset enrichment (GSEA) functional profiles between BC tissue PPI dysregs and BC cell line drug response-associated PPI dysregs, identified two PIK3CA inhibitors as potential therapeutic drugs for H/I-low tumors. For each

PIK3CA drug, the set of leading-edge genes associated with the genesets important to the observed correlation were isolated. Z-score transformed PPI dysreg count data across the BC samples was used to calculate the average dysreg scores for each sample based on the drug-associated leading-edge genes. The samples were sorted based on scores associated with each drug and GSEA was run on each ranked list looking for an association between the dysreg magnitude and PIK3CA mutation status. Results: Targeted DNA sequencing identified copy number variants for in H/I-high and low tumors, the most common of which are: ERBB2 (3/44 H/I-high; 1/30 H/I-low; p: 0.642), FGF19 (3/44 H/I-high; 1/30; p: 0.642), CCND1 (3/44 H/I-high; 1/30 H/I-low; p: 0.642). Sequencing identified a similar distribution of single nucleotide variants (SNVs) between the H/I-high and H/I-low groups. The most common SNVs identified in order of prevalence are PIK3CA (18/44, H/I-high; 6/30, H/I-low; p: 0.078), TP53 (12/44 H/I-high; 6/30 H/I-low; p: 0.585), CDH1 (4/44 H/I-high; 5/30 H/I-low; p: 0.471), BRCA2 (4/44 H/I-high; 2/30 H/I-low; p: 1). No significant difference in mutational prevalence was identified between the H/I-high and H/I-low BCs. No-significant associations between the PPI dysreg magnitude of the drug-associated leading-edge genes and PIK3CA mutational status was observed (AZD6482 FDR=0.736 and A66 FDR=0.95). Conclusion: No significant genetic alteration, including PIK3CA mutational status, was identified between H/I-high and H/I-low groups. Thus, protein-protein interaction (PPI) dysregulation analysis identifies H/I-low BC tumors as those that are predicted to response to PIK3CA inhibitors independent of PIK3CA mutational status.

Real world treatment of node negative low and intermediate recurrence score breast cancer

Presenting Author(s) and Co-Author(s):

Introduction: Patients younger than 50 years old with node negative hormone receptor (HR) positive her2 negative breast cancer and oncotype Dx recurrence scores (RS) under 16 do not benefit from adjuvant chemotherapy. Those with a RS between 16-25 may have a marginal benefit from the addition of adjuvant chemotherapy, however a similar benefit may be achieved with adjuvant ovarian function suppression (OFS). The aim of this study is to describe real world treatment patterns and outcomes of premenopausal node negative patients with low and intermediate RS, with an emphasis on adjuvant OFS, endocrine therapy (ET), and menopausal status during adjuvant treatment. Methods: We retrospectively reviewed the records of all node negative patients under 50 years old who were sent for oncotype testing between 2008 and 2018. One hundred and sixty-five patients with low or intermediate RS were included in our analysis. Continuous variables were described using medians and interquartile range (IQR). Categorical variables were described as frequencies and percentages. Differences between categorical variables were analyzed with the chi squared test and survival was analyzed using the Kaplan-Meier method. The cox proportional hazards model was used to test the effect of multiple factors on survival. Breast cancer specific survival (bcss) was defined as the time to first breast cancer recurrence (local recurrence, second breast cancer, distant recurrence) and distant disease-free survival (ddfs) was defined as the time to any distant recurrence. Results: The median age was 44 (41-47) and median RS was 17 (14-20). Median follow-up time was 82 (61-108) months. One hundred and three (62.4%) patients had low clinical risk as defined in TailorX and 136 (82.4%) had intermediate RS. Fourteen (8.5%) patients with nodal micrometastases were also included. Only 5 (3%) patients received adjuvant chemotherapy and 74 (44.8%) received adjuvant OFS. Of the 91 (55%) of patients who did not receive OFS, 21 (23%) went into menopause or underwent subsequent oophorectomy while on adjuvant ET. One hundred and three (62.4%) patients received adjuvant tamoxifen alone, 16 (9.7%) received an aromatase inhibitor alone, and 40 (24.2%) underwent an endocrine switch with all but 1 beginning treatment with tamoxifen. There were no significant differences in clinical risk or RS risk group between patients that received and did not receive OFS. There were 22 (13.3%) bcss recurrences. Twelve (7.2%) patients had a local recurrence, 5 (3%) patients had second breast cancers, and 5 (3%) had a distant recurrence as their first recurrence. Overall, only 6 (3.6%) patients had a distant recurrence. Both OFS and ET type were not significantly associated with bcss or ddfs. On univariate analysis menopause during ET was significantly associated with improved bcss (HR= 0.2, 95% CI 0.05-0.85), however on multivariate analysis it was no longer significant. Conclusion: With only 6 (3.6%) distant recurrences over a median follow-up of over 6.5 years node negative premenopausal women with low or intermediate RS treated in our institution show an excellent prognosis regardless of treatment type. Our results support the evidence that most of these patients do not need chemotherapy and suggests that

most patients do not require OFS as well. Additional data examining the relationship between gene expression profiles and OFS benefit are needed to help guide OFS treatment in premenopausal patients who do not require chemotherapy.

Background: Prognosis in older patients with breast cancer (BC) is worse compared to younger patients. No robust and specific tool to predict the risk of recurrence (TTR) for women aged 70 and over is likely due to the lack of representation of this group in the data from clinical trials. In the POETIC trial, of estrogen receptor-positive (ER+) and mainly human epidermal growth factor receptor 2 negative (HER2-) BC (88%), peri-operative aromatase inhibitor (POAI) did not improve treatment outcome, but patients with low baseline Ki67 value (Ki67B) or low POAI-induced Ki67 value (Ki67_2wk) had good outcome with standard of care therapy (usually adjuvant endocrine therapy (adjET) with the addition of chemotherapy as clinically indicated). In this study, we sought to develop a multi-parametric algorithm, named Ki67Cal, by integrating Ki67_2wk value with tumour characteristics to predict TTR for patients > 70 years old (yr) with early ER+HER2- BC treated with adjET only.

Methods: Within POETIC, 39% (n=1744) of the randomised patients (n = 4480) were >70 years old. There were 813 patients aged > 70yr, with ER+HER2- BC, randomised to POAI treatment and treated with adjET only. A power calculation indicated that 811 such patients were sufficient to develop a prediction model that minimized overfitting, allowed up to 8 predictors, for predicting 5-years TTR with a median follow-up of 5.24 years and an overall event rate per 1000 person-years = 0.027, and provided an anticipated performance in terms of model fit $R^2 = 0.08$ (Riley et al. *BMJ* 2020). A three-fold cross-validation approach was applied; an optimal list of features was selected in the training set (n = 538, events = 70); the agreement between expected and observed outcomes from the algorithm on the validation set (n = 275, events = 37) was evaluated by calibration plot. Multivariable Ridge Cox Regression model of significant parameters was built on the dataset merging training and validation datasets (n = 813) for precise estimates of the coefficients of parameters. A subset of post-POAI samples (n = 99) was gene expression profiled with Nanostring to allow pseudo-Oncotype, pseudo-EndoPredict, and RUO-Prosigna scores calculated (Buus et al. *npj Breast cancer* 2021). The risk groups classified by the Ki67Cal and gene-expression assays (GEP) were compared.

Results:

Within this cohort, the 5-year TTR was 34.5% (C.I. 24.9-47.9) for those with a high Ki67_2wk ($\geq 10\%$) and 12.3% (C.I. 9.1-16.7) in those with a high Ki67B that was suppressed to Ki67_2wk < 10%. The significant features were Ki67_2wk, sampling type (core vs. excision) at surgery, and pathological variables (tumour size, grade, and nodal status) for the final Ki67Cal algorithm. Stratifying patients into five groups (quintiles) by Ki67Cal identified 60% of patients with TTR of < 5% at 5yrs, and 20% of patients with TTR of > 30% at 5yrs.

As an exploratory analysis, the risk groups by Ki67Cal and GEP were compared (Table 1). To

date, these assays are optimized to be used on untreated ER+HER2- samples; there were fairly good agreements between the high-risk group defined by Ki67Cal with pseudo-EndoPredict and RUO-Prosigna respectively, and low-risk groups by Ki67Cal with Prosigna probably because Prosigna scores are driven by proliferation score.

Conclusion:

The relatively poor outcome of patients >70yrs in POETIC emphasizes the need for prognostic tools that identify patients who may be treated with endocrine therapy alone or conversely should be considered for additional therapy. Ki67Cal provides a simple tool that identified very low-risk and high-risk patients in 80% of patients with ER+HER2- BC.

Table 1: Comparison of the risk groups defined by Ki67Cal algorithm with the three commonly used gene-expression assays (pseudo-EndoPredict, pseudo-Oncotype and RUO-Prosigna) applied on the post-peri-operative aromatase inhibitor samples.

	Risk Groups as defined by Ki67Cal algorithm									
	High risk		High-Moderate		Moderate		Moderate-Low		Low	
	N	%	N	%	N	%	N	%	N	%
	42	100	21	100	14	100	12	100	10	100
Pseudo-EndoPredict										
High	38	90.5	18	85.7	10	71.4	8	66.7	7	70
Low	4	9.5	3	14.3	4	28.6	4	33.3	3	30
Pseudo-Oncotype: Low: < 18; Intermediate: >= 18 & <= 31; High : > 31										
High	13	31	4	19	3	21.4	0	0	1	10
Intermediate	21	50	10	47.6	5	35.7	5	41.7	3	30
Low	8	19	7	33.3	6	42.9	7	58.3	6	60

Background

POETIC was a phase III clinical trial, with patients randomised 2:1 to 2-week perioperative aromatase inhibitor (POAI) vs control for postmenopausal women with oestrogen receptor positive (ER+) early breast cancer (BC) (Smith et al., *Lancet Oncology* 2020). Our previous study on POETIC trial patients with ER+ human epidermal growth factor receptor 2 positive (HER2+) BC suggested both HER2 enriched subtype (HER2-E) and immune enrichment pre-POAI (baseline, B) are main drivers of poor early response to POAI (Bergamino et al., 2022). However, some patients with HER2-E or immune enriched BC at B still showed good response to POAI. In this study, we aim to further investigate a sub-cohort of ER+ HER2+ BC from the POETIC trial, including a subset of aforementioned HER2-E tumours, to further explore the multi-modal molecular characteristics of the tumours resistant to POAI.

Methods

Proliferation rate was assessed as percentage of cancer cells stained by Ki67. Patient POAI response was determined by Ki67 reduction at 2 weeks of treatment. A sub-cohort of 37 patients were selected based on response and classified as poor responders (PR, reduction < 30%, n=18), good responders (GR, reduction > 90%, n=11) and good responders with HER2-E BC at B (GR, reduction > 65%, n=8). Paired B and post-POAI (surgery, S) samples were taken from each patient of the sub-cohort. Multiplex immunofluorescence (mIF) was performed on these samples, measuring the immune cell densities in stroma and tumour compartments using five biomarkers: CD3 (all T cells), CD20 (B cells), CD68 (Macrophages), FOXP3 (regulatory T cells), and CD3 FOXP3 co-expression. The samples were also profiled using Breast Cancer 360TM (NanoString, BC360), covering the expressions of 758 genes and 46 biological signatures. Wilcoxon test, hierarchical clustering and spearman correlation test were performed to compare the tumour characteristics of GR and PR.

Results

In this study, two B and four S samples were not achievable for mIF experiments due to low tumour content. At B (n = 35), among the five mIF biomarker measurements in stroma and tumour, only the stromal CD3 density was significantly different between GR (median = 0.0013) and PR (median = 0.0003, p = 0.041). In GR, HER2-E BC at B were separated into immune-high and immune-low groups with mIF biomarkers at B; the immune-high group was more likely to change into luminal subtypes post-POAI, while the immune-low group remained HER2-E. After POAI, the density changes in five mIF biomarkers in stroma and CD68 in tumour were all significantly higher in PR than GR (Table 1, n of paired samples = 62). The BC360 signatures of BC p53 (p < 0.001), BC proliferation (p < 0.001), LumB (p < 0.001) and HER2-E correlation coefficients (p < 0.001) were significantly downregulated in GR after POAI, while LumA correlation coefficients (p < 0.001) were notably increased.

Conclusions

Our results suggest that for this sub-cohort, increased stromal immune response is associated with poor response to 2-week POAI in ER+ HER2+ early BC. HER2-E GR display visible immune heterogeneity at B. Lower-risk BC characteristics were exhibited in GR after the 2-week treatment. Further integrating mIF imaging data and additional digital spatial profiling are ongoing to reveal additional characteristics of ER+ HER2+ BC and tumour microenvironment predicting POAI resistance.

Table 1

		Medians of 2-week density changes in mIF biomarkers (log2)		Wilcoxon Tests
		GR(n=15)	PR(n=16)	P-value

DNA replication licensing is associated with resistance to CDK4/6 inhibitors in ER-positive breast cancer

Background: The use of CDK4/6 inhibitors (CDK4/6i) has led to a remarkable progress in the treatment of advanced ER-positive (+) breast cancer (BC). The fact that both CDK4/6i and endocrine therapy (ET) target cell-cycle G1-S transition suggests some overlap of resistance mechanisms. However, clinical variability in response to CDK4/6i in patients progressing on ET suggests the involvement of additional or unique resistance mechanisms. Using bioinformatics analyses of clinical and preclinical data, we now identified genes involved in DNA replication licensing, in particular, excess MCM2 as a new mechanism of resistance to CDK4/6i. Methods: Gene expression data from the neoadjuvant NeoPalAna trial of the CDK4/6i palbociclib (Palbo) and the aromatase inhibitor (AI) anastrozole in ER+ BC was downloaded from Gene Expression Omnibus (GSE93204). Response to AI and Palbo was obtained using the published Ki67 immunohistochemistry data and cutoff on biopsies post treatment. Gene Set Enrichment Analysis comparing tumors with different sensitivity to AI vs. Palbo was performed using the Gene Ontology related to DNA replication, DNA repair, and DNA damage checkpoint. The DNA replication gene set was further sub-assigned by their selective role in origin licensing, firing, elongation, replication repair, and checkpoint regulation. A series of bioinformatics analyses was applied on five ER+/HER2-negative BC cell lines with gene expression and DepMap (from CCLE) and Palbo sensitivity data (from GDSC). Two ER+ BC cell models (MCF7 and T47D) and their estrogen deprivation (mimicking AIs)-resistant (EDR) derivatives were used for further

studies including RNA-seq, Palbo sensitivity (data from PMID: 33536276), and chromatin fractionation assays. Results: We found that the DNA replication-associated gene set, comprising > 80% genes outside the Rb-loss gene signature, was significantly enriched in baseline biopsies of Palbo-resistant (PalboR) tumors from patients in the NeoPalAna trial. Of the DNA replication genes, the subset of genes involved in origin licensing were preferentially enriched in PalboR vs. AI-resistant tumors. Similarly, the enrichment of genes involved in replication initiation was also seen in ER+/HER2-negative BC cell lines with a decreased response to Palbo. Notably, these PalboR cell lines showed a reduced vitality to shRNA knockdown of the replication initiation genes compared to randomly selected other genes or the Rb-loss gene set. Based on the modeling of DepMap gene dependency score and Palbo sensitivity, we nominated minichromosome maintenance 2 (MCM2), the key origin licensing factor, as the top gene that is essential for PalboR cell survival. Additionally, using our previously reported MCF7-EDR and T47D-EDR cell models with increased or decreased sensitivity to Palbo compared to their parental lines, respectively, we observed a corresponding decrease or increase in the expression of origin licensing genes and MCM2 in EDR vs. parental lines. Decreased Palbo sensitivity in the EDR cells was associated with sustained MCM2 chromatin loading and reduced expression of genes including the cyclin-dependent kinase inhibitor p21. Ongoing studies investigate whether elevated MCM2 levels confer resistance to CDK4/6i by resolving replication stress. Conclusions: Our strategic bioinformatics analyses reveal that excess DNA replication licensing is associated with CDK4/6i resistance in clinical and preclinical settings upon resistance to estrogen deprivation. Among the replication initiation-associated genes, MCM2 plays a potential role in conferring CDK4/6i resistance via sustaining origin licensing and suppressing p21. Our study provides a new avenue via lens of replication licensing to explore novel mechanisms and therapeutic opportunities in CDK4/6i resistance.

Background: Tamoxifen is a standard endocrine therapy for both pre- and postmenopausal ER-positive breast cancer patients. Patients with ER-positive disease have a long-term risk of distant recurrence, thus, long-term follow-up studies are essential to understand true treatment benefit. Clinically used tumor characteristics are prognostic 5-10 years after primary diagnosis, however, whether these characteristics are predictive of long-term tamoxifen benefit is largely unexplored. Therefore, we aimed to determine the long-term tamoxifen therapy benefit by the clinically used tumor characteristics in pre- vs postmenopausal patients in the Stockholm tamoxifen (STO)-trials with 20-years complete follow-up.

Methods: Secondary analysis of 1242 ER-positive/HER2-negative patients from the STO-trials, randomized to at least 2 years of 40 mg tamoxifen vs no endocrine therapy (control). Premenopausal lymph node-positive patients were allocated to chemotherapy as standard of care and postmenopausal high-risk patients were further randomized to chemotherapy vs radiotherapy. Tumor immunohistochemical analysis was recently conducted. Complete 20-year follow-up was obtained from Swedish high-quality registries. Long-term distant recurrence-free interval (DRFI) was assessed by multivariable Cox proportional hazard regression and time-varying analysis using flexible parametric modelling.

Results: Premenopausal patients showed significantly improved long-term DRFI from tamoxifen vs control if they were lymph node-negative (Hazard Ratio [HR]=0.46; 95% CI, 0.24-0.87), PR-positive (HR=0.61; 95% CI, 0.41-0.91), or of genomic low risk (HR=0.47; 95% CI, 0.26-0.85), see Table.

In postmenopausal patients, significantly improved long-term DRFI from tamoxifen vs control was seen for all good prognosis tumor characteristics, i.e. small tumor size ($pT \leq 20$ mm: HR=0.55; 95% CI, 0.39-0.77), tumor grade 1-2 (HR=0.55; 95% CI, 0.41-0.73), lymph node-negative (HR=0.44; 95% CI, 0.30-0.64), PR-positive (HR=0.60; 95% CI, 0.44-0.80), Ki-67-low ($< 15\%$: HR=0.51; 95% CI, 0.38-0.68), and genomic low risk (HR=0.53; 95% CI, 0.37-0.74), see Table. Also, postmenopausal patients with large tumor size ($pT > 20$ mm: HR=0.64; 95% CI, 0.44-0.94) and PR-negative tumors (HR=0.51; 95% CI, 0.32-0.81) showed significant long-term tamoxifen benefit.

Time-varying analysis in premenopausal patients indicated that tamoxifen therapy benefit diminished over time. Significant tamoxifen benefit until year 5, 10, and 15 after primary diagnosis was observed for PR-positive, lymph node-negative, and genomic low-risk patients, respectively. Postmenopausal patients had a significant long-term tamoxifen benefit if they had tumors of small or large tumor size, tumor grade 1-2, lymph node-negative status, PR-positive status, low Ki-67 levels, or genomic low risk.

Conclusions: This study suggests a differential long-term tamoxifen therapy benefit in pre- vs postmenopausal patients. Clinically defined low-risk postmenopausal patients have long-term tamoxifen benefit, whereas the benefit is absent or diminish over time for premenopausal patients. Improved long-term prognostic and endocrine therapy predictive markers in premenopausal breast cancer patients with poor prognosis and long life-expectancy is needed, which could involve molecular tools.

Long-term tamoxifen benefit in premenopausal and postmenopausal breast cancer patients by the clinically used tumor characteristics.

Clinically used tumor characteristics		Trial arm	Premenopausal patients (n=381)	Postmenopausal patients (n=861)
			HR (95% CI)	HR (95% CI)
Tumor size	pT ≤ 20 mm	Tamoxifen	0.74 (0.46-1.18)	0.55 (0.39-0.77)
		Control	1.00 (Ref)	1.00 (Ref)

Background: Adjuvant endocrine therapy (ET) in ER+ breast cancer (BC) reduces local, distant, and contralateral BC events and improves overall survival (OS). Furthermore, decreased adherence or omission of ET increases the risk of death. However, in ER+ pts with early-stage BC treated with NAC who have a pathologic complete response (pCR), the importance of adjuvant ET may be called into question. We sought to examine the impact of ET omission on the survival of pts with ER+ BC treated with NAC, according to pCR vs residual disease.

Methods: We queried the National Cancer Database (NCDB) 2010-2018 for female pts with stage I-III ER+ BC treated with NAC followed by surgery. pCR was defined as ypT0/ypTis, ypN0. The percent receiving adjuvant ET and the impact of adjuvant ET omission on overall survival (OS) in patients with and without pCR were assessed separately based on HER2 expression. OS was analyzed with adjuvant ET as a time-dependent covariate using Cox proportional hazards regression.

Results: We identified 34,394 pts treated with NAC for ER+ BC (28,434 ER+/HER2-, 5960 ER+/HER2+). Pts with ER+/HER2+ BC were less likely than pts with ER+/HER2- BC to have received adjuvant ET (61.6% vs 88.8%, $p < 0.001$). Overall, 4505 (13.1%) had pCR (9.1% of ER+/HER2- and 32.0% of ER+/HER2+). Within each subtype, pts with pCR were significantly less likely to start adjuvant ET after surgery than pts with residual disease (78.4% vs 89.8% for ER+/HER2- and 46.5% vs 68.7% for ER+/HER2+, each $p < 0.001$), Table 1. Regarding those with residual disease, pts with ER+/HER2+ BC were less likely than ER+/HER2- BC to receive adjuvant ET (68.7% vs 89.8%, $p < 0.001$). Median follow-up was 4.4 years. Among pts with

pCR, 5-year OS was 93.2% (95% CI: 92.1-94.4%) for ER+/HER2- BC and 94.3% (95% CI: 93.1-95.5%) for ER+/HER2+ BC (p=0.08), while among patients with residual disease 5-year OS was 81.7% (95% CI: 81.1-82.2%) and 85.7% (95% CI: 84.5-86.9%) for the two subtypes respectively (p< 0.001). On multivariable analysis, omission of adjuvant ET was significantly associated with poorer OS in patients with residual disease for both ER+/HER2- BC (adjusted HR 1.72, p< 0.001) and ER+/HER2+ BC (adjusted HR 1.63, p< 0.001). In contrast, omission of adjuvant ET was not significantly associated with OS in patients with pCR, regardless of HER2 status (ER+/HER2- adjusted HR 1.28, p=0.20; ER+/HER2+ adjusted HR 1.13, p=0.54), Table 1.

Conclusions: In pts receiving NAC for ER+ BC, those with ER+/HER2+ disease were less likely to have received adjuvant ET compared to ER+/HER2- patients, regardless of pCR. In pts with residual disease after NAC, omission of adjuvant ET was associated with significantly higher risk of death. These data provide strong support for interventions to increase utilization of ET, especially for patients with residual disease following NAC. The observation that ET omission did not impact OS in pts with ER+ BC who achieve pCR following NAC is hypothesis generating and may have implications for future de-escalation trials for this subset of patients.

Table 1. Differential use of adjuvant endocrine therapy by subtype and pCR and the impact on overall survival

Background: Invasive ductal carcinoma (IDC) and invasive lobular carcinoma (ILC) are the first and second most common histologic subtypes of breast cancer. Both IDC and ILC present distinguishing clinicopathologic features that contribute to differences in response to treatment and long-term prognosis. BCI is a validated gene expression assay that provides the risk of overall (0-10y) and late (5-10y) distant recurrence (DR) and predicts the likelihood of benefit from extended endocrine therapy (EET). In this analysis, BCI results between groups of HR+ ILC and IDC breast cancer patients were compared. Methods: The BCI Clinical Database for Correlative Studies is an IRB-approved de-identified database containing >50 clinicopathologic and molecular variables from cases submitted for BCI testing in clinical practice (N=19,126). Molecular variables include BCI Prognostic score, HOXB13/IL17BR ratio (H/I), and molecular grade index (MGI). Clinicopathologic variables were abstracted from pathology reports when available. Chi-squared tests and Kruskal-Wallis tests were used to compare categorical and numeric factors, respectively, between IDC and ILC subgroups. Kaplan-Meier survival analysis and Cox proportional hazards regression were used to analyze BCI Predictive performance in the lobular patients from IDEAL study. Results: The current study included 3814 patients submitted for BCI testing during years 4-7 post-diagnosis with available histologic subtype data (80.5% IDC; 13.2% ILC; 3.0% mixed; 3.3% other). Among those with either ductal (n=3072) or lobular (n=504) carcinomas (71% node-negative and 29% node-positive), patients with ILC were older compared to IDC (>70 y: 17% vs 12%). Clinically, ILC was generally less aggressive than IDC (Grade 3: 7% vs 21%; lymphovascular invasion: 9% vs 20%; HER2+: 2% vs 13%; Ki67 % positive stained cells: 29% vs 46%; p< 0.001 for all comparisons), with the exception that ILC had larger tumors than IDC (T2/T3: 46% vs 24%) due to its unique histology. This was

consistent with BCI Prognostic results showing fewer ILC patients at high risk for late DR compared to IDC (43% vs 55%, $p < 0.001$). BCI (H/I) showed a similar trend with fewer patients with High Likelihood to benefit from EET (39% vs 43%) although the difference was not statistically significant ($p = 0.169$). The combination of BCI prognostic and predictive results revealed that more ILC patients were classified as Low Risk/Low Likelihood of benefit (43% vs 38%) and fewer were called High Risk/High Likelihood of benefit (25% vs 35%) ($p < 0.001$) compared to IDC. The IDEAL BCI translational study included 142 ILC patients with 9.3 years of median follow-up. Similar to the BCI Clinical Database results, ILC was associated with less aggressive disease than IDC (Grade 3: 18% vs 41%; HER2+: 11% vs 24%). 39% and 61% of ILC patients were classified as BCI (H/I)-High and -Low, respectively. Given the small sample size, BCI (H/I)-High showed a non-significant absolute benefit of 11.9% (HR=0.44, 95% CI 0.09-2.14; $p = 0.298$) and BCI (H/I)-Low showed no benefit (HR=2.63, 95% CI 0.70-9.93; $p = 0.138$). An analysis of the 3-way interaction among treatment, biomarker and histology showed a non-significant p-value of 0.28, suggesting BCI (H/I) provides similar predictive information in ILC as in the overall population. Conclusion: BCI identified a smaller proportion of patients with ILC at High Risk of late DR and High Likelihood of benefit from EET compared to IDC. Data from the IDEAL translational study showed that while fewer patients with ILC were identified as BCI (H/I)-High, they still derived similar absolute benefit compared to the overall cohort, while those classified as BCI (H/I)-Low derived no benefit from EET.

INTRODUCTION

Circulating tumor cell (CTC) count and levels of circulating tumor DNA (ctDNA) have proven their individual prognostic value in metastatic breast cancer (MBC). Whereas CTCs can be quantified by enumeration, levels of ctDNA are often expressed as the variant allele frequency of the dominant mutation. The modified fast aneuploidy screening test-sequencing system (mFAST-SeqS) estimates ctDNA-load by measuring chromosomal aneuploidy instead of mutations. The mFAST-SeqS method is cheap and provides a comprehensive overview of the tumor genome without prior knowledge on genomic tumor aberrations. Previously, we showed in a small MBC cohort (n=50), heterogeneous with regard to subtype and line of treatment, that the mFAST-SeqS-derived genome-wide aneuploidy score (GWA-score) was an independent prognostic biomarker (1). Our current aim was to provide evidence for the prognostic value of GWA-score in a homogeneous cohort of estrogen receptor positive (ER+), HER2 negative (HER2-) MBC patients, starting first line treatment with an aromatase inhibitor.

MATERIALS & METHODS

CTCs were enumerated using the CellSearch-system (Menarini) and screened for ctDNA fraction using mFAST-SeqS in ER+, HER2- MBC patients, starting with first line aromatase

inhibitors. CTC-count was divided into high (CTChigh) and low (CTClow) using the validated cut-off of 5 CTCs/7.5 ml blood; similarly GWA-score was divided in high (GWAhigh) and low (GWAlow) based on the previously described cut-off of 5 (2). PFS and OS were estimated using Kaplan-Meier. Cox regression was used for uni- and multivariable analysis.

RESULTS

One hundred and thirty-four patients were included in this analysis. Mean age was 68 (range 40-90). Median follow up was 26 months. Sixty-five samples had both scores low and 30 both high, 25 samples were CTChigh/GWAlow and 14 were CTClow/GWAhigh. PFS and OS were not significantly different between CTChigh versus CTClow groups (p=0.07 and p=0.26, median PFS 15 vs 24 months, median OS 45 vs 49 months). However, PFS and OS were significantly different between GWAhigh versus GWAlow groups (p < 0.01 for both, median PFS 11 vs 24 months, median OS 31 vs 51 months). In multivariate analysis, GWA-score was a significant prognostic factor for both PFS and OS while presence of visceral disease was also prognostic for OS (table 1).

CONCLUSIONS

In patients treated with aromatase inhibitors in the first line of treatment, GWA-score was an independent prognostic marker for a worse PFS and OS and may have added value beyond CTC-count.

Background: Only old evidence exist to back up the use of medroxyprogesterone acetate (MPA) in endocrine therapy. Therefore, this study aimed to explore the factors that influence the time to treatment failure (TTF) of MPA in real world settings as late-line treatment following aromatase inhibitors and fulvestrant.

Methods: This was a cohort study that used the database of the Safari study, on estrogen receptor-positive (ER+) post-menopausal advanced breast cancer previously treated with fulvestrant (UMIN000015168). We created Kaplan-Meier curves for TTF treated with MPA. Further, univariate and multivariate analyses were performed using a Cox hazard model of the clinicopathological factors involved in the TTF of MPA.

Results:

First, we made Kaplan-Meier curves by treatment line for MPA in TTF analysis population 1 (n = 244), excluding HER2+ and HER2 with unknown status. The median TTF for MPA was 8.2 months (95% CI 5.1–14.9) for first- and second-line treatments, 3.0 months (95% CI 2.5–3.9) for third-line treatment, and 4.1 months (95% CI 3.5–5.0) for fourth or later treatment lines. The first- and second-line treatments had significantly longer TTF than the third-line treatment (P < 0.001) and fourth-line or later treatments (P < 0.001). No difference in TTF was observed between the third and fourth or later treatment lines. Similar results were obtained in the analysis population 2 (n = 203) for TTF, excluding cases in which MPA was considered to have been used in palliative care. The median TTF for MPA was 7.9 months (95% CI, 5.1-16.0) for first- and second-line treatments, 3.0 months (95% CI 2.8–4.6) for third-line treatment, and 4.3 months (95% CI 3.7–5.6) for fourth or later treatment lines. The first- and second-line treatments had significantly longer TTF than the third-line treatment (P < 0.001) and the fourth-line or later treatments (P < 0.001). No difference in TTF was observed between the third and fourth or later treatment lines.

Second, Table 1 shows the clinicopathological factors involved in the TTF of MPA. In univariate analysis, long DFI (≥ 6 years), small nuclear or histological grade, and the presence of visceral metastases correlated with significantly long TTF (P < 0.05). Whereas PgR, adjuvant chemotherapy, and adjuvant endocrine therapy did not affect the TTF of patients treated with MPA. However, in the multivariate regression analysis, only longer DFI (≥ 6 years) was correlated with a significantly longer TTF.

Third, we compared the clinicopathologic factors in the groups that received MPA as the fourth or later treatment lines and achieved a TTF of more than 1 year with those that did not. There were no characteristic clinicopathological factors distinct between the two groups.

Conclusion: In actual clinical practice, patients treated with MPA alone as the fourth or subsequent treatment lines showed a TTF of 4 months, suggesting that there is merit in using MPA even in late treatment lines, especially in patients with long DFI and those who are difficult to treat with other antineoplastic agents.

Table 1. Univariate and Multivariate analyses to investigate association between clinicopathological factors and TTF of MPA (n = 170)

Background: Recent guidelines regarding estrogen (ER) and progesterone (PR) receptor testing from the American Society of Clinical Oncology and College of American Pathologists defined a new reporting category of ER-low positive breast cancer for tumors with 1-10% ER expression by immunohistochemistry (IHC). The clinical implications of ER-low positivity are incompletely understood, especially in invasive lobular carcinoma (ILC), the second most common type of breast cancer. Given the rarity of low-ER positivity in ILC, we evaluated tumor features and outcomes associated with a spectrum of ER/PR positivity in a monoinstitutional ILC cohort. Methods: We analyzed cases of stage I-III ILC with available IHC reports. Based on prior published categories in ILC, we classified ER as low, medium, or high as defined by ER staining of 10–69%, 70–89%, and $\geq 90\%$ respectively. PR negative, low, and high tumors were defined by 0%, $< 20\%$, or $\geq 20\%$ staining respectively. We used chi-squared tests, t-tests, and Cox proportional hazards models in Stata 16.1 to evaluate associations between ER/PR categories including clinicopathologic variables and event-free survival (EFS). Results: Of 744 cases, 24 (3.2%) were ER negative and 10 (1.3%) were ER-low positive as defined by 1-10% positive staining. 713 remaining cases had ER positivity $\geq 10\%$ and comprised the cohort categories of ER low, medium, and high for this study (11.2%, 15.0%, and 73.8% respectively).

In 751 cases with PR data, 122 (16.2%) were PR negative, 145 (19.4%) were PR low and 483 (64.3%) were PR high. ER high status was significantly associated with older age (mean 56.7, 56.7, and 60.6 years in ER low, medium, and high respectively, $p=0.0005$). ER low was associated with PR negative and low status (42.3% were PR neg/low and ER low, versus 37.4% with ER medium and 29.9% in ER high, $p=0.045$), and more likely to have overexpression of HER2 (9.7%, 9.0%, and 2.9% ER low, medium, high, respectively, $p=0.002$). ER low tumors were more likely to be grade 1 than ER medium or high (41.8%, 29.8% and 24.5% respectively, $p=0.025$), and have positive surgical margins (39.4%, 35.9% and 23.9% respectively, $p=0.002$). ER status was not associated with Ki67, stage, body mass index (BMI), lymphovascular invasion, lobular carcinoma in situ (LCIS), pleomorphic histology, local therapy, or chemotherapy use. In contrast, PR high was significantly associated with younger age (57.6 versus 63.5 years in PR low, $p< 0.0001$). PR low was associated with HER2 overexpression (8.6% versus 3.2% in PR high, $p=0.002$). PR low cases were more likely to present at higher stages (15.8% stage III versus 10.1% stage III in PR high, $p=0.032$), to be pleomorphic (16.8% versus 8.2%, $p< 0.001$), and to receive chemotherapy (30.8% versus 23.1%, $p=0.022$) but were less likely to have associated LCIS (64.0 versus 74.2%, $p=0.004$). PR status was not associated with Ki67, BMI, lymphovascular invasion, local therapy, or surgical margins. In a Cox proportional hazards model adjusting for age, stage, grade, pleomorphic histology, and chemotherapy use, ER category was not associated with EFS but both PR negative and PR low status each had significantly worse EFS compared to PR $\geq 20\%$ (HR 3.5, 95% CI 1.8-6.7, $p< 0.001$ for PR negative, and HR 2.0, 95% CI 1.1-3.5, $p=0.015$ for PR low). The estimated cumulative 5-year EFS for patients with ER low, medium, and high tumors was 87.1%, 93.4%, and 90.1% respectively. The estimated cumulative 5-year EFS for patients with PR negative, low, and high tumors was 78.9%, 90.2%, and 92.7% respectively. Conclusions: Using ILC-specific categories for ER expression, we found associations between ER category and clinicopathologic variables but not with EFS. In contrast, PR negative and low status was associated with worse EFS. These findings highlight the importance of exploring the spectrum of ER/PR activity within ILC, a classically strongly hormone receptor-positive tumor type, using more quantitative methods.

Fluoroestradiol (FES) and Fluorodeoxyglucose (FDG) PET imaging in patients with ER+, HER2+ or HER2- metastatic breast cancer

Natasha Hunter, Lanell M Peterson, Dave A Mankoff, Mark Muzi, Delphine L Chen, William R Gwin, Shaveta Vinayak, Nancy E Davidson, Jennifer M Specht, Hannah M Linden

Background: 18F-Fluorodeoxyglucose (FDG) has long been used for measuring tumor glycolytic activity in clinical PET imaging. The FDA recently approved 18F-Fluoroestradiol (FES) (Cerianna) as a PET imaging tracer for characterizing disease in patients with estrogen-receptor positive (ER+) breast cancer. As FES PET enters clinical practice it is important to establish its utility in the full population of hormone-receptor positive patients, including for patients with human epidermal growth factor 2 (HER2)-overexpressing tumors. Patients with HER2-positive metastatic breast cancer have historically been treated with combination cytotoxic and HER2-directed therapy, with the understanding that HER2 is the primary driver in this disease state. This retrospective study examined uptake in matched lesions for both FES and FDG PET and compared activity in patients with HER2 positive versus HER2 negative metastatic breast cancer.

Methods: Patients were selected from the UW research database who had a history of biopsy-proven primary ER+ breast cancer as well as FES and FDG PET scans within 30 days. We examined FDG and FES scans and recorded SUVmax in up to 16 matched lesions between the two scans. Patients were also divided by HER2 status (+/-). In addition, a subset of patients who underwent at least 2 paired FDG and FES scans were reviewed.

Results: 270 matched FDG and FES scans were analyzed in 216 patients with history of ER+, and HER2+ or HER2- breast cancer who were not part of an ongoing clinical trial. 158 (73%) had ductal disease, 38 (18%) had lobular disease. 183 (85%) had HER2- breast cancer. Of the 33 patients who had HER2+ breast cancer, 28 (85%) had ductal carcinoma. 40 patients underwent serial scans, allowing tracking over multiple timepoints. A total of 1323 metastatic sites were recorded (average = 5/scan (range 1,16)), with the majority (71%) representing bony lesions. No difference in quantitative FES or FDG avidity was observed between soft tissue and osseous sites. FES and FDG SUVmax were similar among patients with either HER2- or HER2+ breast cancer (Table 1). Among 40 patients with multiple paired FDG and FES scans, 26 (65%) had 2 scans while the remaining 14 had 3, with FES avidity remaining stable over time. There was no correlation between FES or FDG scans and HER2 status.

Conclusion: In a cohort of ER+, HER2+ and HER2- patients undergoing concurrent FDG and FES PET scans, FDG and FES activity was similar regardless of HER2 status. FES uptake in both HER2- and HER2+ patients and stability over time in serial scans suggest that HER2 does not affect ER density. This suggests that in many patients with so-called "triple positive" disease, endocrine therapy may offer a powerful primary rather than ancillary tool in select patients. FES combined with FDG PET may offer utility in predicting and assessing response to therapy in this patient population.

Table 1. FES and FDG uptake in patients with HER2- or HER2+ disease

Table 1. FES and FDG uptake in patients with HER2- or HER2+ disease

FES SUVmax	HER2- (n=1139 lesions)	HER2+ (n=184 lesions)
Mean	4.1	3.4
Min	0.1	0.3
Max	22.8	13.7
FDG SUVmax		
Mean	5.1	4.4
Min	1.1	1.5
Max	26.7	11.6

Background: The decision to extend adjuvant endocrine therapy beyond five years is often individualized. Breast Cancer Index (BCI) (Biotheranostics, Inc.) is a validated multigene-expression tissue-based analytic tool used in early hormone-positive breast cancer to predict the response to extended endocrine therapy, based on the HOXB13/IL17BR ratio (H/I ratio), and prognosis 5-10 years after diagnosis, based on the molecular grade index (MGI) and H/I ratio. It is presumed that if BCI shows a high likelihood of benefit from endocrine therapy (BCI-high), the treating clinician would recommend extended adjuvant endocrine therapy and if the primary prediction shows a low likelihood of benefit (BCI-low), the clinician would recommend discontinuation of therapy; however, this may not always be practiced. The Clinical Treatment Score post-5 years (CTS5) is a validated clinicopathologic tool that provides a calculated risk assessment of late distant recurrence (LDR). Clinicians may use the calculated CTS5 score in deciding whether to extend adjuvant endocrine therapy and forego additional prognostic testing, such as BCI. The aim of the study is to understand how clinicians integrate BCI results into medical decision making and to determine the correlation with CTS5 scores in making the decision to offer extended endocrine therapy. Methods: This is a single institution retrospective study. All patients within Henry Ford Health System who had BCI testing ordered, between April 2016 and January 2022, were included. Recommendations regarding extended endocrine therapy were collected. CTS5 scores were calculated based on patient's age, tumor size, tumor

grade, and number of involved lymph nodes. If available, the 21-gene recurrence scores (Oncotype-DX) and Ki-67 scores were collected for additional comparison. Results: A total of 165 female patients were included in this study. The average age at diagnosis was 58.5 ± 10.4 years old; 116 (70%) were Caucasian, 35 (21%) were African American; 132 patients (80%) were post-menopausal. The decision regarding extending endocrine therapy was concordant with BCI predictive results in 93.3% of patients; endocrine therapy was continued in 87% of patients in the BCI-high group and discontinued in 95% of patients in the BCI-low group ($p < 0.001$). In comparing the categorical results of BCI predictive scores (low vs. high) and the CTS5 results (low vs. intermediate vs. high) univariate analysis did not detect a statistically significant relationship. In comparing BCI prognostic LDR risk percentage with the CTS5 LDR (5–10 year) risk percentage, a statistically significant, but weak, positive correlation was observed (Pearson correlation coefficient of 0.38487, $p\text{-value} = < 0.0001$). The odds of a BCI-high primary prediction were 1.031 (95% CI: 1.005, 1.057) times higher for every-one percentage increase in Ki-67 ($p\text{-value} = 0.0172$), 1.052 (95% CI: 1.003, 1.057) times higher for every one-unit increase in Oncotype-DX score ($p\text{-value} = 0.0353$) and 1.232 (95% CI: 1.24, 1.351) times higher for every-one percentage increase in BCI prognostic LDR risk assessment ($p\text{-value} < 0.0001$). No statistically significant association was found between the BCI predictive score and age, race, stage, lymph node involvement, and HER2 receptor positivity. Conclusions: This single-institution study revealed that clinicians make decisions regarding extended endocrine therapy that are usually concordant with BCI predictive results. CTS5 results weakly correlate with BCI prognostic results but may not provide conclusive information to support a clinical decision. For patients with early hormone-receptor positive breast cancer the BCI tissue-based analysis may influence a decision regarding extending endocrine therapy.

Background: Although neoadjuvant endocrine therapy has been used to improve breast conservation rate, its prognostic relevance is unknown. The search for a valid prognostic factor equivalent to pCR in neoadjuvant chemotherapy is a current challenge in neoadjuvant endocrine therapy. In this study, we investigated the efficacy of short term neoadjuvant endocrine therapy utilizing the waiting period for surgery and the prognostic factor including Preoperative Endocrine Prognostic Index (PEPI) score.

Patients and Methods : A total of 269 postmenopausal women with hormone receptor-positive, HER2-negative breast cancer was treated with endocrine therapy with non-steroidal aromatase inhibitor during the waiting period for surgery between October 2012 and November 2021. Of the entire 269 patients, 92 and 177 patients had anastrozole and letrozole, respectively. The primary endpoint was change in tumor size by ultrasound and Ki67 before and after short-term endocrine therapy. The secondary endpoint was prognosis of patients divided by PEPI score which was calculated using tumor size, lymph node metastasis, Ki67, and ER Allred score. This study was approved by the institutional review board of Teikyo University.

Results: Median age was 68 years old (range, 41-89). ER and PgR was positive in 266 (98%) and 232 (86%) of the entire 269 patients, respectively. Median tumor size was 1.65 cm (range, 0.4-7.5). Seventeen (6.3%) pts were clinically node-positive. Patients with histological grade I tumor were 190 (70.6%). The median duration of endocrine therapy was 39 days (range, 2-88). Average pretreatment Ki67 expression was 10% (range, 0-90). Tumor diameter was significantly decreased to 1.43cm (range,0.45-5.83) after short-term endocrine therapy ($p=0.01$). The Ki67 expression was significantly decreased to 3.0% (range, 0-85) after endocrine therapy ($p< 0.01$) and only five patients (1.9%) showed marked increase in Ki-67 expression. PEPI score 0, 1-3 and ≥ 4 was found in 83 (30.9%),147 (54.7%) and 39 patients (14.5%), respectively. After the median observation period of 928 days, patients with PEPI score ≥ 4 showed worse disease-free survival (Figure) compared with patients with PEPI score 0 and 1-3 ($p=0.06$). In terms of mortality, patients with PEPI score ≥ 4 had worse overall survival than patients with PEPI score 0 and 1-3 ($p=0.07$).

Conclusions: These results suggested that neoadjuvant endocrine therapy during the waiting period for surgery might be effective in reducing the size and Ki67 expression level and PEPI score might be useful in predicting the prognosis of postmenopausal hormone receptor positive breast cancer patients.

1. Background and Aim

Breast cancer has the highest incidence among the world's population. One third of patients diagnosed with early breast cancer progressed into metastatic outcomes due to the inherent heterogeneity and evolutionary features of tumors.

The main clinical manifestation is the discordance of receptor expression in metastases. ESR1 the estrogen receptor(ER) encoding gene, has been proved affected ER expression.

Nevertheless, the correlation between ER transformation and the somatic mutation profiles in breast cancer metastatic lesions remains unclear. Availability of advanced high-throughput technologies, and the development of bioinformatics tools has greatly accelerated our cognition of the molecular basis of cancer.

In this study, we aimed to evaluate the frequency, clinical characteristics and prognostic value of ER receptor conversion between primary and first metastatic lesions in 115 patients whose primary ER status are positive. We also compared the results of NGS of 42 patients and explored latent genes related to ER discordance in expression.

2.Method

Qualified metastatic tumor tissue sequencing information was available for 42 patients. Samples were accessed using the FoundationOne CDx assay (Foundation Medicine, Cambridge, MA, USA) panel including 733 tumor related genes. High frequency mutant genes were defined as the genes count more than 4 times in each group. All data were analyzed using SPSS 25.0 software (Chicago, IL, USA). Pearson's chi-squared (χ^2) test, Fisher's exact test, were used to test the associations between different variables. The Cox proportional hazard models was used to evaluate the relationship between KMT2C mutation and Disease free survival (DFS) in the patients cohorts. The results with $p < 0.05$ were considered statistically significant.

3.Results and Conclusions

All 115 patients (primary ER status is positive) were divided into two groups, 70(60.87%) patients ER status remained positive while 45(39.14%) patients ER status transformed into negative. The histological type ($p=0.008$) and DFS ($p=0.004$) were significantly different in two subgroups. There were no significant correlations between the age at the time of diagnosis, BMI classification, menopausal status, surgery, histological grade, tumor size, lymph node status, metastasis, Ki67, adjuvant radiotherapy, neoadjuvant, metastasis site before second biopsy, first treatment after recurrent and first PFS after rebiopsy.

Univariable analysis of DFS proved metastasis to be distinct risk factor for poor survival (hazard

ratio [HR] > 1, p = 0.001). By contrast, neoadjuvant proved to be protective factor for better survival (hazard ratio [HR] < 1, p < 0.001) . The surgery, histological type, histological grade, tumorsize, metastasis, neoadjuvant, first treatment after recurrent, first PFS after rebiopsy were subsequently analyzed with the multivariable Cox analysis. Metastasis (HR > 1 , p=0.007) and neoadjuvant (HR < 1 , p<0.001) remained independent prognostic factors of DFS.

We compared the differentially mutated genes in the ER differential expression BC patient groups. Mutations in TP53 (n=24) and PIK3CA (n=19) occurred most frequently in both groups and account for 57.14% and 49.23% separately. Notably, mutations in KMT2C (n=6) was detected in ER+ to – subgroup and accounted for 37.5%. According to the results of NGS, the distribution of KMT2C mutations was different among the two cohorts. We identified the mutation in codon 321 was the hot spot of KMT2C in our patient cohort. Next, we used the Kyoto Encyclopedia of Genes and Genomes (KEGG) database to analyze the enriched pathways of KMT2C. KEGG pathway analysis revealed that patients with KMT2C mutations harbored significantly more mutations in genes involved in the Ubiquitin mediated proteolysis and Lysine degradation signaling pathway.

Table.1 Patients' basic clinicopathological characteristics among two groups

Background: The RxPONDER trial demonstrated that chemotherapy improves survival in premenopausal, node-positive, HR+HER2- breast cancer patients irrelative of genomic risk. However, the rate of ovarian function suppression (OFS) was under 20%, questioning whether hormone therapy with OFS would be sufficient in genomic low risk patients. The survival outcome of premenopausal, node-positive, HR+HER2- breast cancer patients were retrospectively reviewed, to investigate the non-inferiority of only hormone therapy with OFS in this population. We also retrospectively reviewed patients who underwent genomic multigene assay in this population. Patients and methods: Breast cancer patients who underwent primary surgery between 1990 – 2013 at Asan Medical Center were retrospectively reviewed in this study. Patients who were 50 years old or younger, HR+HER2- breast cancer and T2/3N0 or T1/2N0 were included. Premenopausal patients who underwent the MAMMAPRINT® test between January 2018 – April 2021 were also reviewed and analyzed. Recurrence was defined as locoregional recur and distant metastasis. Disease-free survival (DFS) and distant

metastasis-free survival (DMFS) was analyzed using the Kaplan-Meier survival analysis and log-rank test. Results: A total of 6,220 patients who were 50 years or younger underwent primary breast cancer surgery for HR+HER2- breast cancer between 1990 – 2013. Among them, 762 patients were T2/3N0 and 1,283 patients were T1/2N0. Most of the patients (N=1,652, 80.8%) underwent chemotherapy. Among patients who only had hormone therapy, 48 (12.2%) patients only had tamoxifen and 345 (87.8%) patients had tamoxifen with OFS (TAM+OFS). The median follow-up was 107 months. The 8-year DFS was 87.2% in the chemotherapy group, compared to 90.2% in the TAM+OFS group (log-rank test p-value 0.499). The 8-year DFMS had no significant difference also between the chemotherapy and TAM+OFS group also (90.7% vs. 93.5% retrospectively, log-rank test p-value 0.184). DFS and DMFS did not differ in the subgroup analysis of T2/3N0 and T1/2N0 too. A total of 270 premenopausal patients underwent the MAMMAPRINT® test for HR+HER2-, N1 breast cancer between Jan 2018 – April 2021. Among them, 136 (50.4%) patients had low genomic risk and 134 (49.6%) had high genomic risk. Among the low genomic risk patients, 17 (19.9%) patients had only tamoxifen, 107 (78.7%) had TAM+OFS and 1 (0.7%) patient had aromatase inhibitor. The median follow-up period was 26 months. There were seven recurrence events, 2 distant metastasis and 5 locoregional recurrences. Among the low genomic risk patients, 1 patient had lung metastasis and 1 patient had local recurrence. Both patients had only TAM+OFS. Conclusion: In this study, TAM+OFS showed no significant survival difference compared to chemotherapy in premenopausal, HR+HER2- patients. Patient selection is essential to omit chemotherapy in this population. The predictive value of genomic multigene assay for chemotherapy in premenopausal, HR+HER2-, node positive patients warrant further evaluation. Several clinical trials are being prepared to answer this question.

Background Hormonal therapeutic agents such as the selective estrogen receptor modulator, tamoxifen, as well as the aromatase inhibitors (AIs), anastrozole, exemestane, and letrozole, are a mainstay in the treatment of patients with hormone-receptor positive (HR+) breast cancer. Despite the effectiveness of hormonal therapy in the treatment of patients with HR+ breast cancer, acquired resistance to both AIs and tamoxifen does occur, often associated with mutations of the estrogen receptor 1 (ESR1). Although the acquisition of ESR1 mutations in patients with HR+ breast cancer treated with hormonal therapy has been established as a mechanism of resistance, there is a paucity of data on the relationship between the duration of treatment with hormonal therapies and the development of ESR1 mutations. Using a cohort of patients with HR+ breast cancer who underwent next generation sequencing (NGS) as part of routine clinical care, we aim to assess the relationship between the duration of exposure to aromatase inhibitors and the detection of ESR1 mutations. The results of this study will further our understanding of ESR1-mutations and provide insight into strategies to optimize therapy for patients with HR+ breast cancers. Methods This is a retrospective analysis of patients 18 years of age or older treated at a single academic cancer center in the USA, diagnosed with HR+, HER2-negative breast cancer and who have received somatic NGS as part of clinical care over a six-year period through July 2019. Demographic, disease-related, and treatment related variables were collected along with genomic testing variables (ie. ESR1-mutation status) for each patient who met the inclusion criteria. Two patient groups were formed on the basis of ESR1-mutation status (present vs. absent) and compared on the basis of duration of treatment with AI, and other clinical and demographic categories. Results A total of 247 patients who were diagnosed with HR-positive, HER2-negative breast cancer and received NGS were identified and are included in this analysis. A total of 138 (56%) patients were assessed via tissue based NGS and 109 (44%) by liquid biopsy. The median age at time of sequencing was 58 years [57 years (ESR1-absent) vs. 60 years (ESR1-present); $p=0.009$]. The majority of

patients were white (83%) and post-menopausal (57%). Invasive ductal carcinoma was the most common histological type (82%). Nearly all (96%) patients had stage IV disease at time of sequencing and ESR1 mutations were found exclusively in those with stage IV disease. ESR1 mutations were identified in 62 patients (25%). The median duration of treatment with aromatase inhibitors prior to testing was 19.3 months in both groups (ESR1 mutations absent vs. detected). There was no difference in prior tamoxifen use between groups (absent 43%, present 48%; $p=0.48$). In patients tested by tissue based NGS, ESR1 mutations were more frequently detected in metastatic sites (28% vs. 13%; $p=0.03$). Twenty-two patients for whom NGS did not identify an ESR1 mutation prior to July 2019 received subsequent NGS testing. Of these 22 patients, six (27%) had ESR1 mutations detected by subsequent NGS. In these six patients, ESR1-mutations were detected by NGS a median of 2.2 years (range 1.7 years to 2.6 years) after prior NGS. Conclusion There was no difference in duration of treatment with aromatase inhibitor therapy in patients with ESR1 mutations vs. those without ESR1 mutations detected by NGS. Patients with ESR1 mutations tended to be older. Although the detection of ESR1 mutations is associated with acquired therapy resistance and progression on treatment, a longer duration of treatment may make the emergence of ESR1 mutations more likely. These counterbalancing factors may have contributed to the results reported here.

Background: EndoPredict is a prognostic and predictive gene expression assay that provides an EPclin risk score, which can be used to identify individuals with low enough risk of distant breast cancer recurrence that they may forgo chemotherapy. In clinical studies, EndoPredict has been validated to predict risk of distant recurrence up to 15 years and chemotherapy benefit. To date, real-world studies evaluating patient outcomes after prospective EndoPredict testing have been limited. Here, we report on outcomes collected via survey from patients enrolled in a registry created to generate real-world evidence from over 800 patients routinely tested with EndoPredict at Charité University Hospital Berlin. Methods: Female patients with hormone receptor positive, HER2 negative primary breast cancer with up to three positive lymph nodes who received prospective EndoPredict testing at Charité University Hospital Institute of Pathology between 2011 and 2016 were contacted to complete a survey for participation in this study. Surveys included questions on treatment and recurrence history. Patient demographics, clinical characteristics of the cancer, and EndoPredict results were retrieved from Charité records. All patients received EndoPredict test results before decision making on systemic treatment. After testing, treatment included either adjuvant endocrine therapy or adjuvant endocrine therapy plus adjuvant chemotherapy, and may have included radiotherapy. Cox proportional hazards models were fit with binary EPclin risk category (high, low) or continuous EPclin risk score predicting 5-year distant recurrence or recurrence of any kind. Analyses were performed across all survey responses, and in subsets of patients stratified by adjuvant chemotherapy treatment. Kaplan-Meier estimates of 5-year risk of recurrence were also calculated. Results: 842 patient survey responses were returned with informed consent and met study inclusion criteria. The median age at diagnosis was 54 years (IQR 49, 63), and across survey responses, 63.5% (N=535/842) of patients were lymph node negative, 60.9% (N=513/842) were T1, and 43.9% (N=370/842) were treated with adjuvant chemotherapy. Among included patients, 49.5% (N=417/842) were classified as EPclin low-risk and 50.5% (N=425/842) were high-risk. The concordance between EPclin risk category and chemotherapy status was 0.89 with 5.5% (N=23/417) of EPclin low-risk and 81.6% (N=347/425) of EPclin high-risk patients receiving treatment with chemotherapy. In the subset of patients not treated with adjuvant chemotherapy (N=472/842, 55.7%), continuous EPclin score was a significant predictor of distant recurrence (N=469; HR: 4.34, 95% CI 1.75-9.58); $p = 2.4 \times 10^{-3}$), and recurrence of any kind (N=468; HR: 3.39, 95% CI 1.61-6.58); $p = 1.9 \times 10^{-3}$). In EPclin low-risk patients treated with endocrine therapy alone, there was a low risk of 5-year distant recurrence (1.6%, 95% CI 0.7%-3.4%). In EPclin high-risk patients the risk of distant recurrence at 5 years was 6.8% (95% CI 2.6%-17.4%) in patients without chemotherapy and 3.6% (95% CI 2.1%-6.3%) in patients treated with chemotherapy. In an exploratory subgroup analysis in patients with node negative and node positive disease, risk of 5-year distant recurrence in EPclin low-risk patients without chemotherapy was 1.3% (95% CI 0.5%-3.5%) and 2.4% (95% CI 0.6%-9.2%), respectively. Conclusion: In this real-world cohort of patients with prospective routine testing with EndoPredict, EPclin scores were a significant predictor for patient-reported outcomes. Patients with EPclin low-risk scores had a low risk of 5-year distant recurrence even in the absence of chemotherapy treatment. This real-world result supports previous clinical studies demonstrating that patients with EPclin low-risk scores can safely forgo chemotherapy.

Authors: Apoorva Anandan, MD (1,2), Trinetri Ghosh (3), Jiwei Zhao (3), Kari Wisinski, MD (1,2) (1) Department of Medicine, Section of Hematology/Oncology, University of Wisconsin-Madison School of Medicine and Public Health, Madison, WI (2) University of Wisconsin Carbone Cancer Center, Madison, WI (3) University of Wisconsin Department of Biostatistics and Medical Informatics Madison, WI Background: A combined analysis of the SOFT/TEXT trials demonstrated an overall survival (OS) benefit to endocrine therapy in addition to OFS compared to endocrine therapy alone, further establishing the importance of adequate OFS in premenopausal women with HR+ breast cancers. Factors associated with inadequate OFS are ambiguous, but younger age, type of chemotherapy, high body mass index (BMI), and time from treatment completion seem to be important. Additionally, data remains limited regarding whether monitoring of OFS should be routinely performed and optimal timing of hormone levels. We sought to identify predictors of inadequate OFS among an AYA population of hormone receptor positive breast cancer receiving OFS at our institution. Methods: A retrospective, descriptive study was conducted looking at AYA patients (pts) aged 18-39 with a diagnosis of HR+ breast cancer who previously and/or currently received oncologic care for management of their breast cancer at the institution. Data was collected from pts diagnosed between 2000-2022. Patients who had previously received or are currently receiving OFS in the adjuvant and/or metastatic setting were included in the study. Data was collected regarding age, BMI, chemotherapy regimen received in the neoadjuvant and/or adjuvant setting, type, dose, and frequency of ovarian suppression, number of times estradiol was monitored, and frequency of estradiol levels >20. This was used as the cut off based on a comprehensive review of data consistently categorizing levels >20 as not to be postmenopausal. Results: 74 AYA patients who received OFS were included with median age of 28 (range 20-39) and average BMI 27.7 (range 15-45). 70% of the population was Caucasian, 10% African American, and 20% Hispanic. Estradiol levels were monitored in 46 of the 74 pts (62%). The frequency of estradiol monitored ranged from 1-22 times. 16 out of the 46 (35%) pts had estradiol checked only once, 10 (22%) twice, and 16 (35%) four or more times. 22 out of 46 pts (48%) had estradiol levels

>20 when checked at least once. 9 out of 22 (41%) had estradiol >20 when checked more than four times. Out of 74 pts, 36 received OFS every month (49%), 32 received OFS every three months (43%). Only 4 out of 74 pts (5%) switched from monthly to every three months, meanwhile only 1 (1%) switched from every three months to monthly. 18 out of the 36 pts (50%) receiving monthly OFS had estradiol levels checked with 9 (50%) having estradiol >20. Meanwhile, 20 out of the 32 pts who received OFS every 3 months (63%) had estradiol levels checked with 10 (50%) having estradiol >20. The average age of pts with estradiol >20 was 33.6 while the average BMI of those with estradiol >20 was 29.2. Finally, 64 out of 74 pts (86%) received chemotherapy in the neoadjuvant and/or adjuvant setting. 41 out of 64 (64%) had estradiol levels checked. 18 out of 41 (44%) had estradiol >20. Discussion: Our data indicates a high degree of clinician variability in monitoring estradiol levels in AYA pts treated with OFS. Lack of adequate OFS was seen in nearly half of pts in this cohort. Higher BMI and young age may be predictors of lack of adequate ovarian suppression, supporting the findings of other studies. An algorithm for routine monitoring of estradiol may improve outcomes with OFS especially in young pts or those with a high BMI.

Background: 18F-FES is an FDA-approved estrogen analogue PET imaging tracer (Cerianna) which measures tumor estrogen receptor (ER) expression at multiple tumor sites simultaneously and predicts response to endocrine therapy. 18F-FDG is a commonly used glucose PET imaging tracer which measures glycolytic metabolic activity in tumors. Elevated plasma ctDNA has been associated with an increased risk of relapse and can identify actionable genomic alterations. This pilot research study explored the relationship between somatic copy-number variants (CNVs) and cell-free DNA mass using low-pass-whole-genome (LPWG) ctDNA in the blood to FES and FDG PET/CT findings with both qualitative and quantitative image analysis in metastatic breast cancer patients.

Methods: Two(2) 10ml Streck tubes were collected from 20 patients with metastatic ER+ breast cancer +/-30 days of their FDG-PET/CT scan (n=19) or their FES-PET/CT scan (n=9). 8 patients had both scans. Somatic mutations were assessed using comprehensive genomic profiling of tissue samples from 19 patients using the clinically validated UW-Oncoplex assay. Qualitative analysis included detection of LPWG ctDNA, presence of PIK3A mutations in tissue, and intensity of uptake in PET/CT imaging. LPWG ctDNA of blood samples evaluated ctDNA mass and CNVs that comprised at least 8% of total ctDNA. Total lesion glycolysis (TLG) in FDG scans and total lesion estrogen receptors (TLER) in FES scans were calculated using a dedicated workflow in MiM software (MiM Software Inc. Cleveland OH). Quantitative analysis included the circulating fraction (ctDNA), PET/CT SUVmax of the index lesion, number of lesions, TLG and TLER. For TLG, the threshold for determining measurable lesions was calculated using liver SULmean + 1.5*SD. The threshold for TLER was calculated using SUVmean of the mediastinal blood pool. The ctDNA fraction and the number of lesions for both FDG and FES were each ranked into 3 categories. FDG and FES data (SUVmax of index lesion, # of lesions, and TLG or TLER) were correlated to the calculated ctDNA fraction values. TLG and TLER were also correlated to each other.

Results: ctDNA was classified as no ctDNA present (n=9), ctDNA present (n=8) and indeterminate (n=3). Average neoplastic ctDNA fraction was 0.114 (range 0.03-0.423). PIK3A mutations were: 10 absent and 9 present. Ranked categories for ctDNA fraction, FDG TLG and FES TLER are shown in Table 1. Table 2 shows results of FDG and FES analysis and correlation with ctDNA. Ranked ctDNA findings correlated with both the FDG number of lesions (R2=0.69) and TLG (R2=0.83), but not the SUVmax of the index lesion (R2=0.29). Correlation decreased for ctDNA versus FES number of lesions (R2=0.51), TLER (R2=0.61), and SUVmax of index lesion (R2=0.16). TLG and TLER significantly correlated with the 8 patients that had both an FDG and FES PET/CT scan (R2=0.77).

Conclusions: In this pilot study, FDG TLG showed a significant correlation with ctDNA. There is an encouraging association with ctDNA fraction and number of FDG lesions and with ctDNA fraction and extent of FES avid disease (TLER) in the 9 patients that had FES.

Introduction: Breast cancer is a heterogeneous disease with well-defined molecular subtypes and variable clinical behavior. The overexpressed HER2 subtype represents approximately 20% of all breast carcinomas. It is associated with a poor prognosis, increased risk of systemic and brain metastases, and poor overall survival until the advent of anti-HER2 therapies, such as trastuzumab. Its introduction into clinical practice has improved the prognosis in cases of breast cancer with overexpressing of pure HER2. However, some cases develop resistance to this drug. Objectives: To evaluate immunoexpression of possible markers involved in the HER2 pathway in breast carcinoma with overexpressing of pure HER2 treated with trastuzumab. Methods: We included 90 patients diagnosed with pure positive HER2 breast carcinoma treated with trastuzumab at the IBCC and HSP/Unifesp public hospitals between 2009 and 2018. Through immunohistochemistry, markers involved in the HER2 pathway (MUC4, IGF-1, IGF-1R, EGFR, p21, p27, p53, p16, cyclin D1, PTEN, CDK4, Bcl-2, VEGF, AR, MDM2, and TNF α) were analyzed samples paraffin-embedded of tumor and compromised lymph nodes and then, correlated with clinicopathological variables. The statistics were performed using the SPSS® software, version 25, from the company IBM, values equal to or less than 0.05 were considered significant ($p \leq 0.05$). To verify possible associations between the clinical-pathological variables and the analyzed markers, Pearson's X2 test, and Fisher's exact test were used; for survival analysis, the Kaplan-Meier method was used. Results: Treatment resistance of pure HER2-positive breast cancer cases after trastuzumab treatment was 40%; the OS of this series was 4.13 years (95% CI 5.1 - 12.5) and the DFS was 3.6 years (95% CI 5.1 - 13.1). In the tumor

samples it was possible to determine potential markers of good prognosis: cyclin D1 with nuclear grade ($p=0.049$) and recurrence ($p=0.038$); IGF-1 with tumor size ($p= 0.015$) and death ($p= 0.046$); p16 with response to treatment ($p= 0.016$); PTEN with response to treatment ($p= 0.050$) and death ($p= 0.030$). The results also showed possible markers of poor prognosis such as p53 with SBR GH ($p= 0.003$) and GN ($p= 0.048$); and IGF-1R with compromised lymph node ($p=0.016$). In compromised lymph nodes samples, the correlations showed TNF α with tumor size ($p=0.043$); and CDK4 with the response to treatment ($p=0.011$) as possible markers of good prognosis; only p53 with GH SBR grade ($p= 0.045$) maintained its potential for poor prognosis. Conclusions: In tumor samples, it was possible to demonstrate that the markers: cyclin D1, IGF-1, p16, and PTEN had the potential for a good prognosis panel and p53 and IGF-1R for worse. In samples of compromised lymph nodes, p53 remained as a marker of poor prognosis, while TNF α and CDK4 of good prognosis.

Aims: While women with breast cancer may have increased survival when compared to other cancers, aggressive, multi-modal treatments are often required with significant impact on quality of life and economic cost, highlighting the importance of breast cancer prevention and screening. For the estimated 10 million women in the United States who meet high-risk criteria for breast cancer, evidence-based interventions may be implemented to reduce risk, including long-term chemoprevention. Engaging in preventative care requires a healthy woman to navigate a complicated decision-making process involving the woman's perception of risk, access to information about risk and prevention strategies, access to care, social support, and the financial ability to manage cost of preventive care. Even with substantial evidence supporting chemoprevention for risk reduction, there is significant lack of uptake and adherence, especially among racial and ethnic minorities and underserved women. Given the missed opportunity for breast cancer prevention that this represents, it is critical to characterize the experience of women with chemoprevention to improve uptake and adherence to chemoprevention. Our aims were to explore the patient experience of women recommended to receive chemoprevention for breast cancer prevention. **Methods:** Sampling from a unique high-risk specialty care setting, we interviewed a diverse cohort of thirty women recommended to receive chemoprevention for breast cancer to learn about their experience in single semi-structured qualitative interviews. Content analysis was used to describe their experience and identify barriers to chemoprevention uptake and adherence. The MDASI-Breast was used to capture patient reported symptom burden at the time of interview. **Results:** Mean participant age was 54.6 years (range 34-87 years); 44.0% Hispanic; 20.0% Black; 81.0% receiving a selective estrogen receptor modulator, 19% receiving an aromatase inhibitor. Mean time since initiating chemoprevention was 14.0 months (range 1.1-49.3 months). At the time of the interview, women reported multiple symptoms, with the most severe reports of fatigue (mean severity 3.77, SD 2.91), sleep disturbance (mean severity 2.90, SD 2.47), problems with memory (mean severity 2.48, SD 2.07), drowsiness (mean severity 2.23, SD 2.14), and decrease in sexual interest or activity (mean severity 2.09, SD 2.38). In qualitative interviews, women reported barriers to preventive care related to symptom burden, access to care, access to accurate information, lack of understanding of breast cancer risk, and financial concerns. Content analysis found 20 symptoms related to both risk and preventive treatment, with 8 symptoms reported by $\geq 20\%$ of women. All women described distress related to their risk, with 23.8% of women describing sadness related to their risk. In addition, 33.3% of women reported distress related to the impact of their own risk on their family, primarily on their children. Women (23.8%) described breast changes that were present when their risk was identified, such as a lump or pain. Treatment-related symptoms varied based on type of endocrine therapy received and history of surgery and included sleep disturbance (23.8% of women), pain (28.6%), hot flashes/night sweats (33.3%), fatigue (28.6%), and joint stiffness or soreness (23.8%). Women shared ways in which symptoms impacted daily functioning, work, relationships, and ability to enjoy life. **Conclusions:** Women at risk for breast cancer recommended to receive chemoprevention experience multiple barriers to adherence including symptoms related to their risk and preventive care, access to care and accurate information, and financial burden. Interventions are needed to improve access to care and symptom management.

【Introduction】 Personalized health care is recommended for the prevention and early detection of breast cancer. Advances in technology have made it possible to estimate genetic risk, PGV (pathogenic/likely-pathogenic germline variant) or PRS (polygenic risk score), in practice. However, linkage after risk assessment to personalized health care is still developing. One of the issues is how to tell the result especially in case of newly diagnosed PGV after Genetic Panel Testing or PRS. In this study, we evaluated genetic counseling (GC) using an established patient-reported outcome measure for clinical genetics services scale (Genetic Counseling Outcome Scale²⁴ (GCOS24)) at genetic counseling for disclosure the results of the previous study, and examined the association with management after GC. **【Method】** We performed targeted sequencing for 11 breast cancer-related genes using peripheral blood DNA from 1995 female breast cancer patients. Of 1995 cases, 101 patients were PGV carriers, who were candidates of this study. Participants were referred to the Clinical Genetics unit, Kyoto University Hospital from 10 institutions (January 2018-March 2022). GCOS24 and relating questionnaires were asked before and after GC. GCOS24 is a scale consisting of 24 items that assess five factors: decision control, cognitive control, behavioral control, emotional regulation, and hope. (In light of the current status of hereditary breast cancer care in Japan, 23 items were used.) Each item is rated on a scale of 1-7 points, for a total score of 23-161. In addition, we reviewed medical records to evaluate the post-GC management. **【Results】** Of the 101 cases, 38 cases were enrolled. The reasons of 63 not-enrolled cases were: 30 cases without follow-up (deaths or transfer to another hospital), 11 cases already diagnosed in clinical practice, 18 cases that did not wish to know their results, and 4 cases whose hospital were developing for hereditary breast cancer care. Median age at the time of genetic GC was 55 (min-max 30-83) years. Details of PGV cases were: BRCA2 23 cases, BRCA1 2, PALB2 4, PTEN 3, TP53 3, ATM 1, CHEK2 1 and NF1 1. GCOS24 after GC were improved than before GC. (Average 99 (min-max 17-124) vs 114 (91-138), Mean difference 23.9, 95% Confidence intervals (CI) 29.6 to 18.3). Thirty patients (79%) had higher increase in scores than 10.3, which was the previously reported Minimum Clinically Important Difference (MCID) of this scale. In all items except 4 items (#6,11,13,21), GCOS24 after GC were significantly improved than before GC. In post-GC management, 8 patients received or planned RRSO (risk reducing salpingo-oophorectomy) among 25 BRCA1/2 cases. There was a case with dysplastic cells detected in the resected ovary. After GC, average of GCOS24 in RRSO cases was 120 (95% CI 110 to 129), while average of GCOS24 of other BRCA1/2 cases was 110 (95% CI 104 to 116). On the other hand, two patients stopped visiting to the hospital because of fear after GC. Average of GCOS24 of 15 junior-high/high school graduate cases were 111 (95% CI 105 to 117), while average of GCOS24 of 23 college graduate cases were 117 (95% CI 111 to 122). **【Discussion】** In patients diagnosed with hereditary breast cancer by genetic panel testing, GC worked well except for 4 items. These 4 items (#6,11,13,21) were related to emotion. This study revealed there was also a risk to reject surveillance due to fear, suggesting that it is necessary to provide psychological support in some cases. Although the limitation of this study is the small number of cases, GCOS24 were high in RRSO cases, suggesting that GC played

an important role when proceeding with intervention. We believe that the findings are helpful for the future implementation of genetic panel testing or PRS testing in healthy subjects for personalized health care.

Background: Canadian and US Task Forces recommend against routine mammography screening for women age 40-49 at average breast cancer risk on the basis that harms outweigh the benefits. Both cite the importance of supporting women's individualized decisions based on the relative value placed on potential benefits and harms of screening (2, 4). Population-based data reveal that screening rates in this age group are influenced by the woman's primary care provider (PCP), suggesting some providers refer more often than others. This highlights the need to explore PCP perspectives on screening and how this informs clinical behaviour.

Methods: Qualitative semi-structured interviews were performed by phone with PCPs in Ontario, Canada. Interviews were structured using the Theoretical Domains Framework (TDF) to explore determinants (barriers/facilitators) of three screening-related behaviours: 1) conducting a risk assessment; 2) discussion regarding benefits and harms; and 3) making a decision regarding referral for mammographic screening.

Analysis: Interviews were transcribed and analyzed iteratively until saturation was reached. Two independent researchers coded all transcripts deductively both by behaviour and according to TDF domain. Findings that did not fit within a TDF code were coded inductively. Data were then grouped by screening behaviour and the associated codes were used to generate descriptive narratives of the determinants influencing PCP behaviour.

Results: Eighteen physicians (mean age 48, 72% identified female) were interviewed. Table 1 outlines the determinants of the three screening behaviours. Analysis of inductive codes revealed two key contextual themes that influenced behaviours and moderated TDF codes: perceived guideline clarity (a lack of clarity on which behaviours (if any) were guideline-concordant) and deferral to patient preference (patient decision regarding screening without a complete discussion of benefits and harms). PCPs who perceived that the guidelines stated definitively that screening was not recommended had improved knowledge of harms and stronger beliefs about capabilities to educate patients about why screening was not recommended routinely. Deferral to patient preference seemed to occur when PCP's knowledge was low and/or if they were impacted by experience of a younger woman diagnosed with breast cancer, which often led to anticipated regret (TDF domain: emotion).

Discussion/Conclusion: Low knowledge related to formal breast cancer risk assessment, combined with a tendency to over-estimate benefits of screening relative to harms could explain some inappropriate variation in practice. All 3 PCP screening behaviours appeared to be affected by both perceived guideline clarity and deferral to patient preferences. These may all be effective targets for future interventions to address variation in care.

Table 1: Unique Barriers and Facilitators of Three Screening Behaviours

Table 1: Unique Barriers and Facilitators of Three Screening Behaviours					
Behaviour 1: Risk Assessment		Behaviour 2: Informed Discussion		Behaviour 3: Guideline Concordant Decision/Mammography Referral	
Facilitators	Barriers	Facilitators	Barriers	Facilitators	Barriers
	<ol style="list-style-type: none"> 1. Knowledge of risk factors & risk assessment tools 2. Skills to synthesize risk 3. Beliefs about consequences: tools don't guide management 	<ol style="list-style-type: none"> 1. Beliefs about capabilities / Skills for discussion to support patient choice 2. Professional Role to inform patients 	<ol style="list-style-type: none"> 1. Knowledge – incomplete knowledge of benefits and harms 2. Beliefs about Consequences: discussion of screening harms will sway patients against screening 	<ol style="list-style-type: none"> 1. Beliefs about capabilities to explain why screening not recommended 	<ol style="list-style-type: none"> 1. Knowledge / Beliefs about consequences: Overestimate benefits + underestimate harms of screening 2. Emotion: past experience & belief that screening would have changed outcome 3. Social Influence: radiology guidelines, patient concerns about cancer risk 4. Environment: actions of radiology departments to accept all referrals

INTRODUCTION: Breast MRI (bMRI) has become a standard of care (SOC) modality for both screening and diagnostic work-up of breast disease (1-2). Despite availability of larger bores,

claustrophobia remains the most common reason for patients declining MRI (3). Anesthesia service can offer sedation during MRI improving patients' acceptance. However, unlike routine MRI, bMRI is performed with patient positioned prone. Our anesthesiologists observed patients' expectation of receiving general anesthesia, without understanding the risks associated with sedation/anesthesia in this particular setting and no prior trials of oral anxiolysis. **OBJECTIVE:** This project retrospectively reviewed bMRI exams with sedation for image quality and potential complication to identify areas for intervention such as provider education on anesthesiology risks in the bMRI environment and the implementation of an institution-approved oral anxiolysis program. **METHODS:** Patients receiving bMRI exams with sedation/anesthesia at a large academic cancer center were identified from the existing institutionally approved Report Imaging Quality Issue database after receiving institutional approval for this quality improvement project with waiver for consent obtained from Institution Review Board. Patient demographics, imaging data, and clinical notes were reviewed by two board certified breast radiologists with over 15 years of experience in MRI interpretation. Safety reports were reviewed in consensus between two radiologists and lead anesthesiologist for MRI department. **RESULTS:** Of 4844 bMRI exams, 33 were performed with sedation/anesthesia. Mean age was 60 years (range 37-77), with mean body mass index of 34 (range 21-45). Reason for anesthesia included claustrophobia in 13 (40%) patients, pain in 6 (18%), and 14 not clearly documented (42%). Eighteen of 33 (55%) exams were rated as poor quality, 7 (21%) as average, and 8 (24%) good or diagnostic. Most common reasons for poor quality included motion from snoring or pain and poor fat suppression due to body habitus. In 11/33 (33%), repeat imaging with still poor quality was documented in technologists' comments. Length of exam appointment ranged from 52 – 155, average 90 minutes. Only one case documented facial bruising due to prone positioning and one case of positioning requiring up to 7 staff. **DISCUSSION:** Availability of on-site anesthesia has enabled some patients to receive bMRI. These patients present to MRI with expectation of sedation/anesthesia without understanding risks or prior trial of anxiolysis and most have a challenging body habitus contributing to difficulty in prone positioning and decreased image quality while under sedation/anesthesia. Development of an oral patient anxiolysis program and provider education may improve image quality and reduce utilization of anesthesia.

Background: In spite of aromatase inhibitors reducing risk of recurrence and mortality, painful side effects often cause women to discontinue use of the drug. Side effects of aromatase

inhibitors include joint and muscle pain, loss of bone mineral density, and impairment of heart functioning. Discontinuation of aromatase inhibitors due to these side effects occur in up to 40% of breast cancer survivors, and consequently risks of recurrence and mortality increase. Objective: We developed two interventions designed to reduce inflammation, alleviate pain and stabilize bone mineral density. Methods: We are currently conducting a pilot parallel intervention trial that is targeted toward alleviating side effects from aromatase inhibitors through dietary and exercise controlled interventions lasting for three months. The dietary intervention is an anti-inflammatory Mediterranean diet designed to decrease inflammation and lessen joint and muscle pain. Participants randomized to the Mediterranean dietary intervention are exclusively consuming food provided by Territory Foods®, an outside food preparation and delivery service, local to Los Angeles. Our exercise intervention is designed to mobilize the joints, and strengthen and reduce bone loss. Participants are visiting the UCLA Kinross gym for three days per week and are undergoing tailored exercise sessions delivered from personal trainers following our bone strengthening intervention protocol. Anthropometric measures, muscle strength, DXA scanning of bone mineral density, peripheral arterial tonometry, pulse wave velocity and biomarkers of inflammation, bone turnover and heart functioning are conducted at baseline, mid- and end of intervention. Results: Our trial is targeted to accrue 20 participants. Thus far we enrolled six participants, with three participants completing the trial. Analysis is ongoing and preliminary results will be presented at the San Antonio Breast Cancer Symposium in December, 2022. Post intervention reports from participants have noted a reduction in pain symptoms, moderate weight loss and increase in muscle strength.

Introduction: Soy intake is associated with lower breast cancer risk in observational studies of Asian women, but clinical trials of soy isoflavone (ISF) supplements report no effect on biomarkers of breast cancer risk among Caucasian women. To date, there are no such trials among Asian women living in Asia. We conducted a three-armed, randomized controlled trial (RCT) to assess the effects of one-year intervention of soy isoflavone supplements (100mg/day) or soy isoflavones through diet (50mg/day) on mammographic density (MD) change among peri- and postmenopausal Malaysian women. Methodology: Healthy women

between 45-65 years old were enrolled between November 2018 and December 2019 at a private tertiary hospital in Malaysia. Women were randomly assigned into the 100mg/day ISF Supplement arm, 50mg/day ISF Diet arm, or Control arm. Dense area was assessed from digital mammograms conducted at enrolment and after 12 months. We compared absolute and relative change in dense area over the study period by study arm using Kruskal Wallis tests. Results: Of the 118 women who received the intervention, 91 women completed the study whilst 27 women (23%) were lost to follow up. After 12 months of intervention, women in the ISF Supplement arm observed a marginally larger decline in dense area (-1.3cm²), compared to women in the ISF Diet arm (-0.5cm²) and Control arm (-0.8cm²), but this difference was not statistically significant (p=0.479). Notably, these effects appear to be stronger and limited to women who enrolled within 5 years of menopause, where up to 6cm² decline in MD was observed in the ISF Supplement arm, compared to < 1.0cm in the Control arm (p=0.131). Conclusion: This RCT demonstrates a possible causal association between soy ISF intake and lower breast cancer risk among Asian women, specifically around the time of menopause, but these findings will require confirmation in a larger trial.

Background: Acrylamide is classified as a probable human carcinogen by the IARC but epidemiological evidence on the carcinogenicity of acrylamide from dietary sources is limited. This study aimed to investigate the associations between dietary acrylamide and breast cancer risk in the NutriNet-Santé cohort. Methods: This prospective cohort study included 80,597 French women (mean [SD] age at baseline: 40.8 [14] years) during a mean (SD) follow-up of 8.8 (2.3) years. Acrylamide intake was evaluated using repeated 24h dietary records (n= 5.5 [SD 3.0]), linked to a comprehensive food composition database. Associations between acrylamide intake and breast cancer risk (overall, premenopausal and post-menopausal) were

assessed by Cox hazard models adjusted for known risk factors. Results: The mean (SD) dietary acrylamide intake was 30.1 (21.9) µg/d (main contributors: coffee, potato fries and chips, pastries and cakes, and bread). During follow-up, 1016 first incident breast cancer cases were diagnosed (431 premenopausal, 585 postmenopausal). A borderline significant positive association was observed between acrylamide intake and breast cancer risk overall (HRQ4 vs Q1= 1.21 [95% CI: 1.00-1.47]) and a positive association was observed with premenopausal cancer (HRQ4 vs Q1= 1.40 [95% CI: 1.04-1.88]). Restricted cubic spline analyses suggested evidence for non-linearity of these associations, with higher HR for intermediate (Q2) and high (Q4) exposures. Receptor-specific analyses revealed a positive association with estrogen receptor-positive breast cancer, which represented 86% of total cancer cases. Acrylamide intake was not associated with post-menopausal breast cancer. Conclusions: Results from this large prospective cohort study suggest the potential deleterious role of dietary acrylamide in breast cancer etiology, especially in premenopausal women, and provide new insights that should encourage further mitigation strategies to reduce the content of acrylamide in food.

BACKGROUND: The Dallas Metastatic Breast Cancer Study (DMBCS) is a clinical database that was established in 2021 at a single academic medical system to track patient demographics, associated pathology, treatments, and other variables that are not widely available in the Surveillance, Epidemiology, and End Results (SEER) Program for metastatic breast cancer (MBC). One of many ongoing studies as part of the DMBCS is to investigate how weight loss after diagnosis affects outcomes in MBC patients. Although previous studies have shown that significant weight loss is associated with poorer outcomes in certain cancer types, little is known about its role in breast cancer. **METHODS:** 139 patients who were diagnosed with MBC between 2009-2021 were included in this data collection. BMI at the time of diagnosis of MBC and within 6 months of death or last follow-up were recorded. BMI velocity was calculated by dividing the difference between BMI at diagnosis and BMI at time of death (or last follow-up) by the number of months between initial diagnosis and time of death (or last follow-up). The BMI velocity represents the rate at which patients lost or gained weight during their disease course. A negative BMI velocity indicates weight loss, and a positive BMI velocity indicates weight gain over the defined period. The absolute value of the BMI velocity indicates how rapidly someone gains or loses weight. The association of BMI velocity on the primary outcome (overall survival (OS) and progression-free survival (PFS)) was assessed using Cox proportional hazard (PH) model. Adjusted hazard ratios (HR) with 95% confidence intervals were computed using the multivariable Cox PH model. **RESULTS:** At the time of diagnosis of MBC, 40% were obese and 33% were overweight. At the time of death or last follow-up, 27% were obese and 31% were overweight. The mean BMI velocity was -0.13 per month. Contrary

to previous studies that have shown a negative effect of obesity on OS, we found that obesity at the time of diagnosis of MBC did not statistically worsen OS and PFS. However, compared to patients who had negative BMI velocities, improved OS (lower hazard ratio) was noted for patients with stable or increasing BMI velocities (HR = 0.53; 95% CI = 0.32-0.88, p = 0.014). A greater rate of weight loss was also associated with worse OS (HR = 0.23; 95% CI = 0.12 - 0.47, p < 0.001) and PFS (HR = 0.29; 95% CI = 0.16 - 0.52, p < 0.001). Improved PFS was seen for patients with stable or increasing BMI velocities in the unadjusted analysis (HR = 0.65; 95% CI = 0.42 - 0.99, p = 0.047). CONCLUSION: Our study found that contrary to previously published results in patients with early-stage breast cancer, obesity did not statistically worsen OS or PFS. However, the rate of weight loss, which we defined as BMI velocity, is associated with higher mortality in MBC. Our findings can be applied to clinical practice when advising MBC patients regarding healthy changes in weight during their disease course. BMI velocity could be used as a prognostic indicator to predict outcomes in patients with MBC. In future studies, we aim to quantify the amount of weight loss that is associated with worse outcomes.

Background Breast cancer is the most frequently diagnosed cancer in women in developed countries with increased incidence in women at high risk such as those with strong family history, BRCA mutations, atypical hyperplasia etc. Chemoprevention with drugs like tamoxifen and aromatase inhibitors come with challenges of intolerance and limited efficacy in estrogen receptor negative breast cancers. The purpose of our study was to evaluate the effects of hydroxytyrosol (HT), a component of olive oil on mammographic breast density reduction, which is a validated surrogate biomarker for breast cancer prevention as well as to explore on-target effects on Wingless-related integration site (Wnt) pathway, and alterations in key pathways of proliferation, DNA damage repair and stem cell function. **Methods** This study was conducted using 25mg/day oral dose of HT for 12 months in both pre- and post-menopausal women who are at increased risk of breast cancer with Gail 5-year risk score ≥ 1.67 and/or $> 10\%$ probability of BRCA mutation and had declined standard chemoprevention. These women underwent annual mammograms as well as had the option to have a biopsy of normal breast tissue before and after HT. Maximum volumetric breast density (Max VBD%) was assessed quantitatively using Volpara software (VIS 3.2) and the annualized percent decrease in max VBD% between baseline (BL) and end of treatment (EOT) with HT was analyzed in the study. RNA was extracted from the breast biopsies and RNA sequencing (RNA-Seq) and multiplex analysis of 28 proteins using NanoString nCounter analysis was performed to compare the BL with EOT samples. **Results** A total of 61 women were screened for the trial, 51 were enrolled and 41 patients completed the study. Median age for the study population was 54 years (range

35-76 years). There were 26 patients with paired BL and EOT mammograms. There were 14 patients with paired BL and EOT breast biopsies and seven patients with only BL and seven with only EOT biopsies. Mammographic density as measured by max VBD% showed a non-significant change of -0.038%, $p = 0.49$. However, on subgroup analysis in women 60-years or older, the mean decrease in max VBD% was - 3.7% ($p = 0.0391$), especially in those with high baseline mammographic density ($> 10\%$ baseline max VBD%). RNAseq data was generated from 15 BL and 17 EOT samples and pathways were confirmed by NanoString. Our bioinformatics pipeline identified 190 transcripts that were upregulated and 90 that were downregulated in EOT vs. BL by at least 1.5 fold. Reactome pathway R-HSA-195721 (Signaling by WNT) is identified as the top pathway enriched with EOT downregulated genes. On further review of the expression profiles, 82 of 261 member genes had p -value < 0.05 for EOT vs. BL, among which only 4 were upregulated and 78 were downregulated in EOT samples. These 82 genes were highly interactive with each other, with 379 high confidence protein-protein interactions (PPIs) (confidence score > 0.7 from STRING database) involving 81 out of 82 genes. In addition, mitotic telophase/cytokinesis ($p = 0.004$), ATM signaling ($p = 0.007$) were some pathways that were upregulated whereas, NOTCH signaling ($p = 0.007$), oxidative stress induced senescence ($p = 0.0001$) pathways were downregulated in EOT vs. BL. Conclusions Hydroxytyrosol, a component of olive oil did not show a decrease in breast density in the intention to treat population but showed some reduction in breast density in women 60-years of age and above, especially in those with high baseline breast density. HT showed on target effects by affecting Wnt signaling pathway, as well as decrease in proliferation. This study lays the foundation for future larger studies in exploring a natural compound such as HT for chemoprevention of breast cancer.

Abstract Background: Some special consensus recommended the duration of perioperative antibiotic prophylaxis was within 24 hours postoperatively in breast cancer undergoing postmastectomy implant breast reconstruction. However, surgeons in practice favored to prolong the duration. The aim of this study was to estimate the effects of duration of antibiotics on major adverse outcomes in real clinical practice setting with diverse population using overlap weighting model. **Methods:** In this retrospective study, patients with breast cancer undergoing breast implant reconstructions were collected in Fudan University Shanghai Cancer Center from 1 January 2008 to 31 December 2021. Cases were divided into two groups according to the duration of perioperative antibiotic prophylaxis: short-term group (≤ 24 hours) and long-term group (>24 and ≤ 48 hours). The primary outcomes were unplanned reoperations and complication-related unplanned reoperations. Unplanned reoperation was defined as debridement, expander removal without prosthesis implantation, expander removal and expander implantation, prosthesis removal and prosthesis implantation, prosthesis removal, prosthesis removal and expander implantation. By reviewing the patients' detailed medical history, all unplanned reoperations were divided into non-complication-related unplanned reoperations and complication-related unplanned reoperations. Non-complication-related

unplanned reoperations included: patients voluntarily gave up continuing reconstruction, suspected recurrence of cancer, changed reconstruction methods, unsatisfactory appearance, and unknown reasons. Complication-related unplanned reoperations included: infection, exposure of prosthesis or expander, poor wound healing, rupture of expander, necrosis of skin flap, bleeding. The secondary outcomes were infections that required intervention. It was defined as both met with white blood cells elevation and physician antibiotic prescription during outpatient follow-up. To adjust confounders, propensity score overlap weighting was used, and subgroup analysis and sensitive test were conducted to demonstrate the robustness of results. A P value less than 0.05 was considered statistically significant. Results: In 4367 cases of unilateral implant reconstructions, 4128 (95%) were included in this study. Among them, 1689 were expander implantation, 1124 were prosthesis implantation and 1315 were expander removal and prosthetic implantation. At inclusion, only 283 cases (6.9%) received antibiotics prophylaxis ≤ 24 hours, 3090 cases (74.9%) with duration > 24 and ≤ 48 hours, and 755 cases (18.3%) with duration > 48 hours. Of them, 230 cases (5.6%) underwent unplanned reoperation, including 131 (3.2%) complication-related unplanned reoperations, and 99 (2.4%) non-complication-related unplanned reoperations. And there were 110 cases (2.7%) with infections that required intervention. In unweighted or weighted data set, short-term antibiotic use did not significantly increase the risk of adverse outcomes, including unplanned reoperation, complication-related unplanned reoperation, and infection required intervention, compared with long-term antibiotic use with or without patients with duration more than 48 hours. Most subgroup analysis showed no evidence of heterogeneity of the effects of duration of antibiotic use on adverse outcomes. Conclusion: In clinical setting with diverse population, prolong antibiotic prophylaxis with more than 24 hours is not necessary to reduce major adverse outcomes, even in some critical conditions. Appropriating and accessible prophylactic initiatives should be developed and implemented with shorten the duration of antibiotic prophylaxis and minimized adverse outcomes. Key words: perioperative antibiotic prophylaxis, breast cancer, postmastectomy implant reconstruction, unplanned reoperation

Licochalcone A from licorice reprograms metabolic and antioxidant pathways in the breast leading to a tumor preventive environment.

Background: Increased adiposity is a risk factor for postmenopausal breast cancer. It is often accompanied by chronic low-grade inflammation and elevated levels of reactive oxygen species, which drive breast tumorigenesis. Risk reducing drugs such as selective estrogen receptor modulators and aromatase inhibitors, which have demonstrated efficacy, have had a significantly low acceptance among women at high risk for breast cancer. This hesitancy is mainly due to the adverse side effects of these medications such as vasomotor symptoms, osteoporosis, thromboembolism, and uterine cancer. Therefore, alternative strategies with lower toxicity and greater acceptability are needed. We have previously shown that licochalcone A (LicA) from licorice (*Glycyrrhiza inflata*), which has osteogenic effects, suppresses aromatase expression and activity, enhances the activity of detoxifying enzymes, and reduces estrogen genotoxic metabolism in cell lines and animal models. However, its effects on the breast tissue of high-risk women are understudied. We hypothesize that LicA creates a tumor preventive environment in the breast by locally modulating adipogenesis and antioxidant/anti-inflammatory responses leading to decreased proliferation. Methods: We prepared microstructures from fresh tissue of contralateral unaffected mastectomy specimens of 6 postmenopausal women with incident unilateral breast cancer. We exposed these to DMSO (control) and LicA (5 μ M) for 24 h. Employing total RNA sequencing, we examined differential gene expression between treated and control samples. Up-regulated and down-regulated genes were analyzed using Enrichr gene ontology (GO) pathway analysis. Enriched pathways with combined enrichment scores > 4 and FDR < 0.05 were considered statistically significant. Metabolism flux analysis was performed (FDR < 0.05). Live cell imaging to monitor proliferation of pre-malignant DCIS.COM, DCIS.COM/ER+ PR+; and malignant MDA-MB-231 (ER- PR-), MCF-7 (ER+ PR+), MCF-7aro, and BRCA1 defective HCC-1937, and HCC3153

cells was conducted using IncuCyte. Single versus repeated dosing of various concentrations of LicA were also evaluated. Results: We observed significant ($P < 0.05$) upregulation up to 8-fold of antioxidant genes, consistent with significant upregulation of NRF2, the major regulator of antioxidant pathways. This was accompanied by significant ($P < 0.05$) downregulation of NF- κ B dependent inflammatory pathways. In addition, we observed the significant ($P < 0.05$) downregulation, ranging from 4 to 32-fold of cholesterol biosynthesis and transport, steroid hormone biosynthesis, as well as lipid metabolism genes, consistent with the profound downregulation of SREBF1 and SREBF2, which encode the master regulator of adipogenesis, SREBP. Metabolic flux results demonstrated a robust increase ($FDR < 0.05$) in the pentose phosphate shunt and NAD(P)H generation without enhancing ribose 5 phosphate formation, confirming an antioxidant and anti-proliferative environment. Likewise, LicA suppressed proliferation of pre-malignant and malignant cells dose- and time-dependently. Repeated dosing of lower concentrations of LicA ($< 10 \mu\text{M}$) demonstrated sustained antiproliferative effects even in the aggressive cancer cell lines. Conclusion: Our data suggest that LicA can generate a tumor-preventive breast microenvironment by reprogramming metabolic pathways involved in steroid and lipid homeostasis and antioxidant responses. These observations along with its low toxicity, suggest that LicA is a good candidate for further investigation as a breast cancer prevention agent.

Purpose: To investigate the feasibility of low-dose Positron Emission Mammography (PEM) to identify breast cancer. **Materials and Methods:** In an REB-approved ongoing clinical trial, which started in December 2019, all newly diagnosed women with breast cancer who had not undergone neoadjuvant chemotherapy and consented to the study were randomly assigned independently of their mammographic breast density, tumor size, and histopathology cancer subtype to perform PEM using a novel organ-targeted PET system (Radialis PET Imager, Radialis Inc., FDA cleared to image and measure the distribution of injected positron-emitting radiopharmaceuticals) with either 1mCi, 2mCi or 5 mCi of 18F-FDG. The PEM images acquired 1 and 4 hours after 18F-FDG administration were reviewed in consensus by two fellowship-trained breast radiologists blinded to cancer location. PEM imaging features of known malignancies and additional PEM findings were recorded and correlated with histopathology as the ground truth. **Results:** Our cohort comprised 22 women with a median age of 51 years (range 32-85) with 88 completed bilateral sets of images where 23 cancers (18 invasives, and 5 in situ) were present. The median invasive cancer size on surgical pathology was 28 mm (range: 3-120). Out of 18 invasive cancers, the only PEM images that did not visualize cancer (2 invasive lobular cancers and 2 in-situ cancers) were acquired with the lowest dose of 18F-FDG (1 mCi). A total of 6 (27.3%) subjects received 1mCi 18F-FDG with 5 invasive cancers, 7 (31.8%) of patients received 5 mCi 18F-FDG with 7 invasive cancers, and 9 (40.9%) of patients received 5 mCi 18F-FDG with 6 invasive cancers. A total of 3 false-positive images of benign findings were also present. No additional cancers were identified exclusively by PEM. The PEM performance was similar following an additional 3-hour interval for radiotracer uptake. **Conclusion:** This preliminary data results show the feasibility of invasive breast cancer detection with a decreased 18F-FDG dose, possibly due to the novel PEM system detectors increasing the sensitivity to radiotracer and the perceived spatial resolution by the visual assessment. Larger-scale clinical trials are required to consolidate our preliminary findings. **Clinical Relevance:** A novel organ-targeted PET system enables the detection of invasive breast cancer using low-dose PEM, potentially emerging as a promising novel imaging tool.

Introduction Iron oxide nanoparticles have been used in preclinical and clinical research as imaging agents for decades because of their magnetic properties and their known safety profile. We have been developing the MagSense® HER2 Test Reagent (MSH2TR), a formulation of anti-human epidermal growth factor receptor 2 (HER2) conjugated iron oxide nanoparticles, for the noninvasive detection of metastatic lymph nodes to aid in staging of HER2 positive (HER2+) breast cancer patients. Currently, nodal staging requires a patient's lymph nodes to be surgically removed or biopsied for histopathological examination. MSH2TR is currently being investigated in a first-in-human phase I study in subjects with HER2+ primary breast cancer who, in the judgment of the investigator, have a likelihood of lymph node metastasis. Methods This phase I study is designed to be a preliminary proof-of-principle study with the primary objective of achieving an initial assessment of the safety and tolerability of the MSH2TR injectable imaging agent. A secondary objective of the study is the confirmation that the route of administration is effective in allowing the imaging agent to reach the patient's lymph nodes. The exploratory objectives of the study include a comparison of the two imaging modalities: magnetic resonance imaging (MRI) and a novel proprietary technology called magnetic relaxometry (MRX), to standard clinical tissue histopathology. The exploratory objectives are expected to provide a preliminary assessment as to whether the MagSense® HER2 imaging agent, when used with one or both imaging modalities, might be able to provide a non-invasive alternative to nodal biopsy. All eligible subjects receive a 30mg injection of MSH2TR into the subareolar interstitial tissue or area near and around the primary tumor. MRI of the axilla are performed before and 24 to 72 hours after MSH2TR injection followed by core biopsy or dissection of the suspected lymph node tissue as per standard of care (SOC) procedures for histopathology assessments and also for ex vivo MRX measurements using the MagSense® Relaxometry Instrument. Review of the MRI scans and histopathology are performed in respective central laboratories. The study is currently enrolling in 4 clinical sites in Australia. Results From an interim evaluation of the first five patients that have completed the study, MSH2TR appears to be safe and well tolerated and no safety issues reported related to the imaging agent. The imaging agent, as administered, is reaching the lymph nodes. The study

intends to enroll approximately 15 patients for the preliminary efficacy assessment. Safety and efficacy results from available patients' data will be presented. Conclusion Available data to date from the ongoing phase I study show that the MagSense® HER2 imaging agent, as administered, appear to be safe and drains to the axillary lymph nodes within the timeframe of interest. Further data collection is ongoing for the preliminary evaluation of efficacy.

Background Conventional pathologic scoring of HER2 by IHC is proven to distinguish potential responders to trastuzumab but has not been effective for next generation antibody drug conjugates (ADCs) such as trastuzumab deruxtecan (T-DXd), which is capable of bystander killing. Several alternative approaches have been deployed to measure HER2, including immunofluorescence and mRNA sequencing. We have developed a novel and fully automated computational pathology technique, Quantitative Continuous Scoring (QCS), to quantify the level and distribution of HER2 from digitized HER2 IHC slides in an objective, quantifiable, and reproducible manner on a per-cell basis [Gustavson et al., SABCS 2020]. To further validate this approach, we performed a systematic multi-omic comparison of QCS to orthogonal methods of HER2 quantitation on a cohort of primary and metastatic breast cancer cases (N=30). Methods HER2 was evaluated using three independent methods on serial tissue

sections obtained from 30 archival FFPE breast cancer samples distributed over the full range of HER2 expression, from 0 to 3+. HER2-IHC staining (clone 4B5, Roche Tissue Diagnostics) was performed using standard methods and cases were scored by two pathologists using CAP/ASCO guidelines and H-scores were assigned. We performed FISH (HER2 IQFISH pharmDx [Dako]; PathVysion HER-2 DNA Probe Kit [Vysis]), mRNA quantification of ERBB2 transcript levels (Nano String), and immunofluorescence (IF; HER2 clone 29D8, CST). Imaged with Vectra (Akoya) and analyzed with Halo (Indica). QCS readouts were generated from the above-mentioned digital images of IHC slides by using a fully automated image analysis pipeline; readouts included per-cell staining intensity measurements of membranes and cytoplasmic sub-compartments in terms of optical density (OD) [Van der Laak, JQCS 2000], which were aggregated to a single slide-level score. Additionally, using the OD measurements and the cell locations, a Spatial Proximity Score (SPS) was computed, summing the percentage of cells with $OD \geq 10$ (corresponding to the limit of visual detection of IHC staining) as well as the percentage of cells with $OD < 10$ within a prespecified radius ($25\mu\text{m}$) of a neighboring cell with $OD \geq 10$. Results Our analysis demonstrated that QCS-based scoring correlates with orthogonal measurements used in this study. Comparing protein-based assays, the observed Pearson correlation was $R=0.88$ between QCS median membrane OD and IHC H-scores, $R=0.86$ with IF-based HER2 mean cell expression intensity, and $R=0.85$ with IF-based H-scores. Correlation with transcriptomic profiling was $R=0.81$ for OD vs. mRNA, however ERBB2 transcript levels did not distinguish between HER2 0, 1+, and 2+ FISH negative cases, while QCS was able to do so. Correlation between protein-based and nucleic-acid based assays were numerically worse, with $R=0.64$ for OD vs. FISH. All samples (including those with HER2 IHC scores of 0 and H-Scores < 10) had at least ~20% of cells with quantifiable HER2 expression by OD, the presence of which was confirmed using IF. For cases in the lowest quartile of HER2 expression by OD, SPS identified 20-50% additional HER2-null cells that were in close proximity to HER2-expressing cells that may be vulnerable to bystander killing. Conclusion QCS-based scoring is consistent with orthogonal protein-based measurements across the range of HER2 expression. Most importantly, QCS derived-spatial analysis features identify additional patients in the lower end of HER2 expression that might be highly relevant for ADC response prediction, particularly if a drug exerts bystander activity. Further clinical verification and validation on large cohorts is needed. Footnote: This study was approved by the IRB at MSKCC.

Background

Diffusion-weighted imaging (DWI) is an MRI technique that does not require a contrast agent and can provide quantitative information on tissue microstructure in the form of calculated metrics such as the apparent diffusion coefficient (ADC), which reflects the mobility of tissue water. Initial studies have shown promising results evaluating changes in tumor ADC to predict treatment response in breast cancer patients receiving neoadjuvant chemotherapy¹.

One limitation of quantitative DWI is that MRI scanner gradient non-linearity (GN) results in spatially varying diffusion-weighting gradients, resulting in a bias in calculated ADC values². This effect increases for imaging at greater distances from the magnet isocenter, as required for breast imaging. GN effects are a concern for utilizing ADC as a biomarker of response or for diagnostic use in the clinical trial setting, as they may introduce confounding bias in ADC measures: across different patients, in the same patient at other time points, and between the ipsilateral and contralateral breasts. Previous work has demonstrated that GN effects can be corrected across leading clinical multiple MRI scanner vendors resulting in more accurate ADC values³.

The goal of this work was to implement multi-vendor GN correction (GNC) of DWI data acquired in breast cancer patients receiving neoadjuvant chemotherapy (NAC) from the

multicenter I-SPY 2/ACRIN-6698 trials and evaluate the effects of GNC on 1) cross-sectional tumor ADC values across multiple MRI scanner platforms and 2) on longitudinal changes of ADC values for treatment response evaluation.

Methods

This retrospective analysis utilized DWI data ($b=0, 800$ s/mm² or $b=0, 100, 600, 800$ s/mm²) acquired in women diagnosed with high-risk, stage II/III breast cancer. Patients were recruited from 19 institutions, and data included DWI from 11 different gradient systems from three leading MRI scanner vendors (General Electric, Philips, and Siemens), utilizing both 1.5T and 3T scanners. DWI data acquired before initiation of treatment (T0) and three weeks after the start of NAC (T1) were analyzed. A vendor-agnostic GN correction program³ utilizing vendor-supplied spherical harmonics for gradient characterization was used to generate GN-corrected ADC maps from the DWI data retrospectively corrected. Tumor regions of interest (ROIs) encompassing tissue appearing hyperintense on DWI ($b=800$ s/mm²) images and hypointense on corresponding ADC maps were defined on multiple DWI imaging slices encompassing the full extent of the tumor. The ROIs were applied to both uncorrected and GNC ADC maps. The uncorrected and GNC tumor ADCs were evaluated for mean, standard deviation, and percentage change resulting from GNC. Statistics were calculated for the entire cohort and separately for each MRI scanner gradient system. The effect of GNC on the mean ADC change from T0 to T1 was also evaluated.

Results

A cohort of 131 patients with 262 DWI exams was included in this analysis. Uncorrected and GN corrected mean tumor ADC and Std Dev are shown in Table 1. For DWI in the whole cohort, GNC reduced the tumor ADC from -9.04% to -0.03% from all the gradient systems across vendor platforms. GNC also decreased the Std Dev of ADC distribution from -8.70% to -4.06% from all systems. These align with previous published phantom results and the single vendor investigation.

Tumor ADC value changes measured between baseline (pre-treatment, T0) and after three weeks of treatment (T1) show a small impact from GNC correction (Table 2).

Discussion

This retrospective study of applying GN correction to DWI data acquired in the clinical trials from multiple imaging sites utilizing MRI scanners manufactured by different vendors demonstrated the effect of gradient correction on the tumor ADC measurement.

Background: Improved understanding of factors affecting the accuracy of breast MRI after NST can lead to more tailored use of MRI in deciding surgical extent after NST. **Purpose:** To investigate whether the accuracy of magnetic resonance imaging (MRI) and caliper predicting residual tumor extent is affected by neoadjuvant treatment in estrogen receptor (ER) positive and HER2-negative, lymph node-positive, premenopausal breast cancer breast cancer. **Materials and Methods:** We analyzed the imaging and clinicopathologic data of 123 patients in phase 3, randomized clinical trial (NCT01622361), which compared neoadjuvant chemotherapy (NCT) with neoadjuvant endocrine therapy (NET) in estrogen receptor-positive (ER+)/human epidermal growth factor receptor 2-negative (HER2-), lymph node (LN)-positive, premenopausal breast cancer patients. In this study, we compared the largest size of MRI and Caliper after neoadjuvant treatment with one of pathology. **Results:** In patient with discrepancy in predicting response to NST, the measurement (MRI or caliper) that predict as non-response (SD or PD) was more accurate in both of NCT and NET group (ICC, Intraclass correlation coefficient, MRI; 0.84, 95% CI 0.616-0.942, Caliper; 0.75, 95% CI 0.303-0.931). The accuracy of MRI was better in NCT group than in NET group (ICC 0.86; 95% CI 0.626-0.956 for NCT, 0.47; 95%CI 0.133-0.708 for NET). The mean absolute discrepancies (largest size by MRI or caliper - largest size in pathology) for the MRI and Caliper were, respectively, -0.78cm and -1.04cm in NCT group and -0.44cm and -1.32cm in NET group ($p > 0.05$). The proportion of discrepancy $>1\text{cm}$ or $>0.5\text{cm}$ were not significantly difference between NCT and NET groups among MRI and Caliper. **Conclusion:** In ER-positive, HER2-negative, lymph node-positive breast cancer, both MRI and caliper tend to overestimate residual tumor size than pathology in NET group compare to NCT group. When MRI and caliper show discrepancy in predicting response to NST, the measurement (MRI or caliper) that predict as non-response (SD or PD) was more accurate in both of NCT and NET group. These factors should be considered for deciding the evaluation method of response and surgical decision after NST and surgical decision in this subgroup. **REGISTRATION:** ClinicalTrials.gov identifier: NCT01622361

Introduction: Although breast cancer with high Ki-67 index are likely to have high genomic risk, some of these might have low genomic risk. In ER+HER2- breast cancer patients with low genomic risk identified by the 21-gene assay, we addressed a clinical significance of Ki-67 index in terms of recurrence-free survival (RFS). Methods: We retrospectively identified 2,295 patients with ER+HER2- breast cancer who underwent the 21-gene assay (Oncotype DX®). High Ki-67 LI was defined as 20% or greater, and low genomic risk was defined by recurrence score (RS) from the assay (< 26). Recurrence after 3 year was regarded as secondary endocrine resistance, which is defined as recurrence while on 2 years of adjuvant endocrine treatment. Results: In all patients, Ki67 index assigned 870 (38%) as the high and 1,425 (62%) as the low groups. Thirty percent (263/870) of the high Ki67 index had high genomic risk, whereas 84/1425 (6%) of the low Ki67 did. Among the patients with low genomic risk who did not receive chemotherapy (n=1,807), high Ki67 index was an independent poor risk factor for recurrence. Furthermore, recurrence after 3 years differed significantly according to Ki-67 index (P=0.003), whereas recurrence within 3 years did not differ (P=0.900). Multivariable analysis demonstrated high Ki67 index as a risk factor for recurrence after 3 years (hazard ratio 3.12;

95% confidence interval, 1.28–7.66). Conclusions: In ER+HER2- breast cancer with low genomic risk identified by 21-gene RS, high Ki67 index is associated with secondary endocrine resistance. Novel approach with CDK4/6 inhibitors is demanded to overcome secondary endocrine resistance in tumors with high Ki67/low genomic profile.

Treatment with CDK4/6i plus ET is the standard treatment for mBC with a significantly better progression free survival (PFS) and a long treatment duration response, although there's finally a progression. The expression of cyclin E and progesterone receptor had been related to survival, so analyzing of these potential biomarkers could help to select their effect in patients with a long treatment duration (> 20 months).
We evaluate 68 mBC treated with CDK4/6i plus ET as a clinical practice in a single institution.

Median age was 68 years, 27(39,7%) patients had de novo metastatic disease, 17 (25%) progressed during ET adjuvant, and 24 (35,3%) progressed after 5 years of ET. Forty-eight patients (70%) received CDK4/6i plus ET in first line and visceral disease was present in 40% of patients. The median expression by histoscore with immunohistochemistry of cyclin E (CycE) was 75,3 (4-97) and progesterone receptor (PR) 121.

Median PFS was 16 months (8,3- 23,6) with 45 events, 25 months in patients treated in first line and 12 months in second line (p: 0,0001). We analyzed 59 patients who had already completed CDK4/6i plus ET or had achieved a PFS more than 20 months, 40 (69%) in first line and 18 (31%) in second line. We summarized the related of expression of PR, CycE and this combination with PFS more than 20 month.

CONCLUSION

Treatment with CDK4/6i plus ET achieved long treatment duration in patients with low expression of cyclin E (OR 3,1 p:0,045), positive progesterone receptor (OR 3,89 p: 0023) and specially in patients with positive progesterone receptor and low expression of cyclin E (OR 7,22 p:0,016). Patients with negative progesterone receptor and high expression of cyclin E had a poor prognosis with a median disease-free survival of 6 months (2.8 – 9.2), so these patients required other treatment approaches to improve their outcomes.

DFS (MONTHS)	LINE OF TREATMENT		PROGESTERONE RECEPTOR		CYCLINE E	PROGESTERONE+CYCLINE

ABSTRACT Introduction: Radiation therapy (RT) plays an important role in the management of patients with ductal carcinoma in situ (DCIS) of the breast, treated by breast conserving surgery (BCS). RT reduces significantly the risk of local recurrences (LR). Efforts are being, currently, to de-escalate RT in this scenario with individualized decision-makings. Several biomarkers and clinical tools were developed to predict the probability of LR and aid a tailored clinical decision. The aim of this study is to assess the potential of the MSKCC DCIS Nomogram, which combines clinical, pathologic, and treatment features to forecast LR after BCS for DCIS patients and assist physicians to recommend RT. Methods: Were enrolled into the study women with DCIS undergoing BCS, with clear surgical margins, and external RT from 1993 to 2018 at a specialized breast cancer service in São Paulo, Brazil. The data were collected from medical records. The MSKCC DCIS Nomogram was applied to the study population. Receiver operating characteristic curve were drawn and the area under the curve (AUC) of 10-year risk of LR evaluation was calculated. Results: 110 women were eligible. Eight patients had LR (7,3%), being 5 invasives (62,5%) and 3 in situ (37,5%). The follow-up mean time was 4.8 years. Time to recurrence was 9.6 years with a 10 years risk of LR of 10,3%. The MSKCC DCIS Nomogram 10-year risk estimates showed satisfactory correlation as regard to LR with the AUC of 0.61.

The nomogram is warranted for the 10-year risk LR prediction, and it may reinforce RT indication. Conclusions: The MSKCC DCIS Nomogram may identify patients with DCIS treated by BCS with high probability of LR, and therefore is a useful treatment decision aid for patients with DCIS and may assist the RT recommendation.

Background: We previously demonstrated that intrinsic subtypes were associated with prognosis for early recurrence risk in patients (pts) with early-stage HER2-positive (HER2+) BC treated with trastuzumab (H) in the N9831 trial. Here, we evaluated the prognostic value of Intrinsic subtypes and 21-gene assay and the risk of early and late recurrence in the N9831 trial. Methods: NanoString custom code set, which included PAM50 and housekeeping genes, was used to quantify mRNA and generated intrinsic subtypes and risk of recurrence (ROR) score from the N9831 trial in Arms A and C: Arm A chemotherapy alone and arm C concurrent H. Quantitative RT-PCR of 21 genes, calculation of the axis, including estrogen axis (ER, PGR, BCL2, SCUBE2), HER2 axis (GRB7, HER2), proliferation axis (Ki67, STK15, Survivin, CCNB1, MYBL2), invasion axis (MMP11, CTSL2), and recurrence score (RS) risk group assignment (RS group 1 and 2: RS < 31 and RS group 3: RS ≥ 31) were performed using Oncotype DX assay. Cox regression models for RFS were used for analysis. Early recurrence was defined as a recurrence that occurred at ≤ 5 years, and late recurrence was defined as recurrence at > 5 years. Results: A total of 783 patients (Arm A 409 and Arm C 374) were included in this analysis. Using multivariate Cox regression analysis to evaluate the risk of early recurrence in

patients who received chemotherapy alone in arm A, both invasion genes (MMP11 HR 1.23, 95%CI 1.05-1.44, p 0.01 and CTSL2 HR 1.36, 95%CI 1.1-1.69, p 0.005) and invasion axis (HR 1.64, 95%CI 1.26-2.13, p < 0.001) were associated with a higher rate of early recurrence. CD68 was associated with improved outcomes (HR 0.56, 95%CI 0.38-0.83, p 0.004). For the risk of early recurrence in patients treated with trastuzumab in arm C, ER (HR 0.85, 95%CI 0.74-0.97, p 0.02), PR (HR 0.78, 95%CI 0.64-0.94, p 0.008), and estrogen axis (HR 0.7, 95%CI 0.57-0.87, p 0.001) were associated with improved outcomes. Invasion axis (HR 1.61, 95%CI 1.08-2.41, p 0.02), Oncotype Dx risk group (3 vs. 1 and 2, HR 8.89, 95%CI 1.27-1124, p 0.02), and basal subtype (HR 2.77, 95%CI 1.1-5.95, p 0.03) were also significantly associated with worse outcomes. For risk of late recurrence, in arm A, ER (HR 1.22, 95%CI 1.04-1.44, p 0.02), PR (1.26, 95%CI 1.05-1.5, p 0.01), and estrogen axis (1.39, 95%CI 1.09-1.77, p 0.008) were associated with worse outcomes. Oncotype Dx risk group (3 vs. 1 and 2, HR 0.4, 95%CI 0.16-0.98, p 0.05) was associated with improved outcomes. However, neither individual gene, axis, nor intrinsic subtypes were associated with the risk of late recurrence in patients treated with trastuzumab. Conclusions: For risks of early recurrence, the invasion genes/axis were associated with increased risks of recurrence in patients with early-stage HER2+ BC regardless of trastuzumab treatment. Among patients treated with trastuzumab, ER genes/axis, Oncotype Dx risk group, and intrinsic subtype were prognostic for risks of recurrence in the first five years. For risks of late recurrence, ER genes/axis and Oncotype Dx risk group were prognostic but only in patients treated with chemotherapy alone. The ER genes/axis were associated with less recurrence in the first five years but worse after five years, reflecting a higher risk of late recurrence in ER/PR+ HER2+ BC patients treated with chemotherapy alone. However, none of the individual gene, axis, or intrinsic subtypes were associated with the risk of late recurrence in patients treated with trastuzumab. Therefore, future studies are needed to identify biomarkers for the risk of late recurrence in HER2+ BC patients treated with adjuvant trastuzumab. Objective:

Aberrantly methylated DNA may be used to detect minimal residual disease or early recurrence in breast cancer. As a 1st step, we aimed to develop an MDM panel to delineate between healthy women, stage I-III breast cancer in remission with no evidence of disease (NED), and metastatic breast cancer (MBC).

Methods:

We prospectively enrolled patients into 3 groups: healthy controls (adult females with a normal mammogram in past 12 months with no history of breast cancer), NED [stage I-III breast cancer with no clinical evidence of recurrence 6 months - 3 years post-treatment (adjuvant endocrine therapy allowed)], and MBC (collected either at initial diagnosis of untreated metastatic disease or radiographic progression). DNA was extracted from 6 mL of plasma derived from blood collected in LBGard tubes (Exact Sciences Corp., San Diego CA), and was bisulfite-treated and assayed by target enrichment long-probe quantitative amplified signal (TELQASTM) method for a panel of 15 previously identified MDMs [Table], normalized by the control gene, B3GALT6. Areas under the receiver operating characteristic curve (AUC) were calculated for each MDM to assess discrimination of MBC from other groups. With 60 patients per group, we had greater than 80% power to detect a difference of 0.20 from the null AUC of 0.7.

Results:

We tested samples from 60 MBC (10 untreated, 50 recurrent), 60 NED, and 60 healthy women. The median age was 63 (IQR, 55-72) and was not different between groups. The NED group was all hormone-receptor (HR) positive, with 47 (78%) being human epidermal growth factor receptor 2 negative (HER2-) and 13 (22%) HER2+; 48 (80%) were stage I and 9 (15%) were N+. The MBC group had 35 (58%) patients with HR+/HER2- tumors, 11 (18%) HR+/HER2+, and 6 (10%) HR-/HER2-, 4 (7%) HR-/HER2+, with 4 (7%) unknown. Of the 41 MBC whose original stage and nodal status were known 9 (22%) were stage I and 22 (54%) were N+. The markers were able to discriminate between MBC and NED patient samples with AUCs from 0.97 to 0.72. AUCs for 10/15 MDMs (ITPRIPL1, EMX1, C17orf64, OSR2, TRIM67, CHST2, IFFO1, TRH, FAM59B, and MPZ) were >0.90. No difference in MDMs was observed between the healthy and NED groups.

Conclusions:

MDMs, assayed from plasma, appear highly discriminant for metastatic breast cancer cases in comparison to control patients with NED or healthy controls. Further clinical validation of this MDM panel in a larger cohort is warranted.

Table 1. Plasma MDM discrimination of metastatic breast cancer (MBC) from healthy controls and previously treated breast cancer patients with no evidence of disease (NED)

BACKGROUND

PIK3CA mutations have been shown to be associated with poor prognosis in HER2-positive breast cancer (BC). We combined data from three completed Phase III Roche-sponsored randomized trials of HER2-targeted therapy for the first-line treatment of HER2-positive metastatic BC (MBC); this allowed for exploration of the prognostic impact of PIK3CA mutations observed in the three individual trials across subgroups of interest.

METHODS

Data from CLEOPATRA (pertuzumab + trastuzumab + docetaxel [PHD] vs. placebo [Pla] + HD;

NCT00567190; N = 808), MARIANNE (HD vs. ado-trastuzumab emtansine [K] + Pla vs. K + P; NCT01120184; N = 1095), and PUFFIN (PHD vs. Pla + HD; NCT02896855; N = 243) were included. An individual patient data (IPD) meta-analysis was performed to test the association between PIK3CA mutation status in tumor tissue (mutated vs. wild type [WT]) and efficacy (progression-free and overall survival [PFS/OS]) in different biomarker and clinical subgroups. Confounder adjustment was conducted for age, Eastern Cooperative Oncology Group Performance Status, body mass index, treatment, disease type, and number of metastases (all at baseline). "Study" was included as a random effect in the IPD meta-analysis model to account for variability between studies.

A landmark analysis was conducted on fast and non-fast progressors (cutoff of >137 days [i.e., after six chemotherapy cycles]) from CLEOPATRA and PUFFIN only, since they include the current standard-of-care regimens (PHD), by using Day 137 as the landmark time with separate Cox proportional hazards models.

RESULTS

PIK3CA mutation data were available for 1905/2146 patients (89%; ~80% from primary tissue); mutation prevalence was 27% (n = 521). PIK3CA-mutated vs. WT in association with PFS in pooled treatment arms is shown in the table. OS data were consistent.

CONCLUSIONS

PIK3CA mutations were associated with a worse prognosis across subgroups of interest, including in fast and non-fast progressors, in the two PHD-containing studies as compared with the overall ITT population.

PIK3CA-mutated vs. WT in association with PFS in pooled treatment arms

	PFS events/ patients	Hazard ratio	95% CI	P value
<i>PIK3CA</i> -mutated vs. WT				
Overall ITT	1479/1883*	1.45	1.30–1.63	<0.001
Subgroup analysis for <i>PIK3CA</i> -mutated vs. WT				
HER2				
IHC				
2+	179/202	1.11	0.82–1.50	0.510
3+	1278/1656	1.43	1.26–1.62	<0.001
mRNA				
≤median	723/872	1.36	1.17–1.59	<0.001
>median	648/868	1.34	1.11–1.63	0.003
Gene ratio				
≤median	714/888	1.50	1.28–1.75	<0.001
>median	691/898	1.30	1.09–1.55	0.003
Hormone receptor				
Negative	637/820	1.33	1.12–1.58	0.001
Positive	796/999	1.58	1.36–1.85	<0.001
De novo MBC at first diagnosis				
Yes	667/862	1.58	1.33–1.88	<0.001
No	812/1021	1.32	1.14–1.54	<0.001
Landmark analyses				
Overall ITT				
CLEOPATRA	553/679	1.37	1.13–1.66	
PUFFIN	181/237	1.44	1.06–1.97	
Fast progressors				
CLEOPATRA	81/679	1.25	0.78–2.02	
PUFFIN	36/237	1.96	1.01–3.81	
Non-fast progressors				
CLEOPATRA	472/576	1.40	1.14–1.73	
PUFFIN	145/194	1.33	0.93–1.89	

Hazard ratio >1 indicates *PIK3CA* mutation associated with worse prognosis.

* Patients with *PIK3CA*, specific subgroup, and confounder variables available.

Background: Hormone receptor positive breast cancer constitutes about 70% of newly diagnosed early-stage disease in the United States, and gene-expression based recurrence assays such as Oncotype DX (ODX) are strongly recommended by guidelines to aid in treatment decisions. However, recurrence assays are costly, time-consuming, underutilized in low resource settings, and unavailable in developing countries. Deep Learning (DL) using hematoxylin and eosin (H&E) stained digital pathology has been shown to approximate gene expression patterns for multiple cancer types, and may provide a cost-effective, fast, and scalable method to predict risk of recurrence in community settings. **Methods:** We first developed a model for ODX using only DL on pathology, comprised of two Xception-based modules, trained on 1,039 slides from The Cancer Genome Atlas (TCGA) tessellated into 10x magnification image tiles. The first module predicts tumor likelihood, and was trained using pathologist annotations for tumor regions versus normal stroma. The second module was trained to predict ODX score, estimated from gene expression data within TCGA. Patient-level predictions were calculated by weighting the predicted recurrence score by tumor likelihood for all tiles within a slide. Separately, ODX score was predicted from clinical variables using the University of Tennessee Nomogram, which incorporates grade, progesterone receptor, size, age, and histologic subtype. Finally, we developed a combined model by fitting a logistic regression to the DL pathologic model and the clinical nomogram predictions. Performance of the clinical nomogram, pathologic, and combined models were then compared in a single-institution external validation cohort of patients diagnosed with breast cancer between 2006 and 2020, all of whom had the commercial ODX assay run. **Results:** We identified 428 cases for our diverse validation cohort (69% White, 24% Black, 6% Asian, and 3% Hispanic) with mean ODX score of 18. Chemotherapy was administered for 104 (24.3%) of patients, the remaining 323 (75.4%) received endocrine therapy alone. Area under the receiver operating characteristic curve (AUROC) for prediction of high ODX score (≥ 26) of the combined model was 0.83 (95% confidence interval [CI] 0.78 – 0.89) in the validation cohort, which was higher than either the DL pathology model (AUROC 0.80, 95% CI 0.75 – 0.85, $p = 0.026$) or the Tennessee nomogram (AUROC 0.77, 85% CI 0.70 – 0.83, $p = 0.003$). Performance was similar in Black (AUROC 0.86, 95% CI 0.78 – 0.94) and White (AUROC of 0.81, 95% CI 0.74 – 0.88) subgroups. The combined model was more accurate in prediction of recurrence-free interval in patients receiving endocrine therapy (hazard ratio [HR] 2.02 per standard deviation [SD], 95% CI 1.16 – 3.52, $p = 0.013$, Concordance [C]-index 0.75) than the clinical nomogram (HR 1.75 per SD, 95% CI 1.09 – 2.81, $p = 0.021$, C-index 0.68). No model was prognostic in patients receiving chemotherapy. Pathologist review of heatmaps of DL model predictions identified lymphovascular invasion, necrosis, high grade, and infiltrative borders as features contributing to model prediction of high risk. **Conclusions:** DL can improve on existing clinical prediction of breast cancer with low recurrence risk. This approach could improve the speed at which treatment decisions are made due to the time-consuming nature of genomic testing and simultaneously reduce the cost of care. Given the equal performance in racial subgroups, this approach has promise for application in global health settings where genomic assays are not widely available or are prohibitively expensive.

Background: The 21-gene recurrence score (RS) assay is a prognostic measurement originally established for distant recurrence in estrogen receptor-positive and node-negative breast cancer. Retrospective studies and the Trial Assigning Individualized Options for Treatment (TAILORx; ClinicalTrials.gov NCT00310180) validated its significance besides testing chemotherapy benefit in patients with midrange RS (11-25). However, unclarity remains as to whether RS has comparable prognostic value for overall survival (OS) in the TAILORx trial population. Methods: Association between the recurrence scores (midrange or high-range 26-100 vs. low-range 0-10) and OS was evaluated in all eligible patients with clinicopathological and treatment information by multivariable Cox proportional hazards regression model including RS, tumor size, tumor grades, chemotherapy, endocrine regimens, surgery type, progesterone receptor and demographics. We also evaluated the association between RS and invasive disease-free survival (DFS), recurrence-free interval (RFI) or distant recurrence-free interval (dRFI) by multivariable Cox analysis. Results: Median follow-up was 95.5 (range 0.1 to 138.6) months for OS, 89.6 months (range 0 to 134.8) for DFS, 87.7 (range 0 to 134.8) months for RFI or 87.6 (range 0-134.8) months for dRFI. Compared with low score group, midrange and high-range scores were associated with RFI and dRFI, respectively ($P \leq 0.01$ each). However, midrange score was neither associated with OS (adjusted HR 1.15; 95% CI 0.87-1.52; $P=0.33$) nor associated with DFS (HR 1.16; 95% CI 0.97-1.38; $P=0.11$). High-range score was associated with DFS (HR 1.58; 95% CI 1.21-2.06; $P < 0.01$) and had a trend towards association with OS (HR 1.44; 95% CI 0.95-2.19; $P=0.08$). Conclusions: The data indicate that the recurrence scores provide independent prognosis for breast cancer recurrence at both distant and locoregional sites and for distant recurrence, respectively. High-range score is prognostic of disease-free survival, with the midrange score showing marginal association. Midrange and high-range recurrence scores do not provide independent prognostic information for overall survival in hormone receptor-positive, HER2-negative, node-negative breast cancer in the TAILORx trial population.

Background: Women with HR+ breast cancer experience a persistent risk of distant recurrence (DR) even after completion of 5 years of adjuvant endocrine therapy, with more than 50% of DR occurring after 5 years (late DR). The prognostic genomic signatures currently being used in the clinic were not developed or optimized specifically for late DR. We have previously shown that the Breast Cancer Index (BCI) and BCIN+ prognostic models were significantly prognostic for risk of overall (0-10y) and late (5-10y) distant recurrence (DR) in N0 and N1 HR+ patients in the Tamoxifen and Exemestane Adjuvant Multinational (TEAM) trial. Here, the prognostic performance of the BCI and BCIN+ models with alternative cut-points optimized for late DR were evaluated in patients from the TEAM trial, who were free from DR for at least 5 years. Methods: BCI testing was performed blinded to clinical outcome. The pre-specified alternative cut-points 4.4 and 1.8 for BCI and BCIN+ models were determined previously from Trans-aTTom and IDEAL studies, respectively (ESMO 2021). Kaplan-Meier analysis and log-rank test were used to evaluate the prognostic significance of BCI/BCIN+ risk groups based on DR. Univariate and multivariate Cox models were used to estimate hazard ratios (HRs) and the associated 95% confidence intervals (CIs).

Results: 1285 HR+ N0 (median age 69.2, 54.2% T1, 92.5% G2-3, 21.3% chemotherapy) and 1762 N1 (median age 68.5, 49.7% T1, 80.8% G2-3, 42.6% chemotherapy) patients who remained free from DR at 5 years post randomization were included in the current analysis. For N0 patients, BCI identified 439 (34%) and 846 (66%) patients as low and high-risk with late 10-year DR rates of 3.8% (95% CI: 1.5-6.0%) and 9.1% (95% CI: 6.8-11.4%), respectively (HR: 2.6, 95% CI: 1.4-5.0; p=0.0025). For N1 patients, BCIN+ identified 287 (16%) and 1475 (84%) patients as low and high-risk with late 10-year DR rates of 3.4% (95% CI: 1.2-5.5%) and 12.3% (95% CI: 10.4-14.2%), respectively (HR: 3.5, 95% CI: 1.8-6.9; p< 0.0001). Similar results were observed in the HER2- patients. Notably, BCI/BCIN+ remained a statistically significant prognostic factor in the multivariate analysis after controlling for age, tumor size, grade, treatment. (Table).

Conclusions: Compared to the original BCI/BCIN+ models, the optimized BCI and BCIN+ models showed improved prognostic performance for identifying low-risk patients with a very low risk of late DR (< 4%), for both N0 and N1 patients. These results provide further validation

of BCI clinical utility as an aid in the decision-making for extended endocrine therapies for HR+ breast cancer, particularly in patients with N1 disease that may be spared extended endocrine treatment.

Nodal Status	Her2 Status	BCI/BCIN+ Status	10-year risk of DR % (95% CI)	Adjusted HR (95% CI)	P Value
N0	All Pts	Low	3.8 (1.5, 6.0)		
		High	9.1 (6.8, 11.4)	2.6 (1.4, 5.1)	0.0025
	Her2-	Low	3.2 (0.9, 5.3)		
		High	9.0 (6.4, 11.6)	3.2 (1.5, 6.9)	0.0020
N1	All Pts	Low	3.4 (1.2, 5.5)		
		High	12.3 (10.4, 14.2)	2.9 (1.4, 5.6)	<0.0001
	Her2-	Low	3.0 (0.8, 5.1)		
		High	12.4 (10.2, 14.4)	3.3 (1.5, 7.1)	0.0001

Background: Adjuvant chemotherapy is a common treatment for breast cancer patients with aggressive tumors, but imposes severe side effects. Although lymph node involvement is associated with higher likelihood of mortality, a subset of LN+ patients can survive without relapse, even without adjuvant chemotherapy. SWOG-8814 (S8814) was a randomized clinical trial of hormone receptor positive, LN+ post-menopausal women (pathologic stage T1-3N1-2) to compare patient outcome between endocrine therapy alone (tamoxifen), chemotherapy (cyclophosphamide, doxorubicin, and 5-fluorouracil) followed by 5 years of tamoxifen, and chemotherapy with concurrent tamoxifen. In this work, we evaluated the ability of a machine learning approach called multiple instance learning (MIL) to predict long-term overall (OS) and disease-free survival (DFS) in patients from the S8814 clinical trial via analysis of digitized H&E

tissue slides. Methods: The training set (St, n=121) consisted of digitized H&E Whole Slide Images (WSIs) of ER+ LN+ patients from ECOG-2197 - a clinical trial to compare patient outcome under chemotherapy with doxorubicin/docetaxel vs. doxorubicin/cyclophosphamide. For each WSI, the nuclei of ten tumor patches (2000x2000 pixels) were automatically segmented by a pretrained machine learning algorithm called Convolutional Neural Networks (CNN). The results of the CNN's segmentations were used to obtain ten corresponding feature vectors of 3963 features relating to nuclear morphology and spatial arrangement. Five top discriminative features (Haralick texture, Delaunay triangulation, orientation entropy, perimeter kurtosis, architecture) were identified by reliefF-MI feature filtering and forward selection on St. A Normalized Set Kernel Support Vector Machine classifier was trained on St to construct a MIL binary classifier (M+), which generates a continuous survival score to predict which patients would have >10-years of DFS and OS. The score cutoff that maximized F1 score on St was used to generate binary predictions of patient outcome. Blinded validation of the risk scores on S8814 was performed by SWOG. Results: M+ was significantly prognostic of OS in univariate analysis (HR=0.72, p=0.020, 95% CI= 0.55 – 0.95) on S8814. M+ stratifications remained statistically significant after multivariable analysis controlling for treatment, number of positive lymph nodes, and tumor size (HR = 0.71, p=0.017, 95% CI=0.54-0.94). M+ predictions did not achieve statistical significance for DFS in univariate analysis (HR=0.81, p=0.081, 95% CI 0.64-1.03) nor multivariable analysis (HR=0.81, p=0.080, 95% CI 0.63-1.03). M+ was not predictive of chemotherapy benefit for OS (p=0.88) and DFS (p=0.65). There was no correlation of the generated continuous score with Recurrence Score (r=-0.05), previously shown to be a predictive factor for chemotherapy benefit. Conclusion: Our findings demonstrate that nuclear morphology provides insight into overall survival in ER+ LN+ breast cancer patients. Future work will involve combining the MIL based morphologic predictor with other clinicopathologic factors to improve DFS risk stratification. Background: All intrinsic molecular subtypes are represented among HER2-positive breast cancer, with implications on clinical outcome and treatment sensitivity. The impact of molecular subtypes on the pattern and site of relapse is largely unexplored.

Methods: 677 patients with HER2-positive early breast cancer from the Shorther trial (n=437), the CherLOB trial (n=84) and two Institutional cohorts (Istituto Oncologico Veneto IRCCS Padova n=39 and Hospital Clinic Barcelona n=117) were included. Only patients with available PAM50 intrinsic molecular subtyping were considered. We analyzed the incidence of distant relapse (at any site and at specific sites) as the first event. Cumulative incidence was estimated according to competing risk analysis (Fine and Gray's method). Competing risk regression was used to calculate the subdistribution Hazard Ratios (subHR) and their 95% Confidence Interval (CI).

Results: The distribution of molecular subtypes was: 130 LumA (19%), 75 LumB (11%), 347 HER2-e (51%), 46 Basal (7%), 79 Normal (12%). Median follow up was 8.4 years (95%CI 8.2-8.6).

The 10-yr cumulative incidence rates of distant relapse as first event were: LumA 7.9%, LumB 14.8%, HER2-e 14.7%, Basal 15.5%, Normal 10.4% (HER2-e vs LumA: SubHR 2.21, 95%CI 1.05-4.64, p=0.037).

Table 1 shows the 5-yr and 10-yr cumulative incidence rates of distant metastases at specific sites (as first event) according to intrinsic subtype.

HER2-e enriched and Basal tumors were more prone as compared to other subtypes to develop brain and lung metastasis as first event, respectively. Isolated brain metastases without extracranial disease occurred only in patients with HER2-e tumors. All brain metastases as first event occurred within 5 years from diagnosis. Bone-only disease as first event was less frequent in HER2-e and Basal subtype (subHR HER2-e vs LumA: 0.32, 95%CI 0.10-10.4. p=0.058).

Next, we analyzed the frequency of site-specific first metastasis among patients who experienced a distant metastasis as first event (n=77). Lung metastases were more frequent in Basal tumors (LumA 25.0%, LumB 20.0%, HER2-e 24.4%, Basal 71.4%, Normal 0.0%, p=0.037) and bone metastases were more frequent in Luminal tumors (LumA 100.0%, LumB 60.0%, HER2-e 31.1%, Basal 42.9%, Normal 57.1%, p=0.006). Among 45 HER2-e patients with a first distant relapse, 25.6% were diagnosed with a brain metastasis and 15.6% had brain-only disease.

Conclusions: Molecular subtypes influence the metastatic behaviour of clinically HER2-positive breast cancer. These results, if further validated, may have implication in planning personalized monitoring strategies.

Table 1.

Background PD-1 inhibitors have shown significant efficacy in triple negative breast cancer (BC), however, durable responses are less common in estrogen receptor-positive (ER+) BC. Better markers are therefore needed that will identify likely responders to PD-1 inhibitors among patients with luminal BC. While most efforts have focused on the immune checkpoint protein PD-L1, the alternative PD-1 ligand, PD-L2, has been largely overlooked. We aimed to

determine if PD-L2 is associated with unfavorable prognosis in ER+ BC. Methods PD-L2 protein levels in cancer cells and stromal cells were measured retrospectively by quantitative immunofluorescence histocytometry in tissue microarrays of therapy-naïve, localized or locoregional ER+ BC and correlated with progression-free survival (PFS). Evaluable tumor PD-L2 data were derived from a main study cohort A diagnosed between 1988-2005 (n=684) with extensive clinical and outcome data and from an independent validation cohort B diagnosed between 1992-2012 (n=273). Patients received standard-of-care adjuvant therapy without immune checkpoint inhibitors after tumor resection. Results Univariate analysis of the main cohort A revealed that high PD-L2 expression in cancer cells was associated with shorter PFS (HR=1.8; 95%CI:1.3-2.6; p=0.001), an observation that was validated in an independent cohort B (HR=2.3, 95%CI:1.1-4.8; p=0.026). Approximately one third of ER+ BC cases were classified as high PD-L2. After multivariable adjustment for common clinicopathological variables, high cancer cell levels of PD-L2 remained independently predictive of early recurrence (HR=2.0; 95%CI:1.4-2.9; p< 0.001). Sub-analysis of ER+ BC cases treated with adjuvant chemotherapy (n=197) suggested that high PD-L2 levels in cancer cells was associated with particularly increased risk of progression (multivariable HR=3.4; 95%CI:1.9-6.2; p< 0.001). The observed frequent expression of PD-L2 protein in BC provided scientific rationale for the design of our ongoing phase II clinical trial (NCT04243616) of neoadjuvant combined PD-1 inhibitor (cemiplimab; Regeneron Pharmaceuticals Inc) and chemotherapy in patients diagnosed with PD-L1+ and/or PD-L2+ BC. The primary objective of this trial is to assess pathologic responses to neoadjuvant treatment with secondary objective of assessing the correlation between PD-L1/PD-L2 status and tumor responses. Pathologist review of PD-L1 and PD-L2 expression in an initial set of ER+ tumors (n=15) screened for trial eligibility revealed frequent discordance between cancer cell positivity for PD-L1 and PD-L2 protein (PD-L1: median=0%; range 0-2% vs. PD-L2: median=18%; range < 1-60%) as well as immune cell positivity (PD-L1: median=5%; range 0-50% vs. PD-L2: median=0; range 0-50%). Conclusions In treatment-naïve ER+ breast tumors, high cancer cell expression of PD-L2 protein was an independent predictor of poor clinical outcome, with evidence of further elevated risk of progression in patients who received adjuvant chemotherapy. Preliminary analyses of ER+ tumors from our ongoing clinical trial showed frequent discordance between baseline PD-L1 and PD-L2 protein expression in both cancer cells and immune cells. Collectively, our analyses indicate that PD-L2 has prognostic value for ER+ BC, and our progress justify further studies to determine whether PD-L2, alone or in combination with PD-L1, may serve as a predictive marker of response to PD-1 inhibitors.

Purpose: Estrogen receptor (ER) expression predicts response to endocrine therapy and is a prognostic biomarker. However, no ER-associated biomarker is able to identify patients with particularly favorable outcome among ER+ tumors. We investigated the value of ESR1 amplification in predicting long-term outcome in tamoxifen-treated postmenopausal women with early breast cancer with and without nodal involvement. Patients and Methods: 394 patients with ER+ breast cancer (235 node-negative, 159 patients node-positive), who had received adjuvant tamoxifen for 5 years in the prospective randomized ABCSG-06 trial, and in whom FFPE tumor tissue was available, were included in this analysis. ER alpha immunoreactivity was evaluated using the Allred score, while ESR1 gene amplification was evaluated by FISH analysis. Results: Focal ESR1 amplification was detected in 187 (47%) tumors, and was associated with a favorable outcome. After a median follow-up of 10 years, women with focal ESR1 amplification had a significantly longer distant recurrence-free survival (DRFS; adjusted HR 0.48; 95% CI 0.26-0.91; p=0.02) and breast cancer-specific survival (BCSS; adjusted HR 0.47; CI 0.27-0.80; p=0.01) compared to women without ESR1 amplification. The association between ESR1 amplification and improved DRFS and BCSS was only found in node-positive tumors, but not in nodal-negative tumors. ER alpha immunoreactivity, evaluated by Allred score, correlated significantly with focal ESR1 amplification (p< 0.0001; Chi-squared test), but without prognostic significance. Conclusion: We suggest focal ESR1 amplification as predictor of improved long-term outcome in postmenopausal women with node-positive ER+ early breast cancer.

Background: Lymph node (LN) involvement is a strong indicator of poor prognosis for breast cancer (BC), with adjuvant chemotherapy remaining fundamental to management of these patients. SWOG S8814 was a Phase III randomized trial of postmenopausal patients with pathologic LN-positive BC who were hormone receptor positive (HR+). The objectives of the clinical trial were to compare disease free survival (DFS) and overall survival (OS) of 1) these postoperative patients treated with a combination of cyclophosphamide, doxorubicin, fluorouracil (CAF) plus tamoxifen versus tamoxifen alone; and 2) patients treated with CAF followed by tamoxifen versus CAF plus concurrent tamoxifen. In this study we sought to evaluate the potential of applying computational image analysis on whole slide images (WSI) for predicting DFS and OS in SWOG S8814. Methods: A cohort of 135 patients (N=53 DFS event) diagnosed with HR+ & LN+ BC from clinical trial ECOG 2197 was utilized as training set D1. Validation set D2 comprised 630 patients (N=260 DFS event, N=195 death) with HR+ & LN+ BC from SWOG S8814. Three deep learning models were employed to respectively detect nuclei, mitosis, and tubules in WSIs. Subsequently, a total of 1,810 features relating to nuclear morphology (e.g., spatial distribution, shape, texture, orientation), mitotic activity (e.g., mitosis hotspot, mitotic rates) and tubule formation (e.g., tubular nuclei distribution, ratio of tubule to non-tubule area) were extracted from each WSI. A lasso regularized Cox regression model (IbRiS) was trained on D1 to respectively identify four features from each of the feature categories (nuclei morphology, mitotic activity, and tubule formation) most strongly associated with DFS, a continuous risk score based on the selected features was then constructed. An optimal risk threshold was identified on D1 to dichotomize the risk scores into high vs. low risk of recurrence categories. Blinded validation of the machine learning model on SWOG S8814 using Cox regression was performed by SWOG to evaluate its performance in terms of DFS and OS. Results: In D2, patients identified as high risk of recurrence by IbRiS had a significantly worse prognosis in terms of DFS with hazard ratio=1.30 (p=0.039, 95% CI=1.01-1.66). IbRiS was also found to be significantly prognostic of OS with hazard ratio=1.38 (p=0.026, 95% CI=1.04-1.83). IbRiS was however, neither prognostic of DFS (HR = 1.20; 95% CI 0.93-1.54) nor OS (HR = 1.28; 95% CI 0.96-1.71) in multivariable analysis adjusting for treatment, tumor size, and number of positive nodes. IbRiS was also not a significant predictor of chemotherapy benefit (DFS p=0.45; OS p=0.25). Conclusion: We developed a prognostic model (IbRiS) based on the combined features of nuclear morphology, mitosis count, and tubule formation that can help further risk stratify HR+ & LN+ BC patients by only using H&E slides.

Background: Since the development of anti Trop2 antibody-drug conjugates (ADC), Trop2 has been validated as a major therapeutic target for antibody-drug conjugates in metastatic triple-negative breast cancer (TNBC). However, very few data have been reported regarding the prognostic implication, or clinicopathological variables, associated with Trop2 expression levels in early TNBC. Our aim was to evaluate Trop2 expression and its prognostic value in a retrospective series of patients with non-metastatic TNBC and a long follow-up, characterized for Basal-like (BL) or molecular apocrine-like (MA) IHC profiles as well as TILs infiltrate, PDL1 expression and PIK3CA / PTEN mutations. Patients and methods: The analysis was performed in a series of 228 patients with non-metastatic TNBC treated in our center between 2002 and 2012 arrayed on 6 TMA. BL and MA profiles were defined as IHC CK5/6 and/or EGFR expression, and Androgen-receptor and FOXA1 IHC expression, respectively. Trop2 expression levels were tested for their association with baseline clinicopathological variables, and for Relapse-Free Survival (RFS) and Overall survival (OS). Trop2 IHC level of expression was evaluated using the ENZ-ABS380 mouse monoclonal antibody and the methodology described by Bardia et al. (*Annals of Oncology*, 2021) to quantify the membrane signal. First, we established a score grid, according to staining intensity (no labeling: 0; weak labeling: 1; moderate labeling: 2; strong labeling: 3). Then, for each sampled core, the percentage of labeled invasive tumor cells in each intensity was reported. The overall membrane expression was then calculated using the H-Score method ($3 \times \% \text{ of cells with labeling intensity } 3 + 2 \times \% \text{ of cells with intensity } 2 + 1 \times \% \text{ of cells with intensity } 1$). The scores obtained ranged from 0 to 300. Results: Median age was 58.2 years (range 28.5-89.1). 43.9% of tumors were classified

pT1 and 63.5% pN0. 83.8% of patients had ductal carcinomas. Histological grade 1-2 represented 22.7% of all tumors. A BL phenotype was observed in 68.1% of cases, and an MA profile in 39.4% of the cases. Adjuvant chemotherapy (ACT) was delivered in 74% of patients. We observed low Trop2 expression (H-Score < 100) in 12.3% of the cases (28/228 samples), moderate Trop2 expression (H-Score 100-200) in 28.9% of the cases (66/228 samples), and strong Trop2 expression (H-Score >200) in 58.8% of the cases (134/228 samples). We only identified 3 tumors without any Trop2 expression. Regarding baseline clinicopathological correlations, Trop2 levels were only found significantly associated with pT stage, pT1 tumors displaying more frequently high Trop2 scores compared to tumors \geq pT2 ($p=0.002$). No significant correlation was found between Trop2 expression levels and HER2 levels (0 vs. 1+/2+), BL or MA status. With a median follow-up of 9.7 years, Trop2 levels were not associated with RFS nor OS in univariate analysis. In multivariate analysis, poor RFS was associated with classical variables in the early TNBC setting: tumors \geq T2 stage (Hazard Ratio (HR) 2.13, $p=0.02$), N+ status (HR 3.51, $p<0.001$), while high (>5%) TILs infiltration levels (HR 0.54, $p=0.03$) and adjuvant chemotherapy use (HR 0.49, $p=0.007$) were associated with improved RFS. Conclusions: Trop2 is expressed in nearly all early TNBC cases, and Trop2 levels of expression, while associated with T stage, did not impact survival in this population. These results are consistent with the ones reported in the metastatic setting in the ASCENT trial. Trop2 level of expression appearing homogeneous distributed in all the clinicopathological subtypes of TNBC, advocating for the evaluation of combined treatments with anti-Trop2 ADCs and dedicated targeted therapies in specific TNBC subgroups.

Introduction: Methylmalonic acid (MMA), a metabolite and by-product of propionate metabolism, promotes breast cancer (BC) progression in mice via the transforming growth factor-beta (TGF β) signaling pathway (Gomes et al, Nature 2020). It is currently unknown if this effect also exists in patients with BC. **Objectives:** To investigate the association between baseline serum MMA concentrations in patients at BC diagnosis and development of distant metastases via a matched case-control study. **Methods:** We included 32 patients with early Luminal B-like BC (Lumb, median age 62.4y) and 52 patients with early triple-negative BC (TNBC, median age 50.5y) who developed distant metastases within 5 years. They were matched to an equal number of early BC patients with at least 5 years of follow-up (median age 62.2y for Lumb and 50.5y for TNBC) who did not develop distant metastases with at least 5 years of follow-up. Matching was performed based on age at diagnosis date (\pm 5y), tumor stage, and treatment received ((neo)adjuvant chemotherapy and radiotherapy, yes/no). Serum MMA concentrations were determined by liquid chromatography with tandem mass spectrometry (LC-MS-MS). **Summary statistics, paired analyses, and multiple conditional logistic regression analyses** were performed with and without adjusting for potential covariates (age, kidney function, and tumor stage). **Results:** Baseline serum MMA at BC diagnosis significantly correlated with age ($r_s=0.35$, $p=.005$ in Lumb; $r_s=0.35$, $p=.0003$ in TNBC), and negatively correlated with kidney function assessed by estimated glomerular filtration rate (eGFR, $r_s= -0.42$, $p=.0005$ in Lumb; $r_s= -0.32$, $p=.0009$ in TNBC). MMA concentrations at diagnosis were not associated with distant metastases in either subtype, after adjusting for kidney function, age, and tumor stage (all $p>.05$). Next, we categorized BC cases in the public TCGA ($n=174$ for Lumb; $n=140$ for TNBC), METABRIC ($n=461$ for Lumb; $n=199$ for TNBC), and GSE25066 ($n=78$ for Lumb; $n=182$ for TNBC) database according to their 5-year metastatic status, and analyzed the TGF β signaling pathway activity of primary BC. Like MMA concentrations, a gene expression signature of TGF β signaling was not associated with distant metastases in patients with BC. **Conclusion:** Baseline serum MMA concentrations and a gene signature for TGF β signaling at BC diagnosis are not associated with distant metastases among patients with Lumb and TNBC subtypes.

Background The identification of treatment selection biomarkers for advanced triple negative breast cancer (aTNBC) patients remains an unmet need. The immune system is known to be involved in the microenvironment of triple negative breast cancer (TNBC). Immune ratios like the neutrophil-to-lymphocyte ratio (NLR), the platelet-to-lymphocyte ratio (PLR), the monocyte-lymphocyte ratio (MLR) and the systemic immune-inflammation index (SII) may reflect the immune system functional status in these patients and the involvement of circulating immune cells in cancer progression. In particular MLR showed to predict overall survival (OS) in aTNBC and to contribute to migration of circulating tumor cells [1]. **Methods** A retrospective-prospective, observational multicenter study from the GIM-14 experience was performed to investigate the association between inflammatory indexes (NLR, MLR, PLR and SII), as measured at baseline and at progression, and clinical and survival aspects in patients with aTNBC in first line setting. The optimal cutoff values between low and high expression of inflammatory indexes were established on the basis of cut-off values determined in a previously conducted study in order to validate them[1], and was used to predict progression-free survival (PFS) and OS. Time-to-event variables (PFS; OS) were calculated using Kaplan-Meier method, while Cox regression model was used to estimate HRs and their 95% CI. **Results** 105 consecutive patients with a diagnosis of aTNBC were fully evaluated for the final analysis. The median age at diagnosis was 55 years (33-86). Of them, 80 patients received a neo/adjuvant treatment after diagnosis. At first progression the majority of patients (n= 97) received chemotherapy, while only 8 patients were treated with chemo-immunotherapy due to the programmed death ligand 1 (PD-L1) expression in the immunohistochemical analyses. At a median follow-up of 54 months, median PFS in the whole patients population was 13 months (95% CI 9,4-16,5), while median OS was 17.3 OS (95% CI 13-22,2). All high inflammation based scores evaluated at diagnosis of metastatic disease were significantly associated with lower PFS, in particular high NLR (≥ 3) and high MLR (≥ 0.34) ($p = 0.0006$ and $p = 0.011$, respectively). Similarly, all high indexes appeared significantly associated with a lower OS, especially NLR (>3), SII (≥ 836) and MLR (≥ 0.34) ($p < 0.0001$, $p = 0.0005$, $p=0.001$ respectively). In particular also NLR and SII evaluated at disease progression after first line treatment were significantly associated with a worse OS ($p=0.0006$ and $p=0.001$ respectively). In multivariable analysis for predictors of overall survival, the number of metastatic sites, NLR, SII and MLR remained significant ($p < 0.0001$, $p=0.006$, $p=0.005$ respectively). **Conclusions** NLR, SII and MLR are predictors of OS in aTNBC. Although our results need validation with larger studies, we suggest that inflammatory ratios could be used as feasible biomarkers of prognosis and treatment efficacy in aTNBC. Further research about HER-2 low categorized patients will be updated and presented at the final meeting. 1. Background: The 2020 ASCO-CAP guidelines (Allison KH, JCO 2020; 38: 1346–66) recommended estrogen receptor (ER) Low Positive as new reporting category for breast cancers with 1-10% of cells staining ER positive to acknowledge their distinct clinical behaviour compared to breast cancers with >10% to 100% of tumor nuclei positive for ER. We evaluated the prognostic impact of low ER positivity with both 10% and 33% as cut-off. Patients and methods: A retrospective study was performed of consecutively treated patients in UZ Leuven between 2000-2017 with ER-positive/HER2-negative early, primary, unilateral and unifocal grade 2-3 invasive breast cancers. Patients treated with neo-adjuvant therapy were excluded. ER-positivity was defined as >1% ER-staining on immunohistochemistry (IHC). Patients were allocated to ER-low or ER-high groups for both the 10% and 33% thresholds according to their ER-status on IHC as derived from the Allred PS or from the H-score. Descriptive analyses and Cox regression analyses were performed for both thresholds ($\leq 10\%$ vs. $\leq 33\%$) with $\alpha=0.05$. Primary endpoints were overall survival (OS) and invasive disease-free survival (iDFS). Secondary endpoints were time to local (TTLR), locoregional (TTLRR) and distant metastatic relapse (TTM). Results: This study included 3629 patients (median age: 60.0 years; median follow-up: 12.3 years), with their tumors classified as low (39) versus high (3590) with 10% threshold and as low (92) versus high (3537) with 33% threshold. According to both cut-offs, grade 3 and PR negativity was more frequent in ER Low Positive breast cancer. These patients also received significantly more adjuvant chemotherapy and less adjuvant endocrine therapy. When looking at iDFS, OS, TTLR and TTLRR, both cut-offs generated groups with similar outcome. However, we observed a significant increased risk for distant metastatic relapse in ER Low Positive disease using the cut-off of 33% (univariate HR 2.0, 95%CI 1.3-3.2; $p=0.009$), which was not present for the cut-off of 10% (univariate HR 0.5, 95%CI 0.1-1.8; $p=0.2$). Nevertheless, when correcting this effect for age, grade, PR, tumor size, nodal status, adjuvant chemotherapy and endocrine therapy in multivariate analysis, ER Low Positive according to the cut-off of 33% did not remain significant to predict risk for metastatic relapse (HR 1.3, 95%CI: 0.8-2.3; $p=0.3$). Conclusion: In our series, patients with tumors expressing low ER, defined as 1-33% had a significantly higher univariate risk for metastatic relapse. ER Low Positive tumors are more frequently grade 3, which greatly determines the prognosis. ER Low Positivity did not remain independently significant after multivariate analysis. However, patients with tumors expressing low ER only constituted small fractions of the investigated population.

Background: To evaluate the outcome the treatment pattern in women diagnosed with T1mic, T1a and T1b, node-negative, hormone receptor (HR) –negative breast cancer.

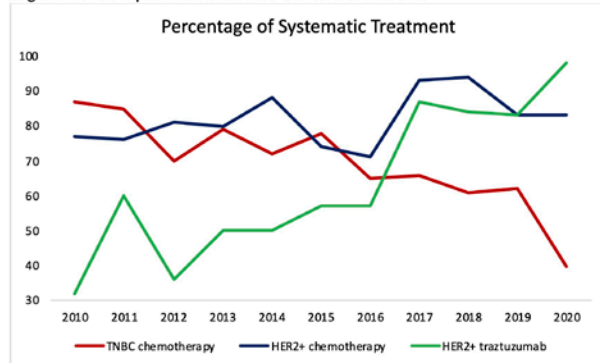

Methods: This was a retrospective cohort study within the Fudan University Shanghai Cancer Center (FUSCC) that included 605 women with T1mic,a,bN0M0 breast cancer treated between 2010 and 2020. Tumors were grouped by size (T1mic, T1a, T1b), biologic subtype defined by hormone receptor (HR) and human epidermal growth factor receptor 2 (HER2) status, and receipt of chemotherapy with or without trastuzumab. Kaplan-Meier product was used to calculate invasive disease-free survival (iDFS), breast cancer-specific survival (BCSS) and overall survival (OS).

Results: Median follow-up time was 5.0 years. Seventy-three percent of patients with triple-negative breast cancer (TNBC) were treated with chemotherapy. For those with HER2- positive breast cancers, 82% received chemotherapy, and 71% received trastuzumab. The treatment pattern varied over the years, with a downward trend of chemotherapy in TNBC and an upward trend of trastuzumab in HER2-positive breast cancer. Survival outcomes diverged by subtype and size. In this retrospective cohort study, the 5-year DFS for treated patients with T1mic,a tumors ranged from 96.2% to 97.7%, and for patients with T1b tumors, it ranged from 92.1% to 95.0%. The 5-year DFS for patients with T1mic,a tumors untreated with chemotherapy or trastuzumab was 100%. The 5-year DFS for TNBC patients with T1b tumors untreated with chemotherapy was 90.5%, while for HER2-positive patients with T1b tumors untreated with chemotherapy or trastuzumab it was 87.5%.

Conclusion: Women with T1mic,a tumors have an excellent prognosis without chemotherapy or trastuzumab, representing an optimal group for evaluating less toxic adjuvant regimens to maintain efficacy while minimizing short- and long-term risks.

Background: Milk whey protein consumption has been associated with breast cancer prevention, therapy and treatment tolerance, and other studies detected these proteins or their mRNAs in breast cancer models or tissues. Our objectives are to ascertain expression of certain whey protein genes in human breast carcinoma cells isolated by Laser Capture Microdissection (LCM) and to determine if gene expression is related to risk of recurrence and overall survival in lesions with various ER/PR status. Genes selected were: LALBA (alpha-lactalbumin), LPO (lactoperoxidase), LTF (lactotransferrin), PAEP (progesterone associated endometrial protein or glycodelin) and SSP1 (secreted phosphoprotein 1 or osteopontin). This retrospective investigation is unique in that highly quantified ER and PR protein levels and ESR1 and PGR relative expression from pure populations of carcinoma cells were employed to stratify cancers into ER/PR subcategories to assess relationships of expression of candidate genes with clinical outcomes. Methods: This investigation of primary breast carcinomas from 170 postmenopausal and 77 premenopausal patients used a matchless deidentified dataset of quantified estrogen receptor (ER) and progesterone receptor (PR) protein results with clinical follow-up. ER/PR protein levels, expressed as fmol/mg cytosol protein, were quantified earlier from each breast carcinoma with FDA-approved kits, either Radioligand-Binding Assay (LBA, NEN/DuPont) and/or enzyme immunoassay (EIA, Abbott Labs). Patients were treated with the standard of care at the time of diagnosis. The PixCell Ite™ (ThermoFisher, Arcturus) LCM instrument was used to procure only carcinoma cells from tissue sections of de-identified, frozen biopsies, using protocols we employed earlier. Total RNA of each fixed specimen was extracted, purified and amplified to obtain relative expression levels of approximately 22,000 genes by microarray, providing an assessment of mRNA in carcinoma cells only. Relationships of relative gene expression, quantified ER/PR and other features of primary breast cancers were analyzed with clinical results using R software v4.2.0 (Vigorous Calisthenics) by Univariable Cox Regression, Kaplan Meier plots and various tests (i.e., Wilcoxon, Log Ranked, Spearman and/or Chi Square tests). Bidirectional elimination stepwise regression was also used to derive best predictors of patient outcomes. Results: Violin plots of expression distribution of each milk protein gene of 247 biopsies regardless of patient menopausal status revealed that LALBA and SSP1 were highly elevated ($p < 0.001$) in ER+ ($n = 146$) or PR+ ($n = 146$) breast cancer cells while PAEP was quite diminished ($p < 0.001$). No difference was observed in LPO expression in ER+ or PR+ cells and LTF was only elevated slightly ($p < 0.05$) in ER+ cells. Regardless of ER/PR status of breast cancer, LTF, LALBA, SSP1, AR and ESR1 gene expression levels were increased significantly in postmenopausal versus premenopausal

patients while PAEP was decreased ($p < 0.001$). No difference was observed in LPO or PGR expression. Correlation matrices examined gene to gene and receptor protein to gene relationships. Using Kaplan Meier analyses of each gene alone with Log Ranked Tests of outcomes, only SSP1 expression was associated with clinical outcome, i.e., overexpression was associated with lower PFS and OS ($p = < 0.05$). Conclusions: Application of bidirectional elimination stepwise regression of gene expression of the five milk proteins collectively with ER/PR protein status of each carcinoma revealed that LALBA gene expression enhanced prediction of PFS in ER+ cancer while PAEP expression was associated with improved prediction of OS in ER+ carcinomas. We report that expression of LALBA and PAEP genes, largely associated with milk production in normal breast tissue, are also expressed in certain breast carcinomas and influence prediction of patient survival.

Purpose. Triple-negative breast cancers (TNBC) are defined as negative for hormonal receptors and human epidermal growth factor receptors 2 and account for 15% of breast cancers. TNBC carry the worst prognosis mainly because of their high proliferation index and the absence of efficient targeted therapies due to their molecular heterogeneity, even though some promising options are emerging. Besides, they do share a very high and distinct tumor-infiltrating lymphocytes (TILs) infiltration. Amongst TILs, CD8+ cytotoxic and CD4+ helper T-cells (TC) proved to be markers of a good outcome. However, pathologists routinely quantify overall TILs density only. Anti-PD-1/PD-L1 immunotherapies recently became available for immunosuppressive TNBC. Unfortunately, neither PD-1/PD-L1 expression nor TILs quantification is able to predict patients' responses accurately. Thus, we aimed at precisely characterizing TILs sub-populations and evaluating their prognostic significance before their predictive one. **Methods.** We selected 91 patients at the time of surgery before any adjuvant

therapy from January 2013 to December 2018 in Rennes, France. TNBC tumors went through TILs quantification on hematoxylin and eosin slides by a trained pathologist and immune microenvironment characterization using flow cytometry. We then compared the prognostic value of immune microenvironment subpopulations vs total TILs count. Results. TNBCs contained a mean of $22.8 \pm 25.9\%$ TILs, including CD4+ TC (14.1%) mainly made of Th2 (11.7%), CD8+ TC (11.1%), and myeloid cells (8.4%) such as antigen presenting cells (APC). TILs groups and percentages were correlated with the abundance of these cellular subpopulations ($p \leq 0.004$). TILs percentage was predictive of overall survival (OS), while high APC infiltration was of relapse-free survival (RFS) in univariate analyses ($p = 0.044$ & $p \leq 0.030$ respectively). Only Th2 infiltration was predictive of both RFS and OS in univariate ($p = 0.009$ & $p = 0.008$ respectively) and multivariate analyses ($p = 0.002$ & $p = 0.010$ respectively). When considering the different Th populations, only Th2 was a better predictive factor of survival than total leukocytes. Discussion. The development of immune therapies aiming at unlocking the anti-tumor immune response has revealed the desperate need to better characterize the tumor immune infiltrate. TILs quantification by pathologists is the only parameter routinely measured so far but it must be standardized since variability can affect their correlation with pCR. In our study, and contrary to most previous ones, stromal TILs were not significantly associated with RFS and OS. Thus, the characterization of TILs subtypes is critical since they can have either a pro- or an anti-tumorigenic function. Thus, we counteracted the limitations of TILs pathological quantification by finely characterizing the immune infiltrate using flow cytometry. Th2 infiltrate was the most frequent, as previously reported, and counterintuitively, was associated with a favorable prognostic value. This is rarely shown as Th2 infiltration is frequently reported to favor pro-tumorigenic immune tolerance. This proves that a more refined characterization of the intra-tumoral immune landscape is essential to derive interesting therapeutic perspectives, either by recapacitating Th2 response or by targeting their interaction with other immune subsets, like fibroblasts, macrophages, dendritic cells, or eosinophils and IgE. Finally, immunotherapies modulating Th2 response could also be used around the time of surgery that has been proved to induce immunomodulation. Conclusion. The characterization of TILs composition is essential to better understand the potential antitumoral functions of these cells and to substantially improve the associated prognostic and predictive values.

Several multigene-based, risk scoring methods are available and their use is recommended to support treatment decision making in breast cancer. Although the value of these tests is established, critical challenges remain that limit their use, especially regarding turnaround time for fast decision making and the associated costs. We have developed DigiStain - a novel technology that uses mid-infrared imaging to precisely measure a surrogate of tumour aneuploidy, across unstained biopsy sections. Considering that genomic context shapes the pattern and consequences of aneuploidy during cancer development and progression, aneuploidy may have valuable prognostic or predictive value. Using bespoke software, DigiStain allows a quantitative score 'DigiStain index' (DI) to be reproducibly extracted from an objective physical measurement of a cancer i.e., aneuploidy. This information is generated within minutes and is available at the same time as routine H&E staining. We previously showed that DI significantly correlates with tumour grade and survival. To further validate the technology, we have investigated the ability of the DI to predict 5-year survival in a retrospective analysis of patients with oestrogen receptor (ER) positive breast cancer. Methods: Clinical samples were obtained from patients (N=944) treated at the University Hospital of Nottingham UK. Using the DigiStain imager, H&E images were registered before acquiring the DI score for the section. Statistical methodology followed the recommended approach of Royston et al. 2009, The BMJ. A multivariate logistic model modelling the 'event' of death by 5 years was generated. The predictive performance of the logistic regression model was assessed using Area Under the receiver operating characteristic Curve (AUC) plots. The predicted vs observed event probability was determined at various cut-offs and the accuracy of the classification was measured by its sensitivity and specificity. Results: Of 944 ER+ patients with follow up information, 77 (8.2%) died in the first 5 years. The age distribution was approximately normal, ranging from 26 to 70 (mean = 54.8 years). Tumour size ranged from 0.2 to 7.5 mm (mean = 1.90 mm and median = 1.70 mm) and had normal distribution when the natural log of size was considered. DI contributed to the prognostic model with (p=0.0018). Odds ratios showed increased odds of death by 5 years with higher DI. The AUC obtained for the model was 0.7722. Due to the number of events the sample was not split into training and validation sets. Instead bootstrapping (n=500) was used to assess performance. When adjusted by bootstrapping the AUC was reduced only slightly to 0.76. Classification tables for sensitivity and specificity across different risk cut-offs and distribution of 5-year predicted probabilities showed the best distinction between groups at low levels of predicted probabilities. As expected, there was a trade-off between sensitivity and specificity when choosing an appropriate cut-off point to define high risk of death by 5 years. Conclusions: The risk score obtained using the DI is a significant prognostic factor for 5-year survival in ER+ breast cancer

($p=0.0018$) with good diagnostic accuracy. Analysis of 10-year survival data is ongoing and plans to expand the sample collection to include patients from other sites are underway.

Background: Triple-negative breast cancer (TNBC) is highly heterogeneous cancer and the most challenging subtype of breast cancer. And its prognosis is poor compared to the other subtypes. Unlike luminal type cancers, there is no valid biomarker to predict the prognosis of patients with early TNBC. To establish an elaborate therapeutic strategy for TNBC, biomarkers that accurately predict the prognosis and response to treatment are needed. Method: 184 patients with early stage TNBC (training cohort, n = 76; validation cohort, n = 108) were enrolled. Median Follow-up period was 51.5 months (range: 4.6-230.8) for training cohort and 58.3 months (range: 6.6-99.8) for validation cohort. Of the patients in training cohort, 13 patients had recurrence or metastasis. Of the patients in validation cohort, 23 patients had recurrence or metastasis. Using a HiSeq sequencer, RNA sequencing was conducted to analyze the gene expression profiles of tumor samples from TNBC patients. Gene signature was analyzed by combination of DEGs which found in gene expression profiles. Cross

validation and meta-analysis were conducted as pre-validation. Meta-analysis was conducted using CBS probePINGS. To compare gene signature and other methods, PAM 50 call and TCR diversity analysis were investigated. Statistical analyses were conducted using R language (v.3.4.3). Result: To predict prognosis of recurrence or metastasis for TNBC patients, we identified the 10-gene signature (DGKH, GADD45B, KLF7, LYST, NR6A1, PYCARD, ROBO1, SLC22A20P, SLC24A3 and SLC45A4) that stratified patients with TNBC by risk score (sensitivity = 92.31%; specificity = 92.06%; accuracy = 92.11%) and validated in a cohort of separate institutions. Meta-analysis supported the biological relevance of the 10-gene signature to well-known driving pathways in TNBC. When compared with other potential biomarkers like PAM 50 call and T-cell receptor β diversity, the 10-gene signature was the only independent factor that can predict prognosis for invasive disease-free survival in multivariate analysis. Conclusion: Our novel findings can contribute to solving the diagnostic challenges in TNBC and the 10-gene signature may serve as a novel biomarker for risk-based patient care.

Background The presence of residual tumour at surgery (non-pathological complete response or non-pCR) occurs in about half of TNBCs treated with neoadjuvant chemotherapy (NAC) and signals chemoresistance and poor prognosis. Although further adjuvant chemotherapy (Capecitabine/Xeloda) results in improved survival in patients with non-pCR, only about 15% of such patients do benefit. Circulating tumor DNA (ctDNA) is a plasma-based biomarker that can be used to reveal real-time data about the disease and treatment progression. We have previously shown that detection of ctDNA after NAC signals poor prognosis. To validate and extend our previous results using an academic hospital-based tumor bespoke assay, we

performed ctDNA measurements in non-pCR TNBC patients at the pre-operative, post-operative, 3 and 6-month time points. Methods Whole exome sequencing (WES) was performed on residual tumors from 34 TNBC patients to identify tumour-specific mutations (5/patient). Digital droplet PCR (ddPCR) assays were developed for these mutations and performed as per our previous work. Patients with at least one detectable mutation were considered ctDNA positive for a given time point. The detection of ctDNA was correlated with relapse-free survival (RFS). Results The overall RFS was 44%, with 56 % of patients received adjuvant Xeloda. Detection of ctDNA at the end of NAC (T1) correlated with poor prognosis of RFS (n = 33, p-value = 0.009, HR = 0.29 (95% CI = 0.12 to 0.74)). Detection of ctDNA after surgery (T2) and while on Xeloda (T3) showed no significant prognostic value for RFS. However, ctDNA detection at the 6-month time point, after Xeloda treatment (T4), showed stronger prognostic value for RFS (n = 17, p-value = 0.004, HR = 0.12 (95% CI = 0.03 to 0.51)). When measuring changes in ctDNA detectability from T1 to T4, 4 patients initially positive became ctDNA negative after the 6-month interval, and only 1 of these 4 had a relapse, compared with 10 of 11 that remained positive at the 6-month time point (p = 0.01, Chi-squared test). 3 of the 4 patients that cleared their ctDNA had received Xeloda. In addition, 2 patients initially negative became ctDNA positive at the 6-month time point (T4) and both relapsed, compared with only 1 of 5 that remained negative at 6 months (p = 0.035, Chi-squared test). For patients who received adjuvant Xeloda ctDNA positivity at T1 was associated with a worse RFS (p-value = 0.028, HR = 3.3884 (95% CI = 1.160 to 13.00)). Conclusion ctDNA testing using ddPCR in an academic hospital-based context at the post-NAC time point as well as at 6 months after surgery identifies an excellent prognostic group in TNBC patients with non-pCR and changes in ctDNA during the adjuvant period have prognostic value. This personalized approach to treatment management is ready for prospective testing in patients who have undergone NAC and require additional chemotherapy.

Background: The peritumoral deposition of collagen is termed desmoplasia. It is characterized by the formation of new extracellular matrix, resulting from activation of tumor-associated fibroblasts. In other cancer entities (e.g. pancreatic and thyroid cancer), the presence of desmoplasia has significant prognostic impact. Furthermore, in preclinical models, targeting desmoplasia therapeutically to normalize the microenvironment has shown promising results. Yet, the role of desmoplasia in breast cancer is still unclear and data regarding this topic is rare. The aim of this study is to investigate whether desmoplasia is present in breast cancer and whether it is associated with other prognostic factors. Methods: We retrospectively analyzed 361 patients with breast cancer who had oncologic surgery at the University Hospital Leipzig, Germany between 2015 and 2018. Patients underwent operation without any preoperative therapy, after neoadjuvant chemotherapy, or after neoadjuvant endocrine treatment. One patient had had radiation in the past. Information regarding desmoplastic tumor reaction and other pathologic characteristics were retrospectively retrieved from the pathology reports. Results: Overall, data regarding desmoplasia was available for 197 patients. Median patient age was 61 years [IQR 50-73] with the most frequent tumor entity (62.9%) being invasive carcinoma of no special type (NST). 184 (93.4%) patients had either a T1 or T2 stadium. Patients had no preoperative therapy, neoadjuvant chemotherapy, or neoadjuvant endocrine treatment in 131 (66.5%), 36 (18.3%) and 29 (14.7%) cases, respectively. Desmoplasia was present in 151 cases. 46 cases showed no evidence for desmoplasia. Median age was almost similar in both groups (60.5 years vs. 61 years). Presence of desmoplasia was not associated with lymph node metastasis (pN1: 26.1% in patients with desmoplasia vs. 31.1% in patients without desmoplasia). Furthermore, there were only small differences in tumor grade between the two groups (G1: 45.7%, G2: 37.8%, G3: 15.9% [patients with desmoplasia] vs. G1: 39.1%, G2: 43.5%, G3: 17.4% [patients with no desmoplasia]). Tumor stages pT1 and pT2 were approximately equal in the two groups (pT1: 66.2% vs. 65.2%, pT2: 29.1% vs. 21.7%). There was a slight trend towards a higher (pT3) tumor stage in patients with desmoplasia (13%) compared to the patients with no desmoplasia (2.7%). Interestingly, the presence of desmoplasia was significantly associated with a higher number of Luminal A subtypes (64.2% vs. 47.8%, p-value: 0.047) and a lower number of triple negative carcinoma (10.6% vs. 17.4%, p-value: 0.22). Conclusions: In our analysis, the presence of desmoplasia is not associated with a more aggressive phenotype of breast cancer. There are hints for an association with a favorable subtype. Larger studies are necessary to validate these data and gain further information.

Background: Triple-negative breast cancer (TNBC) is the most fatal breast cancer subtype, which often shows aggressive progression, a high potential to metastasize, and resistance to chemotherapy. Comprehensive genomic profiling using next-generation sequencing (NGS) has been expected to identify gene alterations that are targetable by drugs. However, the significance of these genomic alterations in the cancer biology of TNBC patients has not yet been fully understood due to the lack of accurate clinical outcome data to compare with the genomic data. The aim of this study was to clarify the clinical impact of genomic profiling data, including copy number alterations (CNAs), in TNBC by comparing comprehensive genomic data with clinical outcomes. Methods: A total of 47 patients diagnosed with stage I-III TNBC (from the cohort reported in JCO Precis Oncol. 2018;2:PO.17.00211) were enrolled in this study. The genomic profiling of 435 known cancer genes by NGS with clinical outcomes were analyzed. Overall survival (OS) was evaluated for its association to gene alterations and distinctively CNAs. The cut-off values of CNA for OS were determined from the receiver operating characteristic curve using the Youden index for area under the curve (AUC). Kaplan-Meier plots and log-rank tests of OS were applied for each group. Univariate and multivariate analyses for OS were performed using a Cox proportional-hazards model to obtain the hazard

ratio (HR) and 95% confidence intervals. Results: Utilizing NGS-based genomic profiling, at least one alteration was found in 82 of the 435 cancer-associated genes, and a total of 162 alterations were found in the 47 patients. Among the 82 genes with alterations, the presence or absence of TP53 and PTEN alterations was significantly associated with OS of TNBC patients; patients with TP53 alterations (n = 31) showed significantly shorter OS than those without TP53 alterations (n = 16, p = 0.023), and patients with PTEN alterations (n = 9) showed significantly shorter OS than those without PTEN alterations (n = 38, p = 0.023). The cut-off value of CNA for OS was set at 25 (AUC, 0.788; sensitivity, 0.727; specificity, 0.900). Interestingly, CNA-high patients (n = 20) showed significantly shorter OS than CNA-low patients (n = 27, p = 0.014). Univariate analysis revealed that TP53 alterations and CNAs were significant prognostic factors for OS (HR, 8.81; p = 0.008; and HR, 8.00; p = 0.014, respectively). Finally, multivariate analysis using background clinical data revealed that CNA was an independent prognostic factor for OS in TNBC patients (HR, 7.15; p = 0.044). Conclusion: Our data suggest that CNA is an independent prognostic marker in TNBC, and that can be estimated from comprehensive genomic profiling data by NGS. Further investigation is needed to clarify the mechanisms of how CNAs are associated with this lethal disease.

Introduction. Claudin-10 (CLDN10), a member of the Claudin tight junction (TJ) protein family, was initially known as Oligodendrocyte-Specific Protein-Like (OSP-L). The distribution of CLDN10 in the body is not ubiquitous and is seen more abundantly in kidney and brain and at modest levels in mammary tissues. Limited information suggests that in cells where CLDN10 is expressed, it interacts with other family members including CLDN-11, 12, 16, 17 and the subcoat zonula occludens (ZO-1 and ZO-3) to regulate TJ functions. The role played by CLDN10 in cancer is not clear but there are suggestions that it is a favourable indicator for disease progression in kidney and gastric cancers but an adverse indicator in hormone related cancers such as thyroid cancer. The role of CLDN10 in breast cancer is otherwise not known. We have investigated the expression profile and in particular in its relationship with hormone receptor status. Methods. We carried out CLDN10 transcript and protein analyses by way of quantitative PCR and immunohistochemistry on an established cohort of fresh frozen mammary tissues and breast cancer tissues. Expression was analysed via QPCR against the staging, histology, clinical outcome, hormone status including ER and Her family members, and also its known interactive TJ molecules available to our database. Results. Compared with its interactive TL partner molecules, CLDN10 was expressed at relatively low levels in mammary tissues. There was no significant difference in CLDN10 transcript levels between normal tissues and tumour tissues. Patients with high levels of CLDN10 in breast tumours had significantly shorter overall survival (OS) ($p=0.041$) and disease free survival (DFS) ($p=0.026$). In our cohort, we found a significant correlation between levels of CLDN10 and Her-1/EGFR ($r=0.201$, $p=0.026$) and Her3 ($r=0.935$, $p< 0.0001$), but not with Her-2 nor with Her-4. It was also surprised to find that CLDN10 did not correlated with the ZO-1, ZO-3, CLDN11, 12, 14, and 17. We then identified a subgroup of patients with low levels of CLDN10 and their overall survival

(OS) and disease free survival (DFS) which were significantly correlated with Her-1/Her-3 expression status ($p < 0.0001$ for both OS and DFS). CLDN10, amongst the clinical, pathological and hormone receptor status, is an independent prognostic factor for DFS ($p=0.008$, Hazard Ratio (HR) =4.228 (95% CI 1.449-12.342)) and for OS ($p=0.025$, HR=3.917 (95% CI 1.187-12.924)). The predictive power for triple negative breast cancer (TNBC) and non-TNBC by CLDN10 otherwise remained similar and not statistically significant. It was noted that stratification by ER and Her-2 did not contribute to the value of independency. Conclusion. CLDN10, although expressed at relative lower levels in breast cancer, is a contributing factor to the survival of the patients. Together with the status of EGFR and Her-3, it makes an independent prognostic factor for both the overall survival and disease free survival of the patients.

Background) Breast cancer is a leading cause of death worldwide. Tumor vascularity is a hallmark of cancer including breast cancer. However, targeting tumor vascularity did not show consistent benefit when applied in clinic. This study aimed to investigate in which group of patients can tumor vascularity be a prognostic factor and how does change of tumor vascularity play in this situation. Materials and methods) Female patients with breast cancer who received preoperative chemotherapy due to breast cancer between 2003 and 2018 at Wonju Severance Hospital, Korea, were included. Clinicopathological characteristics were collected. Hounsfield units(HU) on contrast-enhanced computed tomography(CT) was used as a marker indicating tumor vascularity. Tumor to aortic arch ratio(TAR) of HU on contrast enhanced CT was applied to enhance objectivity of measurement. Patients were categorized according to the cut-off values retrieved from the receiver operating characteristic curve. Kaplan-Meier curves were generated to compare recurrence-free interval (RFI) and overall survival (OS). Results) The final cohort included 162 patients with a mean age of 48.63 ± 7.9 (30-69) years. Initial TAR was 0.38 ± 0.103 (range, 0.184-0.946) and TAR after completion of preoperative systemic treatment was 0.29 ± 0.094 (0.677-0.298). Difference between TAR of immediate before surgery and first clinical presentation was -0.086 ± 0.094 (-0.386 – 0.176). TAR was decreased in 122 (75.3%) patients. Initial TAR was significantly correlated with recurrence free survival(RFS)($p=0.002$). However, TAR after preoperative systemic treatment ($p=0.221$) or delta TAR (area under receiver operating characteristics = 0.498) were not significant. Interestingly, initial TAR was significant only in patients with decreased TAR after preoperative systemic treatment($p=0.005$). Conclusion) Tumor vascularity represented with HU was significantly related with patients' survival only when tumor vascularity was decreased in response to systemic treatment. Considering no antiangiogenic agents were applied as preoperative systemic treatment and still capacity of tumor vascularity as a biomarker was influenced by the change of itself,

antiangiogenic agents could be used as a complimentary agent for the other agents which also impact tumor vascularity.

Background: Recent studies have shown a lower likelihood of locoregional recurrences in patients with low 21-gene recurrence score (RS). In this single institutional study, we investigated any associations between different cut-off values of 21-gene RS and histopathological factors and outcome in patients with long-term follow-up.

Methods: Between February 2010 to February 2013, 61 patients with early stage clinically node-negative hormone receptor-positive and HER2-negative breast cancer tested for the 21-gene RS assay, were included into the study. The clinicopathological, treatment and outcome

characteristics were analyzed.

Results: Median age was 48 (range, 29-72). Of those, 53 patients were diagnosed with Stage 1 (86.9%) and 8 patients were Stage 2 (13.1%) following surgery. Patients with high histologic grade (HG), or with Ki-67 $\geq 25\%$ were significantly more likely to have intermediate/high RS based on RS >11 and >18 (Table 1). Based on the 21-gene RS assay, only 19 patients (31%) received adjuvant chemotherapy. At a median follow-up of 112 months, 3 patients developed local recurrences (4.9%) treated with endocrine therapy alone. Among patients treated with endocrine treatment alone (n=42), the clinicopathological characteristics including age < 40 , age < 50 , high histologic or nuclear grade, high Ki67-scores ($\geq 20\%$, $\geq 25\%$, $\geq 30\%$), presence of lymphovascular invasion, luminal-A type tumor, multifocality, lymph node positivity, tumor size more than 2 cm, RS ≥ 18 or RS >11 were not significantly found to be associated with 10-year locoregional recurrence free survival (LRRFS). However, patients with a RS ≥ 16 have significantly shown a poorer 10-year LRRFS compared to those with RS < 16 (RS < 16 ; 100% vs RS ≥ 16 ; 75%, $p=0.039$, Table 2).

Conclusions: These results suggest that Oncotype DX assay may be of little value in patients with high histologic grade or high Ki67 scores ($\geq 25\%$) as treatment decision criteria to determine any benefit from chemotherapy. Furthermore, patients with a RS ≥ 16 are more likely to benefit from adjuvant chemotherapies, whereas those with a RS < 16 have an excellent outcome and local control on long term follow-up with endocrine treatment alone. Further prospective studies should be performed to validate these findings in future.

Table 1. Correlation of 21-gene Recurrence Score (RS) including different cut-off values with Ki-67 scores and histopathological factors

Characteristics	RS>11	<i>p</i> - <i>value</i>	RS ≥18	<i>p</i> - <i>value</i>	RS >25	<i>p</i> - <i>value</i>	RS >31	<i>p</i> - <i>value</i>
HG low&intermediate (n=51) vs high HG (n=10)	36/51(71%) vs 10/10 (100%)	0.05	16/51(31%) vs 9/10 (90%)	0.001	3/51 (5.9%) vs 4/10 (40%)	0.011	2/51 (3.9%) vs 2/10 (20%)	0.122
Ki67<25% (n=50) vs ≥25% (n=11)	37/50 (74%) vs 9/11 (81.8%)	0.716	17/50 (34%) vs 8/11 (72.7%)	0.038	3/50(6%) vs 4/11 (36.4%)	0.016	2/50 (4%) vs 2/11 (18.2%)	0.146

Table 2. Clinicopathologic factors and 21-gene Recurrence Score (=RS) associated with disease free survival (DFS) and locoregional recurrence free survival free survival (=LRRFS). (DFS is equal to LRRFS since none of the patients developed distant metastases)

Factors	10- year LRRFS=10-year DFS	p-value
Total (N=61)		
RS \leq 11 vs RS>11	100% vs 90.2%	0.292
RS<16 vs RS \geq 16	100% vs 88%	0.149
RS< 18 vs RS \geq 18	91.6% vs 94.1%	0.808
Without Adjuvant Chemotherapy (n=42)		
RS \leq 11 vs RS>11	100% vs 83%	0.180
RS<16 vs RS \geq 16	100% vs 75%	0.039
RS< 18 vs RS \geq 18	91.3% vs 75%	0.274

Introduction. The striatin protein family are calmodulin binding scaffolding proteins. Striatins have been involved in cell signalling and recently found also acting as cell adhesion molecules and adhesion regulators in adherens junctions and tight junctions. Striatins, particularly striatin-2 forms a recently discovered protein complex, STRIPAK, with other complex members including Protein Phosphatase-2 (PP2), STRIP, SIKE1 and certain PP2 regulatory proteins. The STRIPAK regulates multiple cell functions including gene transcription, endo- and exocytosis and cell adhesion, and several other important cell functions in cancer development and progression. The constitute members of the striatin protein complex may thus have important clinical bearings. In the present study, we investigated the expression profile of the striatin family members and key members of their interacting proteins, and discerned the relationship between the expression and disease progression and clinical outcome. Methods. Using an established fresh frozen breast cancer tissues cohort that included both normal mammary tissues and cancer tissues, we quantitatively evaluated the transcript expression of striatin-1 (STRN), striatin-3 (STRN3), striatin-4 (STRN4), its key regulator calmodulin (CALM) and the protein complex regulators protein phosphatase-2A (PPP2A), -2B (PPP2B) and the PPP2 regulatory elements PPP2R4 and PPP2R1A. The expression of each molecule was assessed against the clinical, pathological and prognostic factors of the patients. The integrated pattern of the complex members were also tested against the clinical outcome. Results. All three striatin members were expressed at good levels in mammary tissues and cancer tissues. STRN had little significant value against clinical and pathological factors. STRN3 and STRN4 were seen at high levels in tumours of high grade, with node positivity and with breast cancer

related incidence. It was high level expressions of STRN3, STRN4 and CALM that were respectively associated with shorter overall survival (OS) of the patients and together they formed a poor prognostic indicator ($p=0.034$, $HR=1.7$). STRN had little impact on clinical outcomes. In a clear contrast, high levels of PPP2A, PPP2B and PPPR1A, but not PPP2R4, were seen in patients with significantly longer OS and together form a favourable prognostic indicator ($p=0.034$, $HR=0.685$). Integration of both STRN group and PPP2 group indicators constitutes a highly significant prognostic indicator for OS ($p < 0.00001$, $HR=2.1$ (95%CI 1.36-3.07)) and DFS ($p=0.003$, $HR=1.402$ (95%CI 1.12-1.75)). The predictive value of the integrated profile is independent of other clinical, pathological and hormone receptor status in multivariate analyses with OS ($p < 0.0001$, $HR=3.861$) and for DFS ($p < 0.001$, $HR=2.055$ (95%CI 1.36-3.07)). The same value stands when applied for the subtypes including triple negative breast cancers. Discussion. The STRIPAK complexes including Striatins play important regulatory roles in various cell functions and cancer development. Consistently, we found that high level expressions of STRN3, STRN4 and CALM, as a poor prognostic indicator were associated with shorter overall survival (OS) of the patients, while high levels of PPP2A, PPP2B and PPPR1A, as a favourable prognostic indicator, were seen in patients with significantly longer OS. Combination of both STRN group and PPP2 group indicators constitutes a greater significant prognostic indicator for OS and DFS. Future studies should focus on investigating the exact roles of the STRIPAK in cancer development and progression.

Background: Triple-negative breast cancers (TNBC) exhibit high rates of recurrence and mortality. However, recent studies suggest that a subset of patients (pts) with early-stage TNBC enriched in tumor-infiltrating lymphocytes (TILs) have excellent clinical outcomes even in the absence of systemic therapy. Additional histological biomarkers that could identify pts for future systemic therapy escalation/de-escalation strategies are of great interest. TNBC are frequently highly proliferative with abundant mitoses. However, classic markers of proliferation (manual mitosis counting and Ki-67) appear to offer no prognostic value. Here, we evaluated the prognostic effects of automated mitotic spindle hotspot (AMSH) counting on RFS in independent cohorts of systemically untreated early-stage TNBC.

Methods: AMSH counting was conducted with a state-of-the-art deep learning algorithm trained on the detection of mitoses within 2 mm² areas with the highest mitotic density (i.e. hotspots) in digital H&E images. Details of the development, training and validation of the algorithm were published previously [1] in a cohort of unselected TNBC. We obtained AMSH counts in a centrally confirmed TNBC cohort from Mayo Clinic [2] and focused our analysis on pts who received locoregional therapy but no systemic therapy. Using a fractional polynomial analysis with a multivariable proportional hazards regression model, we confirmed the assumption of linearity in the log hazard for the continuous variable AMSH and evaluated whether AMSH counts were prognostic of RFS. We corroborated our findings in an independent cohort of systemically untreated TNBC pts from the Radboud University Medical Center in the Netherlands (Radboud Cohort). Results are reported at a median follow-up of 8.1 and 6.7 years for the Mayo and Netherlands cohorts, respectively.

Results: Among 182 pts with who did not receive systemic therapy in the Mayo Cohort, 140 (77%) with available AMSH counts were included. The mean age was 61 (range: 31-94), 71% were postmenopausal, 67% had tumors \leq 2cm, and 83% were node-negative. As expected, most tumors were Nottingham grade 3 (84%) and had a high Ki-67 proliferation index (54% with Ki-67 $>$ 30%). Most tumors (73%) had stromal TILs \leq 30%. The median AMSH count was 18 (IQR: 8, 42). AMSH counts were linearly associated with grade and tumor size, with the proportion of pts with grade 3 tumors and size $>$ 2 cm increasing as the AMSH counts increased ($p=0.007$ and $p=0.059$, respectively). In a multivariate model controlling for nodal

status, tumor size, and stromal TILs, AMSH counts were independently associated with RFS ($p < 0.0001$). For every 10-point increase in the AMSH count, we observed a 17% increase in the risk of experiencing an RFS event (HR 1.17, 95% CI 1.08-1.26). We corroborated our findings in the Radboud Cohort ($n=126$). The mean age was 68 (range: 40-96), and 81% were node-negative. While the median AMSH count was 36 (IQR: 16-63), higher than in the Mayo Cohort ($p=0.004$), the prognostic impact was similar, with a significant association between AMSH count and RFS ($p=0.028$) in a multivariate model corrected for nodal status, tumor size, and stromal TILs. For every 10-point increase in the AMSH count in the Netherlands cohort, we observed a 9% increase in the risk of experiencing an RFS event (HR 1.09, 95% CI 1.01-1.17). RFS rates according to AMSH counts for both cohorts are shown in the Table.

Conclusions: AMSH counting is a new proliferation biomarker that provides prognostic value independent of nodal status, tumor size, and stromal TILs in systemically untreated early-stage TNBC. Plans are underway to evaluate AMSH counts in additional cohorts of systemically untreated TNBC, and in other disease settings such as prior to neoadjuvant systemic therapy. If validated, this biomarker should be prospectively evaluated as a potential selection biomarker in clinical trials of systemic therapy de-escalation.

A tight junctional scaffold protein MUPP1/MPDZ and its docking proteins, angiomotins in breast cancer Han Gao¹, Fiona Ruge¹, Lin Ye¹, Jane Lane¹, Eleri Davies², Wen G. Jiang¹, Tracey A. Martin¹ ¹Cardiff University School of Medicine, Heath Park, Cardiff CF14 4XN, UK ²Wales Breast Centre, University Llandough Hospital, Cardiff CF64 2XX, UK Introduction. MUPP1 (Multiple PDZ Domain Crumbs Cell Polarity Complex Component) or MPDZ is a scaffold protein with multiple PDZ domains, critical for multiple protein docking and protein-protein interactions in cells. MUPP1 is particularly interesting as it offers docking sites for a number of tight junction (TJ) proteins and proteins known to regulate cell junction and motility, including angiomin (AMOT) and angiomin-like proteins, the latter being important in regulating cell migration of endothelial cells and an important member in TJ protein complexes. The MUPP1 protein complex at cell junctions also includes CAR/CXADR (coxsackie adenovirus receptor) and members of the ERM (Moesin-Ezrin-Radixin) protein family. It was proposed that the junctional-related MUPP1 docking protein complex may collectively have a role in the development and progression of cancer including breast cancer. The present study examined the profile and integrated expression of these MUPP1 docking molecules in relationship with the outcome, clinical and pathological factors of breast cancer. Methods. Using the datasets of an existing breast cancer cohort at Cardiff, we visited the expression profile of the MUPP1/MPDZ docking molecules including MUPP1, four members of the ERM family, including ezrin, moesin, radixin and EHM2 (also known as NF2) and CAR/CXADR (coxsackie adenovirus receptor). The profile and integrated expression of the profile were analysed against clinical, pathological and outcome factors and also the hormone receptor status of breast cancers. Results. MUPP1 is a weakly linked to the disease progression, so as angiomin, angiomin-like¹ and angiomin-like². Alone, only EHM2 showed significance in linking with

the survival of the patient's OS ($p=0.38$), neither of the remaining MUPP1 complex molecules, including MUPP1, AMOT, AMOTL1, AMOTL2, ezrin, moesin and radixin was able to offer a significant predictive value for the survival of the patients. However, it was found that MUPP1 has a significant correlation with AMOTs, EHM2 and ezrin. When these significantly correlated molecules were integrated in the analysis, the integrated expression pattern showed a highly significant value in evaluating the overall survival ($p=0.003$) and disease-free survival ($p=0.007$). Both of these predictive powers are independent in a multivariate analyses including the clinical and hormone receptors for OS ($p=0.022$, Hazard Ratio (HR)=1.352 95%CI (1.044-1.752)) and RFS ($p=0.023$, HR=1.241 (95% CI. 1.031-1.498)). It was interesting to note that the link between the expression pattern and OS was more prominent in ER negative ($p=0.018$) than in ER positive tumours ($p=0.177$). The same was observed with disease free survival for ER negative ($p=0.011$) compared with ER positive ($p=0.462$) tumours. Non-triple negative breast cancer had shown a similar sensitivity compared with triple negative breast cancer. Discussion. MUPP1, a PDZ domain containing docking protein closed linked with TJ structure, forms an interesting expression profile with its docking molecules including angiomotins and EHM2 that allows evaluation of disease progress and clinical outcome of the patients with breast cancer.

Osteopontin splice variants indicate prognosis in premalignant breast lesions

BACKGROUND: Premalignant breast lesions pose variable risks for transformation, raising the question who should receive treatment to counteract the potential progression to breast cancer. Prognostic indicators will spare low-risk patients the burden of substantial treatment side effects and will enable high-risk patients to comfortably take preemptive action. Osteopontin (OPN) is a secreted mediator of breast cancer progression, which is subject to alternative splicing in transformed tissues and has been known to be a marker for breast cancer aggressiveness. Here, we test the variants OPN-a and OPN-c as potential prognosticators for the transformation of premalignant breast lesions. The presence of spliced Osteopontin-c in these lesions does reflect the risk for cancer development within 5 years. **METHODS:** By immunohistochemistry, we analyze the association of Osteopontin variant expression in healthy breasts, hyperplasias, radial scars, lobular and ductal carcinomas in situ from 434 women as well as papillomas from 114 women to assess a) staining for OPN exon 4 (present in OPN-a and OPN-b) and OPN-c in low-risk to high-risk lesions b) correlations between staining and progression to cancer or survival. **RESULTS:** The staining intensity for OPN-c correlates with risk, and it is prognostic for ensuing invasive disease and survival. About 10% of OPN-c pathology score 0–1 (intensity), vs. 40% of score 3 experience cancer over 5 years. More than 90% of women, who progress, had pathology scores of 2–3 for OPN-c intensity at the time of initial diagnosis. When combining OPN-c and OPN exon 4 staining, all of the low intensity patients are alive after 5 years, whereas women in the high category have a close to 30% chance to die within 5 years. Of patients who succumb, close to 80% had a high combined score at the time of initial diagnosis. In the papilloma patients, fewer than 5% of OPN-c pathology score 0-1 (intensity), versus almost 18% of score 2-3 experienced cancer in follow-up. 9 of 12 women, who progressed, had pathology scores of 2-3 for OPN-c intensity at the time of initial diagnosis, none had a score of 0. When developing a combined risk score from intensity plus percent positivity for OPN-c, the progression risk for patients with low score was 3.2%, for intermediate score was 5.7%, and for high score was 18.8%. Papillomas in patients, who were later diagnosed with cancer in the contralateral breast, displayed stronger staining positivity than non-progressors. **CONCLUSION:** The information of OPN-c immunohistochemistry can provide a foundation for very reliable prognostication and has the potential to aid decision making in the treatment or watchful waiting of early breast lesions. The addition of OPN-a refines the prognostication of survival. The staining intensity for OPN variants may also inform on the cancer risk in the unaffected breast, which may reflect a genetic predisposition for Osteopontin expression and splicing. OPN splice variant immunohistochemistry on breast biopsies will allow counseling of the patients on their risk to develop breast cancer at a later time.

A comprehensive assessment of researcher needs to increase biospecimen donations for breast cancer research: A Patients and Researchers Together (PART) Program Introduction: Tissue-based breast cancer research can help translate scientific discoveries to improve treatments or reduce cancer risk. Tissue donation programs require a partnership between patients being asked to donate tissue and researchers using tissue for translational investigation. Lineberger Comprehensive Cancer Center (LCCC) has established a program called Patients and Researchers Together (PART) to increase the number of patients that donate tissue for research. PART believes patients will be more willing to donate tissue if they are informed about the research process and its impact and are valued as partners of LCCC. The PART program is evaluating the tissue donation process to positively impact efficiencies.

Methods: PART leaders conducted interviews to assess current and future needs of LCCC cancer care providers involved in tissue-based research. A total of 13 breast cancer care providers at LCCC with different lengths of research experience were interviewed. These included 4 surgeons, 4 clinical study coordinators, 2 pathologists, 2 medical oncologists and 1 member of the Tissue Procurement Facility (TPF) staff. Interviewees identified key themes, provided insight into barriers and facilitators, and recommended resources to enhance the tissue-based research process. Results: Interviewees noted the high need for fresh tissue, which requires real-time coordination between clinicians, clinical study coordinators, surgeons, pathologists and researchers. Interviewees identified numerous barriers to the tissue donation process that hinder patient recruitment. These included: lack of knowledge about tissue-based research, time commitment required by an additional procedure, loss of privacy, lack of trust and knowledge about how the tissue will be used and access to cancer care (transportation). Interviewees also identified facilitators for recruiting patients to donate tissue for research, including: tailored communication between the patient and their cancer care team, a high interest in medical research, plain language and understandable educational materials and input of a trusted care team member at the appropriate time. Interviewees identified the need for additional tissue collection support and provided recommendations to improve the tissue donation process. Recommendations included: 1) increase the quantity of tissue available for research, 2) increase the racial and treatment history diversity of patients involved in tissue donation research, 3) increase diversity in the biological types of tissue donations (i.e., blood, stool, tumor), and 4) ensure that the available tissue is optimal for use in research. In addition, interviewees identified resources to enhance the tissue-based research process. One suggested resource is a team of coordinators tasked with managing the day-to-day operations of the tissue collection process and serving as a point of contact throughout. Ideally, the designated team would facilitate communication throughout the tissue collection process from the identification of a patient to the tissue's use in research. Other recommendations included plain language patient educational materials, internal website improvements to enhance communication between researchers, and a written standard operating procedure guide shared with clinical and research team members. Finally, interviewees noted the importance of communication between tissue collection process stakeholders, highlighting the disparity in knowledge regarding best practices between new and more experienced researchers. Findings can inform the development of educational materials and other strategies to increase patient participation in tissue-based breast cancer research.

ClinicalomicsDB - Bridging the gap between clinical omics data and machine learning

Presenting Author(s) and Co-Author(s):

BACKGROUND

Clinical trials are controlled patient studies aiming to objectively assess the effectiveness of treatment interventions. However, the average effectiveness observed at the group level does not directly apply to individual patients. Cancer clinical trials that include molecular profiling on the baseline tumor samples enable the discovery of treatment response-associated molecular features and the development of prediction models that help discriminate responders from non-responders in each treatment arm. Despite potential opportunities, there are many challenges associated with the predictive modeling of such data, as exemplified by the small sample size and large feature space. Advances in machine learning and artificial intelligence (AI) may provide new solutions to address these challenges. However, for machine learning and AI to have an impact, data needs to be carefully curated, high-quality, standardized, and easily accessible and understood by data scientists, who may not have the domain knowledge.

METHODS

Here, we created a python package "ClinicalOmicsDB" to address the challenges of data accessibility and promote development and application of machine learning methods to omics data from clinical trial samples with treatment response information. The package makes data readily analyzable by data scientists so that they can develop, utilize, and optimize their algorithms for predicting treatment responses and discovering novel biomarkers. To promote a two-way dialogue, we have also developed several Jupyter Notebook tutorials for biologists or clinicians who wish to gain expertise in machine learning. Omics data from clinical studies are downloaded from Gene Expression Omnibus (GEO) and responses were determined based on clinical trial primary endpoints. Currently, the package has datasets from 22 breast cancer clinical trials, including a total of 5050 patients (Table 1). It will be continuously expanded to include additional trials for breast cancer and other cancer types.

RESULTS

To evaluate package utility, we built machine learning models to predict neoadjuvant chemotherapy with four cycles of 5-fluorouracil/epirubicin/cyclophosphamide (FEC) followed by four cycles of docetaxel/capecitabine on US Oncology clinical trial 02-103 [GSE42822]. The best performing model was the Random Forest Classifier model, which had an AUC of 0.817.

To determine the generalizability of machine learning models established from the package, we trained a Random Forest Classifier model using the GSE25055 breast cancer dataset and apply the model to a different breast cancer dataset, GSE20194, which yielded an AUC of 0.648. These results suggest utilizing machine learning on clinical omics datasets can provide predictive and generalizable models that could be implemented in clinical settings for future breast cancer patients.

CONCLUSION

We are expanding the database for data scientists, biologists, and clinicians to practice novel biotechnology-derived therapies to facilitate the implementation of precision medicine approaches for future patients. As more people add new data to the package, we will work towards improving pharmaceutical and private companies' clinical trial data sharing policies and practices to promote data sharing.

Varinder Kaur, MD, *Oncologist - University of Virginia Cancer Center*
Country: United States

Background: Breast cancer is the second leading cause of solid tumor brain metastasis. Up to 16% of patients with metastatic breast cancer (mBC), and 50% patients with HER2+ metastatic breast cancer will develop central nervous system (CNS) metastasis overtime. Prognosis in these patients is dismal with a median overall survival of 2-15 months. Despite advances in systemic therapy of mBC, treatment options for patients with breast cancer brain metastasis (BCBM) remain limited. Although newer approaches to treat BCBM are imminently needed, BCBM patients have traditionally been excluded from clinical trials. We aimed to examine the current state of BCBM-related enrollment in ongoing prospective systemic therapy clinical trials for mBC. Methods: We performed a systematic search of the clinicaltrials.gov website on May 1, 2022 to characterize current trends in clinical trial enrollment for BCBM patients in ongoing interventional trials using the key search term "Breast Cancer". Trial search was further limited to "open" and "interventional studies". Data was abstracted and verified by two independent researchers. Trials were excluded if they were specific for other disease types, did not include a systemic anticancer pharmaceutical, or excluded advanced/metastatic disease. Inclusion of active CNS disease [BCMB and leptomeningeal disease (LMD)] and exclusion of CNS disease were the co-primary end points. Covariates of interest were gender, location (US, international or both), disease site (breast cancer specific vs multi-disease trials), therapy category (immunotherapy (IO), targeted therapy, endocrine therapy, chemotherapy, or combination) and sponsor type. Logistic regression was used to model inclusion of active CNS disease. Results: A total of 1720 trials were identified, and 576 trials met the inclusion criteria. 179 (31.6%) were phase I, 129 (22.4%) were phase I/II, 196 (34.0%) were phase II, 60 (10.4%) were phase III and 9 (1.6%) were phase IV. 347 (60.4%) were breast cancer specific and 229 (39.6%) were multi-site trials. 66 (11.5%) trials were specific for HER-2+ cancer and 70 (12.1%) were triple negative breast cancer specific. 238 (41.3%) trials were US only and 290 (50.3%) were pharmaceutical industry sponsored. Overall, only 29 trials (5%) included patients with any form of BCBM and only 11 trials (1.9%) allowed patients with LMD. 12 (2.1%) trials allowed patients with treated BCBMs only. In univariate models, breast cancer only trials (OR 4.07, 95% CI 1.77-9.36, p=0.0009), trials excluding men (OR 1.97, 95% CI 1.03-3.77, p=0.0412), non-IO therapy trials (non-IO vs IO OR 3.57, 95% CI 1.08-11.82, p=0.369), and non-pharmaceutical industry sponsored trials (OR 2.65, 95% CI 1.34-5.22, p=0.0049) were more likely to include patients with active CNS disease. Additionally, inclusion of LMD (OR 7.85, 95% CI 2.19-28.17, p =

0.0016) was a significant predictor of inclusion of active CNS disease. In a combined model, disease site remained significant (breast only vs multi-site OR 4.07, 95% CI 1.77-9.36, p = 0.0009). Conclusion: The vast majority of the ongoing breast cancer clinical trials continue to exclude patients with breast cancer brain metastasis. With an increasing prevalence of breast cancer brain metastasis, evaluating intracranial efficacy of novel therapies early on in drug development remains an area of urgent unmet need.

Country: United States

Background: Breast cancer (BC) is the most frequent cancer and the second leading cause of cancer death for women. Although there is a need of new treatments to improve BC outcome, patients with BC are still under-represented in early phase trials, possibly because of the availability of numerous approved treatments and widely recruiting phase II and III trials. We aim to characterize the molecular profile, outcome and prognostic factors of patients with BC treated in a phase I trial at our institution. Methods: We retrospectively analyzed medical records of every BC patients treated consecutively in a phase I trial in the Early Drug Development Department (DITEP) at Gustave Roussy Cancer Center. Multivariate logistic regression models were used to determine the association between known prognostic factors such as ECOG, LDH or albumin levels, number of previous lines of treatment, metastatic sites and duration of treatment. When available, molecular profile was also reviewed. Results: Between April 1st 2008 and December 31st 2021, 4682 patients were enrolled and treated in a phase I trial in our department. Among them, 272 were treated for BC (5.8%): 271 women and 1 man, in 74 different trials. The median number of BC patients treated per year was 16.5 (min 1; max 33). Median time between consented date and C1D1 was 14 days (min 1; max 63). Median age at C1D1 was 50 years old (min 24; max 82). 5 patients (1.8%) were treated in an adjuvant setting (therapeutic vaccine) while all the others were metastatic. 12 patients (4.5%) had brain metastases and 127 patients (47.6%) had liver metastases. 186 patients (70%) had

only 1 or 2 metastatic sites, and 81 (30%) had three or more sites. Triple negative was the most common subtype, representing 132 patients (48.5%), 125 (46%) were ER+ and 15 (5.5%) Her2+. Patients received a median number of 3 prior lines before enrollment (min 0; max 19). Overall, only 78 patients (28%) had a genetic testing: 30.7% had a germline BRCA1/2 mutation. 146 patients (54%) had a molecular profile (liquid biopsy or tissue sample) before their enrollment and among them 32,9% were oriented in a trial according to their specific profile. Regarding the type of treatments received: 21.7% were immunotherapy, 73.6% were targeted therapies (46.7% in monotherapy, 26.9% in different combinations with immunotherapy, chemotherapy, radiotherapy or endocrine treatments), 2.9% were chemotherapy and 1.8% endocrine therapy. The overall response rate was 11.1% (0.4% complete response, 10.7% partial response, 37.5% stable disease, 43.8% progressive disease and 7.6% not evaluable). Main reasons for discontinuation of treatment were: progressive disease (80.5%), toxicity (9.6%) and end of trial (6.6%). Median duration of treatment was 2 months (min 0; max 44), only 28.6% of patients were still treated after 3 months of trial and 10% at 6 months. At data cut off (June 21st 2022) median overall survival was 11 months. All patients had discontinued the trial by the time of the analysis: median number of lines of subsequent treatment was 2 (min 0; max 10) and 31 patients (11%) were enrolled in another phase I trial in our center. In a multivariate analysis, there was no prognostic factor associated with duration of treatment whether it was albumin ($p=0.76$) or LDH levels ($p=0.68$), ECOG ($p=0.67$), number of prior lines of treatment ($p=0.79$) or number of metastatic site ($p=0.05$). Conclusion: These results are consistent with prior published data as only few patients with BC are addressed for inclusion in a phase I trial, despite response rates and survival rates similar to other phase I patients. We did not find any specific factor associated with duration of treatment. It is likely that a thorough molecular profile could open more treatment options and access to phase I trials.

Objectives: Real-world data (RWD) from the clinical care of patients captured through Electronic Health Records (EHRs) is a valuable resource for research. Understanding the relationship between characteristics and outcomes of patients treated in the real world and in oncology clinical trials by producing evaluable trial-like populations from RWD can advance clinical and regulatory knowledge.

Methods: RWD from the Flatiron Health EHR-derived, de-identified, longitudinal database were compared with pooled patient-level data from the three randomized controlled trials (RCTs) supporting regular approval of CDK4/6 inhibitors for patients with previously untreated hormone receptor-positive, HER- metastatic breast cancer (mBC). The RCT group included patients who received aromatase inhibitor (AI) monotherapy (RCT-control), and an experimental group (RCT-experimental) that received a cyclin dependent kinase 4/6 (CDK4/6) inhibitor + AI. The real-world control group (rwCG) of patients initiating AI monotherapy was selected using the key eligibility criteria across the RCTs. Patients from the rwCG were matched to the RCT-control and the RCT-experimental patients, respectively. Matching (1:1) was performed through the propensity score (PS) method adjusting for baseline covariates of age, race, site of disease, ECOG PS, and metastatic disease (recurrent, De novo). Multiple imputation (MI) was adopted to impute missing ECOG PS in the rwCG due to the high percentage of missingness.

Progression-free survival (PFS) and overall survival (OS) were analyzed for the following groups: A) rwCG and RCT- control B) rwCG and RCT-experimental and C) RCT-control and RCT-experimental. To assess the feasibility of RCT control arm replication, we assessed whether the trial replication hazard ratio (HR) estimates from analysis B were within the published trial estimates' 95% confidence intervals (CIs). HR and their 95% CIs were estimated using Cox proportional hazard model.

Results: A total of 1292 patients were selected from the EHR-derived database to comprise the rwCG and 1827 patients were pooled across the RCTs (1106 for RCT-experimental and 721 patients for RCT-control). With MI, 520 rwCG patients were matched to the RCT-control for analysis A, and 658 rwCG patients were matched to the RCT-experimental for analysis B. The results are summarized in Table 1. The point estimate of the PFS HR comparing the rwCG to the RCT-experimental was within the 95% CIs for three RCTs. For OS, the point estimate of the HR was within the 95% CI for MONALESSA-2 but not for PALOMA-2.

Conclusion: PFS and OS appeared longer in the RCT-control than in the rwCG, and the difference was more pronounced in OS. While it appears that there is greater similarity for PFS than for OS based on the results of the matched analysis of RCT- experimental vs. rwCG, evaluation of PFS results are limited by substantial differences in assessment and outcome definitions for progression between RCT-control (RECIST) and rwCG. Despite PS matching, there are apparent differences between patients treated in RCTs and routine practice, highlighting the importance of clinical setting, trial selection, study design, and use of

randomization. There are still outstanding feasibility questions on the evaluation of OS and further research is required to understand factors potentially impacting the outcomes between RCTs and RWD.

Table 1: Estimated Treatment Effects in PFS and OS, rwCG vs RCT-control vs RCT-experimental

	HR (95% CI)
PFS per Investigator¹	
A) RCT-control (N=520) vs. <u>rwCG</u> (N=520)	0.83 (0.67, 1.04)
B) RCT-experimental (N=658) vs. <u>rwCG</u> (N=658)	0.48 (0.39, 0.60)
C) RCT-experimental (N=1106) vs. RCT-control (N=721)	0.56 (0.49, 0.65)
Published PFS Results	
<i>MONARCH-3: Abemaciclib (N=328) vs. Control (N=165)</i>	<i>0.54 (0.42, 0.70)</i>
<i>PALOMA-2: Palbociclib (N=444) vs. Control (N=222)</i>	<i>0.58 (0.46, 0.72)</i>
<i>MONALESSA-2: Ribociclib (N=334) vs. Control (N=334)</i>	<i>0.56 (0.43, 0.72)</i>
OS	
A) RCT-control (N=520) vs. <u>rwCG</u> (N=520)	0.78 (0.66, 0.93)
B) RCT-experimental (N=658) vs. <u>rwCG</u> (N=658)	0.64 (0.53, 0.77)
C) RCT-experimental (N=1106) vs. RCT-control (N=721)	0.84 (0.72, 0.98)
Published OS Results	
<i>MONARCH-3: Abemaciclib (N=328) vs. Control (N=165)</i>	<i>NR²</i>
<i>PALOMA-2: Palbociclib (N=444) vs. Control (N=222)</i>	<i>0.96 (0.78, 1.18)</i>
<i>MONALESSA-2: Ribociclib (N=334) vs. Control (N=334)</i>	<i>0.76 (0.63, 0.93)</i>

Introduction: Leptomeningeal disease (LMD) is a late complication of metastatic cancer that significantly limits patient survival. LMD is most prevalent in patients with melanoma, lung, and breast cancer, with incidence reaching 24.1% among those treated for brain metastases with both surgery and radiotherapy. As systemic treatment advances in oncology continue to improve patient survival, the incidence of LMD is expected to rise. This necessitates increased efforts to identify effective LMD therapies. Further, recent reporting of focal LMD in asymptomatic patients indicates that unique categories of LMD exist which may not necessarily portend a dismal prognosis. Unfortunately, exclusion of these patients from clinical trials has resulted in a paucity of high-quality evidence to guide management in this patient population. We therefore conducted a systematic review to determine the proportion and characteristics of phase III randomized clinical trials in breast cancer, lung cancer, and melanoma that included patients with LMD and/or included LMD-specific outcomes.

Methods: The online ClinicalTrials.gov database was searched on December 22, 2020 for eligible phase III randomized control trials. No time limits were applied. The 1619 search results were screened by two independent reviewers for randomized, multi-arm therapeutic trials in advanced breast cancer, lung cancer, or melanoma.

Results: 245 trials were included in this review, 75/245 (30.6%) of which included LMD-specific enrollment criteria. 67/245 (27.3%) trials explicitly excluded all patients with LMD, while 8 trials (3.3%) allowed conditional enrollment of patients with LMD; these stipulated that LMD must be asymptomatic/stable, and in some cases, treated. All 8 trials which conditionally allowed LMD patients to enroll were lung cancer trials. No temporal trend towards LMD inclusion was noted. CNS-specific outcomes, which did not include specific mention of LMD, were noted in 13/245 (5.4%) trials, 2 (15.4%) of which used standardized response criteria. No trials included LMD-specific outcomes.

Conclusion: In this review, high rates of LMD exclusion and a complete lack of LMD-specific outcomes were noted in phase III trials for advanced breast cancer, lung cancer, and melanoma, despite these cancers carrying the highest risks of LMD. Lung cancer trials were most likely to include patients with LMD; this may be due to differences in tumor biology, drug penetration in the CNS and drug efficacy. Standardized and validated measures should be integrated into clinical trial design to facilitate inclusion of these patients when feasible and allow for meaningful assessment of LMD response to therapy.

Table 1: Trial factors associated with exclusion of patients with leptomeningeal metastases

Trial Characteristic	Categorization	N	N (%) with complete exclusion of patients with leptomeningeal metastases	p-value	N (%) with conditional inclusion of patients with leptomeningeal metastases	p-value

Introduction: Triple-negative breast cancer (TNBC), an aggressive form of breast cancer (BC) that is associated with poor prognosis, accounts for 10-15% of all BCs. Chemotherapy remains the standard of care (SOC) for advanced disease, with limited clinical benefit. Oncology clinical trials (CTs) are globally recommended and encouraged as the preferred treatment (tx) option for any cancer patient (pt). 'Trialjectory' (TJ) is an artificial intelligence (AI)-based technology that matches pts to oncology CTs. Here, we identified distinct characteristics of TNBC pts who signed up to the TJ platform compared to non-TNBC pts. Methods: Using AI and an unsupervised natural language processing approach, the TJ platform clinically matches pts to CTs. Matching is achieved by pt response to an online dynamic questionnaire (www.trialjectory.com) that collects detailed clinical data including clinico-pathologic characteristics, tx history, general health, and comorbidities. Those are compared to the eligibility criteria of available CTs to yield a high-quality actionable matched-trial list. Results: Between 1/2020 and 12/2021, out of 9796 BC pts that signed up, 2688 were TNBC pts (27%). There was no significant difference in age at sign-up between TNBC and non-TNBC patients (median age of 57 years vs 58 years, respectively). Consistently with Non-hispanic black (NHB) race prevalence in the different molecular subtypes in the general US population, NHB race had higher signup rate in TNBC compared to non-TNBC (9.95% vs 5.76%, respectively). TNBC pts signed up at a later disease stage compared to non-TNBC pts (19% of TNBC reported having a stage 1 disease compared to 27% of non-TNBC pts, $p < 0.001$). A significantly higher percentage of pts with advanced/metastatic TNBC signed up to the TJ platform before starting tx compared to non-TNBC patients (34% vs 22%, respectively, $p < 0.001$). Furthermore, there was a significant difference in the willingness to travel any distance within the US for a matched clinical trial between TNBC and non-TNBC pts (39% vs 34%, respectively, $p < 0.001$).

Conclusions: In this study, we found significant differences in the characteristics of TNBC vs non-TNBC pts that have signed up to the TJ platform. There was an up to 2-fold enrichment of TNBC on the TJ platform pts compared to their frequency in the general population. While previous studies do not show a difference in stage distribution between different subtypes, TNBC patients initiated their search for CTs at a higher stage. In addition, advanced TNBC patients started their search earlier in their journey, before starting chemotherapy. This may reflect the lack of effective SOC and possibly, the motivation to avoid the use of chemotherapy. This is also supported by the willingness of TNBC patients to travel farther in order to identify and enroll in a CT compared to non-TNBC pts. Importantly, the motivation of TNBC pts to travel

any distance has not been reduced despite the COVID-19 pandemic, reflecting a strong drive of this pt population to enroll in CTs. It also demonstrates that with the right access, diverse patient populations are willing to participate in clinical trials. In sum, TNBC pts are more likely to explore CT options, in the advanced stage setting, earlier in their journey. This study demonstrates the power of TJ platform for clinico-pathologic characterization and diverse pt groups, including their drivers and behavioral choices during their battle with cancer.

Introduction: The goal of breast conserving surgery (BCS) for early breast cancer (EBC) is to remove the tumor in toto and preserving as much of the normal breast tissue as possible. In 20-50% of cases a re-excision is necessary because of involved margins. Repeat surgeries are not only a burden to patients physically but also psychologically and can delay recommended adjuvant therapies. Accurate determination of tumor margins during surgery is therefore a critical need. Breast cancer tissue produces significantly higher amounts of VEGF-A than healthy tissue. VEGF-A stimulates tumor angiogenesis and is therefore a target for molecular imaging techniques. The fluorescence imaging agent bevacizumab-IRDye800CW (Beva800) is a conjugate of bevacizumab and IRDye800CW and binds specifically to VEGF-A. Beva800 provides a potentially efficacious approach to imaging specimen and cavity margins during BCS. We are presenting a phase II study that combined Beva800 with the SurgVision Explorer Air camera for intraoperative margin assessment during BCS for EBC. Methods: MARGIN II is a multicenter open-label single arm prospective clinical trial aimed at evaluating Beva800 for assessment of tumor margins in women with EBC scheduled for BCS. The study was a within-patient comparison of positive tumor margin rates using BCS standard of care margin assessment compared to intraoperative assessment with 4.5 mg Beva800 and fluorescence imaging with the SurgVision Explorer Air camera. All patients received an i.-v. bolus injection of 4.5 mg of Beva800 three days before surgery. The fluorescent signal was visualized during surgery using NIR fluorescence imaging (700–1000 nm). Standard of care margin assessment

was defined as visual inspection, palpation and, in cases of pre-operative wire marking, specimen sonography or mammography. Beva800 efficacy was determined as the number of patients in which a pathology-confirmed positive margin was identified by fluorescence-guided surgery using Beva800 but not by standard of care BCS. Results: 49 patients were included in 5 centers. 4 training cases were only included in the safety analysis, 45 patients were evaluable for the efficacy analysis. 8 patients (17.8%) had involved margins after standard of care BCS, 4 of which were detected by molecular fluorescence intraoperatively resulting in the reduction of patients with positive margins by 50% (95% CI: 15.7%, 84.3%). 4 patients (8.9%; 95% CI: 2.5%, 21.1%) needed a re-excision because of involved margins. In 27 patients (60.0%) the additional molecular fluorescence guided cavity shaving did not change the resection status from positive to negative (false positive). Adverse events were reported by 16 of 49 patients (32.7%), but only 3 (6.1%) were related to Beva800 (syncope, hot flush, hypertensive crisis). One patient experienced a treatment related SAE (hypertensive crisis). No anti-Beva800 antibodies were detected. Conclusion: In our analysis the rate of necessary second operations was reduced by 50% using Beva800 and the SurgVision Explorer Air camera. The safety analysis confirmed the positive safety profile of Beva800 found in previous studies. Molecular fluorescence-guided surgery may have the potential to change the practice of breast conserving surgery by reducing unnecessary re-excisions. Future studies will have to address the high false positive rates.

Background: Neoadjuvant chemotherapy (NAC) has evolved significantly and has been widely accepted for downstaging disease in early-stage and locally advanced breast cancer patients. Since the optimal surgical intervention of the breast for patients receiving NAC remains controversial, we aim to investigate the survival outcome of patients treated with different surgical management.

Methods: Patients with invasive breast cancer that underwent NAC in Fudan University Shanghai Cancer Center from January 2010 to June 2019 were involved in this study. Based on surgical intervention of the breast following NAC, patients were divided into mastectomy and breast conservation groups. To be specific, the mastectomy group involved patients who received mastectomy alone or mastectomy plus immediate breast reconstruction (M+IBR), while the breast conservation group evolved patients who underwent conventional breast-conserving surgery (CBCS) and oncoplastic surgery (OPS). Surgical interventions were performed by breast surgeons. Propensity scores matching was utilized for group matching.

Results: A total of 2080 patients were enrolled in this study. Among them, 1819 (87.5%) patients were categorized as mastectomy group, and 261 (12.5%) patients were classed as breast conservation group. In the mastectomy group, mastectomy alone and M+IBR accounted for 82.5% (1715/2080) and 5% (104/2080) patients respectively. As for breast conservation, 170 (8.2%) and 91 (4.4%) patients were treated with CBCS and OPS after NAC. Over 9-years of research, the proportion of breast conservation steadily increased in patients after NAC. Notably, the percentage of patients undergoing OPS increased from 0.43 % to 7.60 % throughout the 9 years. Moreover, increasing rate of M+IBR was also observed in the study cohort, whereas fewer patients opted for mastectomy alone as surgical intervention after NAC. Compared with mastectomy group, patients underwent BCS showed younger age ($P < 0.001$), as well as higher proportion of normal BMI ($P = 0.022$), pre-menopausal status ($P < 0.001$), and triple-negative breast cancer ($P < 0.008$). Additionally, patients with tumors of advanced clinical T stage ($P < 0.001$) and TNM stage ($P = 0.002$) were more often to be treated with mastectomy (Table 1). After propensity score matching, 460 patients were matched successfully (Table 2). Compared with the mastectomy group, significant benefits in overall survival (Hazard ratio 0.51, [95% confidence interval: 0.27-0.96]; $p=0.044$) and disease-free survival (Hazard ratio 0.62, [95% confidence interval: 0.39-0.99]; $p < 0.05$) were observed in the breast conservation group (Table 3A and 3B). Moreover, there was no statistical difference in locoregional recurrence among the surgical groups (Table 3C).

Conclusions: Tumor biology can significantly impact the surgical decision in patients administrated with NAC. Breast conservation was a safe alternative for mastectomy in the NAC setting without compromising survival outcomes.

Backgrounds/Aims: Nipple sparing mastectomy (NSM) is popularly performed as this surgical technique is oncological safety and better cosmetic outcomes. Robot assisted NSM (RANSM) is emerging because of its exceptional advantages: hidden incisions, high resolution, wider visualization and ergonomically moving. Although several studies reported that RANSM has shown a short learning curve, there were few reports about learning curve of this cutting-edge surgical technique. In this study, we reported the learning curve and feasibility of RANSM. **Methods:** A retrospective and prospective study was conducted for women who underwent RANSM with immediate breast reconstruction at Samsung Medical Center from July 2019 to April 2022. All RANSM were performed by a single surgeon. We divided the total cases in half and set up two phases; an early phase (case 1st to 23th) and a late phase (case 24th to 46th). The total operation time, mastectomy time, docking time, pre-console time and console time was defined as the interval between the creation of the skin incision and the end of the reconstructive surgery, the interval between the time of skin incision and the time of the specimen out of the operation field, the interval between the preparation for docking and the end of docking, the interval between the creation of the skin incision and the end of robot docking, and the time spent by a surgeon to operate the console for mastectomy. To evaluate the impact of case experience accumulation on the operation time of RANSM, the cumulative sum (CUSUM) method was used to analyze the learning curve. Clinicopathologic characteristics, perioperative complications, and operation time were collected. **Results:** Overall, 42 women underwent 46 RANSM procedures conducted. The median patient

age was 44.5 years old (26-59 years) and the median breast weight was 338.5 gram (101.4-817 gram). BRCA 1 mutation carriers were 2 patients and BRCA 2 mutation carriers were 3 patients. 5 patients with BRCA 1/2 mutation carriers underwent contralateral risk-reducing RANSM. Clinicopathologic characteristics of patients between the early phase and late phase were summarized in Table 1. There were no significant differences in almost clinicopathologic characteristics. Median time of total operation, mastectomy, docking time, pre-console time, and console time was 344.0 minutes (254.0-480.0 minutes), 238.5 minutes (166-394 minutes), 6.5 minutes (1-25 minutes), 61.5 minutes (29-180 minutes), and 64.5 minutes (33-134 minutes), respectively. Comparing the early phase and the late phase, median total operation time was 357 minutes (273-480 minutes) and 321 minutes (254-459 minutes), ($p = 0.067$); median mastectomy time was 245 minutes (204-394 minutes) and 229 minutes (166-376 minutes), ($p = 0.070$); docking time 7.0 minutes (3-25 minutes) and 5.0 minutes (1-20 minutes), ($p = 0.093$); pre-console time was 70.0 minutes (49-162 minutes) and 54.0 minutes (29-180 minutes), ($p = 0.028$); console time was 71.0 minutes (40-134 minutes) and 60.0 minutes (33-105 minutes), ($p = 0.095$). In the learning curve analysis, it took the 21th procedure in RANSM to decrease the breast operation time. Clavien-Dindo grade III postoperative complication was two cases (8.6%, one case was infection and one case was nipple ischemia) in only early phase and none in the late phase. Clavien-Dindo grade II postoperative complication was absent in all phases. Clavien-Dindo grade I postoperative complications were seven cases (30.4%, all cases were nipple crust) in the early phase and one case (4.3%, one case was nipple crust) in the late phase. Nipple ischemia was found in two cases (8.6%) but only one case required nipple excision given in the early phase.

Conclusions: It has shown that the breast operation time improved from the 21th procedure of RANSM. RANSM is technically feasible and acceptable with a short learning curve.

Introduction: Inflammatory breast cancer (IBC) is an aggressive form of breast cancer with best outcomes result-ing from trimodality therapy: neoadjuvant chemotherapy (NAC), modified radical mastectomy (MRM), and radiation (PMRT). Contralateral prophylactic mastectomy (CPM) is generally discour-aged at the time of MRM due to poor prognosis. Our aim was to identify factors associated with CPM for IBC and determine its relationship with overall survival (OS). Methods: The National Cancer Database was used to identify female patients with AJCC stage IIIC unilateral IBC (cT4d and inflammatory histology code) treated 2004-2018. Patients were stratified by mastec-tomy type: unilateral mastectomy (UM) was defined as MRM or simple mastectomy, and CPM was defined as UM + CPM. Logistic regression identified factors associated with mastectomy type, and multivariable proportional Cox hazards regression identified factors associated with OS. A subset analysis of patients receiving NAC compared complete pathologic response (pCR) between mastec-tomy groups. Results: Of the 2,837 patients with non-metastatic IBC, 2,013 (70.2%) underwent UM and 855 (29.8%) had CPM. The CPM group was significantly younger than the UM group (mean age 52 vs. 56.6 years, $p=0.028$), more frequently identified as Non-Hispanic White (79.7% vs. 70.1%, $p<0.001$), and had private insurance (66.9% vs. 55.6%, $p<0.001$). Nearly all patients received chemotherapy and over 80% were treated with NAC. Receipt of PMRT did not differ by mastectomy type (80% for UM and CPM). On multivariable logistic regression, patients age <40 were more likely to undergo CPM than UM (OR 3.7, 95% CI 1.61-8.5, $p<0.002$). Patients with age >70 , Hispanic ethnicity, and public insur-ance were significantly less likely to receive CPM (all $p\leq0.002$). On

multivariable Cox regression adjusted for patient, tumor, and treatment factors, CPM was not associated with OS benefit (HR 0.86, 95% CI 0.73-1.02, p=0.08). Higher histologic grade, node-positive disease, and greater co-morbidity were associated with poorer OS, while receipt of chemotherapy and PMRT improved OS. In the subset of NAC patients, overall pCR did not differ significantly by mastectomy type (CPM 22.3%, UM 19.4%, p=0.26). When included in multivariable models, pCR rates were not predictive of CPM despite being associated with improved OS. Conclusion: Nearly 30% of IBC patients undergo CPM despite discouragement by guidelines. Demographic characteristics – particularly age < 40 – predicted CPM, suggesting patient preferences and access to care affect surgical decisions. As expected, trimodality therapy and favorable NAC response improved oncologic outcomes, but CPM had no association with OS. While CPM may be chosen for risk reduction and symmetry, patients should be counseled that it does not improve survival for IBC.

Background

As a first-echelon nodal drainage site of breast cancer, the status of axillary lymph nodes (ALN) and internal mammary lymph nodes (IMLN) is both valuable for regional staging and treatment choice. The internal mammary sentinel lymph node biopsy (IM-SLNB) may provide minimally invasive staging, and guide individual IMLN radiation. Modified technique (periareolar intraparenchymal, high volume and ultrasound guidance) got a high internal mammary sentinel lymph nodes (IM-SLN) visualization rate of 71.1% in single center, and the prospective multicenter study was designed to verify its repeatability (CBCSG026, NCT03541278). High visualization rate and low false negative rate are prerequisites for the widespread of IM-SLNB. The question arises as to whether IM-SLN detected with the modified technique should be considered as "true" IM-SLN. The prospective, multicenter, clinical validation study of IM-SLNB followed by internal mammary lymph node dissection (IM-LND) was designed to verify the accuracy of IM-SLNB in patients with ALN positive breast cancer (CBCSG027, NCT03024463).

Methods

While CBCSG026 trial enrolled patients with both axillary negative and positive breast cancer,

CBCSG027 trial only enrolled axillary positive patients receiving mastectomy (either biopsy proving cN+ disease or cN0 with positive axillary SLN). The 1st to 3rd intercostal IM-LND was performed immediately after IM-SLNB to verify its accuracy in the CBCSG027 trial.

Result

From May 2018 to June 2022, 600 and 264 patients were enrolled in the CBCSG026 and CBCSG027 trial from seven centers in China, respectively.

Among the 600 recruited patients in the CBCSG026, the IM-SLN visualization rate was 65.0% (390/600), which was significantly related to patient's age, body mass index, radiotracer intensity and interval time between injection and IM-SLN identification (all $P < 0.05$). The IM-SLNB successful rate was 97.4% (380/390), and the complication was 6.9%. The median number of IM-SLN was 1. The overall IM-SLN metastases rate was 18.9% (72/380), with 33.0% (65/195) and 3.8% (7/185) in ALN positive and negative patients, respectively. Multivariate analysis showed that the tumor size ($P=0.028$), the tumor location ($P < 0.001$) and the number of positive ALNs ($P < 0.001$) were independent predictors of IM-SLN metastasis. Those variables were included in a novel nomogram (Table 1), which was significantly better than the probability based on the number of metastatic ALNs alone according to the current guidelines (area under the curve: 0.860 vs. 0.804, $P < 0.001$).

Of the 264 patients enrolled in the CBCSG027 trial, 185 patients (70.1%) had IM-SLN visualization (included 107 with cN+ disease and 78 with positive axillary SLN). The median number of IM-SLN and IM-nSLN was 2 (1~4) and 3 (1~9), respectively. The positive rate of IMLN and IM-SLN was 37.8% (70/185) and 36.8% (68/185), respectively, yielding the false negative rate of IM-SLNB 2.9% (2/70), the accuracy of 98.9% (183/185) and the sensitivity of 97.1% (68/70). The false negative rate of patients with cN+ disease and patients with positive axillary SLN was 4.8% (2/42) and 0, respectively. The positive IM-SLNs were the only positive IMLNs identified in 51.4% (36/70) patients. IM-SLNB can change the pN stages of 37.2% (68/183) patients. IMLN irradiation could be avoided in 72.7% (80/110) patients with axillary pN1 and 46.7% (35/75) with pN2/N3 disease in the study.

Conclusions

The modified technique of radiotracer injection (periareolar intraparenchymal, high volume, and ultrasound guidance) can significantly improve the detection rate of IM-SLN with very low false-negative rate with the prospective, multicenter validation results, providing minimally invasive staging and guiding individual IMLN radiation. When there is no IM-SLN visualization, the nomogram can predict the risk of IMLN metastasis and guide IMLN radiation.

The nomogram which can predict the risk of IMLN metastasis

size: tumor size; location: tumor location; scale: tumor grade; WS: upper outer quadrant ; WX: lower outer quadrant; ZY: central quadrant; NS: upper inner quadrant; NX: lower inner quadrant; ALN: number of positive ALNs

Background: The Surgical Society of Oncology Choosing Wisely Campaign for breast cancer advocates against the routine use of sentinel lymph node biopsy (SLNB) for women ≥ 70 years with early stage estrogen positive (ER+), clinically node negative (cN0) disease, given the low likelihood of axillary involvement and axillary recurrence risk, absence of survival benefit and greater reliance on genomic testing for therapeutic decisions. We hypothesize that this practice may be extended to a younger cohort of patients. In this proof-of-concept feasibility study, we first sought to determine the incidence of node positive (N+) disease in our health system using natural language understanding (NLU) technology to extract relevant data from the electronic medical record (EMR).

NLU of the clinical narrative has been proven to aid clinical decision support by extracting relevant information and can populate clinical databases to facilitate optimal population management strategies. The advantage of NLU over a cancer registry is the speed and efficiency of data extraction for a large number of patients in real time, plus the capture of data points not conventionally included in a registry.

Methods: All patients with early stage ER+, cN0 breast cancer who had SLNB from January 2015-December 2017 were identified in an integrated academic health network comprised of 15 hospitals in Western Pennsylvania. Patient clinical data were abstracted from the EMR using Realyze Intelligence™ NLU technology. The Realyze NLU pipeline uses a combination of machine learning algorithms and standard terminologies to create a breast cancer patient model that includes genomic, phenotypic, and clinical data. The pipeline gathers information from all data sources – structured and unstructured – and normalizes the information to create a complete model of patient clinical criteria.

Realyze Information Models use clinical data formatting flexible enough to represent clinical disorders on a concept level as well as the encounter, patient, and population levels. A breast cancer model with focus on the lymph node identification, pathological as well as clinical tumor

and node classification were developed and mapped to standard terminology. A Semantic Reasoning layer is provided by different mechanisms including a rule-based layer to render answers to the questions posed in this hypothesis.

NLU performance was validated by manually verifying key clinical variables (i.e., clinical stage, pathologic stage, and nodal positivity) on a subset of patients. Statistical analysis to determine any difference in N+ rates by age was performed using Chi-square testing with significance set at $p < 0.05$.

Results: We identified 602 pts with early stage ER+, cN0 breast cancer over this period who underwent SLNB. Average age was 59.6 years old. As a whole group, there was an increase in N+ rates as the stage increased (Table 1). When comparing incidence of N+ disease stratified by age (< 70 or >70), there was no difference in N+ rates across all stages. In addition, equally low rates of SLN positivity were seen for patients specifically with stage T1a and T1b disease.

Conclusions: These data suggest that the Choosing Wisely recommendation to omit SLNB may be extended to a younger cohort of pts with ER+, cN0 disease, specifically those with stage T1a or T1b tumors. With low rates of N+ disease, and less reliance on axillary stage for treatment decision making, the harms of surgical axillary staging may outweigh the benefits. Future validation is needed with a larger sample size.

Table 1

n = 591 patients who underwent SLNB			
	Rate of SLN Positivity		p-value
	< 70yo	≥ 70yo	
T1a	10.4% (5 / 48)	6.7% (1 / 15)	0.99
T1b	6.8% (5 / 74)	5.9% (1 / 17)	0.99
T1c	17.3% (29 / 168)	13.2% (5 / 38)	0.64
T2	30.4% (45 / 148)	27.8% (10 / 36)	0.84
T3	58.5% (24 / 41)	33% (2 / 6)	0.39

Introduction: Even though randomized controlled trials could not show a significant survival benefit for the use of neoadjuvant systemic therapy (NST), it is increasingly recommended for patients with clinically node-positive breast cancer due to its implications on prognosis, locoregional downstaging and response-driven adjuvant systemic therapy. The aim of this study was to assess the need for international standardization of treatment recommendations by evaluating clinical practice heterogeneity in use of NST for patients with clinically node-positive breast cancer in Europe. **Methods:** The study was preplanned in the international multicenter phase-III OPBC-03/TAXIS trial (ClinicalTrials.gov Identifier: NCT03513614) after randomization of the first 500 patients with clinically node-positive breast cancer who underwent axillary lymph node dissection (ALND) or axillary radiation (ART) without ALND after tailored axillary surgery (TAS) in the context of extended regional nodal irradiation. Clinically node-positive breast cancer was defined by confirmed nodal disease at the time of initial diagnosis; in case of neoadjuvant therapy, residual nodal disease was mandatory. Investigators were encouraged to enroll all eligible patients consecutively. However, TAXIS is unique inasmuch as its pragmatic design allows both the neoadjuvant and adjuvant setting according to the preferences of the treating physicians and institutions and thus provides an excellent opportunity to study patterns and trends in use of NST in patients with clinically positive nodes in Europe. **Results:** A total of 500 patients with a median age of 57 years (IQR: 48-69 years) were included at 44 breast centers in 6 European countries from August 2018 to June 2022. Subtype was hormone receptor (HR) positive (+) and human epidermal growth factor receptor 2 (HER2) negative (-) in 393 (80.0%), HR+/HER2+ in 52 (10.6%), HR-/HER2+ in 5 (1.0%) and HR-/HER2- in 34 (6.9%) patients. The rate of patients undergoing NST was 31.4% with a significant upward trend over time during the study period (from 20.0% in 2018 to 38.1% in 2022; $p=0.044$). The use of NST varied significantly by country ($p<0.001$) and by site ($p=0.015$). For patients with clinical AJCC tumor stage II and III, the rates of patients undergoing NST in Switzerland were 26.5% (18 of 68) and 35.9% (92 of 256), in Germany 22.2% (2 of 9) and 30.4% (7 of 23), in Austria 50% (7 of 14) and 60% (9 of 15) and in Hungary 0% (0 of 15) and 20.7% (18 of 87), respectively ($p=0.019$ and 0.004). Large differences by country were found for ER+/HER2- breast cancer, ranging from 13.1% (11 of 84) in Hungary to 47.8% (11 of 23) in Austria ($p=0.007$). Within Switzerland, which was the country with most included patients (328 of 500) and participating sites ($n=25$), the rate of patients undergoing NST for ER+/HER2- breast cancer varied considerably by site, ranging from 10% (2 of 20) to 50% (11 of 22). **Discussion:** This study revealed substantial heterogeneity in clinical practice in Europe, indicating the need for development of and adherence to consistent guidelines to standardize the international use of NST.

Background:

Since nipple-sparing mastectomy (NSM) has been widely practiced, majority of previous studies have evaluated the effects of Nipple-areolar complex (NAC) preservation on body image adjustment. However, few have evaluated NAC sensation after NSM in a large sample size. This study aims to assess NAC sensation after NSM and compare the results according to different incisional approaches; specifically, inframammary fold (IMF) and peri-areolar.

Methods:

Post NSM patients from Oct 2019 to Nov 2021 have been recruited prospectively. A total of 115 patients (IMF 69 and peri-areolar 36) were evaluated for NAC sensory at various time points during follow up within 1.5 to 4 years after surgery. NAC sensation was scored by pin-prick test in a scale of 0 to 2 (0: no sensation, 1: dull sensation, 2: sharp sensation), divided in 5 areas of the NAC and summed up to a total of 10.

Results:

In all patients, a median of the pin-prick test total score on NAC was 3 (0-10). Pin-prick test of NAC showed numerically higher NAC sensory score in the IMF incision than in the peri-areolar group without a statistical significance (IMF: Median 4 Mean 3.83 ± 3.04 , Peri-areolar Median 2 Mean 2.69 ± 3.64 , $p=0.062$). When sensory scores were evaluated depending on NAC zones (A: Nipple, B: Upper outer, C: Upper inner, D: Lower outer, E: Lower inner) the IMF incision group showed better outcomes in zone B ($p=0.015$) and E ($p=0.043$). Simple linear regression analysis showed the possibility of incisional approach, diabetes mellitus (DM) history, previous radiotherapy of ipsilateral breast, post mastectomy radiotherapy (PMRT), adjuvant chemotherapy, tumor to nipple distance and laterality influencing NAC sensory with $p < 0.2$. When these factors were taken to multiple linear regression analysis, DM history ($p=0.045$), previous radiotherapy ($p=0.001$), postop radiotherapy ($p=0.001$), and adjuvant chemotherapy

(p=0.001).

Conclusion:

NAC sensory deteriorated postoperatively in general. Scores of NAC sensation were numerically higher in the patients with IMF incision, although the difference was not statistically significant. NAC sensation was negatively affected by DM history, previous ipsilateral breast radiotherapy and post-NSM treatments such as chemotherapy and PMRT. While incision type may improve aesthetic outcomes, additional efforts are necessary to ameliorate the post-NSM NAC desensitization.

Axillary Reverse Mapping Aids in Reducing the Rates of BCRL in Underserved Ethnically Diverse Population

Presenting Author(s) and Co-Author(s):

Country: United States

Background: Breast Cancer Related Lymphedema (BCRL), is a long-term side effect affecting the patient's quality of life after lymph node surgery. Historically BCRL is seen in 5-7% and 15-40% of patients undergoing sentinel lymph node biopsy (SLNB) and axillary lymph node dissection (ALND) respectively; with the risk increasing two-fold in low-income and ethnic minority groups. Axillary Reverse Mapping (ARM) is a novel technique to distinguish drainage pathways of the arm and breast, and prior studies have reported significantly lower rates of BCRL with ARM. Lymphatic re-approximation can prevent and/or reduce lymphedema rates in cases where crossover nodes are encountered. Furthermore, blue nodes can be preserved during ALND; however, if resected during ALND, lymphatic venous (LYMPHA) procedure can help to restore lymphatic flow. However, there is a paucity of literature looking at the utility of ARM in ethnically minority groups. Therefore, we aimed to evaluate the prevalence of lymphedema in our patient population with breast cancer undergoing SLNB and ALND using ARM and in turn compare these findings to historical controls.

Materials & Methods: A retrospective study was carried out on patients who underwent axillary surgery with ARM from January 2019 to July 2021. Patient demographics such as age, BMI, gender, and ethnicity were recorded. Patients undergoing mastectomy vs breast conservation with SLNB ± ALND associated with ARM were monitored for lymphedema for a year at 3-month intervals using SOZO® scores, and then for another 2 years clinically. At each follow-up, SOZO® scores were computed using bioimpedance spectroscopy and compared to preoperative baseline scores.

Results: A total of 142 patients' data was evaluated, of which 83.8% belonged to the minority group (African American = 46, Hispanic = 63, Asian = 10). Mean BMI accounted for 29.1±5.31. Breast conservation surgery and mastectomy were performed in 71.8% (n=102) and 28.1% (n=40) of patients respectively. SLNB was performed on 88.7% (n=126) of the patients and ALND was carried out on 11.3% (n=16). Furthermore, 73.9% (n=105) of the patients underwent radiation therapy. Positive lymph nodes were identified in 24.6% (n=35) of patients. Blue nodes and blue lymphatics were encountered in 17.6% (n=25) and 32.4% (n=46) of patients respectively. Out of the blue nodes identified (n=25), 44% (n=11) were excised and 32% (n=8) were diagnosed as crossover nodes. All the crossover nodes were resected but none of them contributed to the development of lymphedema. Moreover, 90.9% of the patients with blue

lymphatics underwent lymphatic re-approximation after excision of the blue nodes. Of the 142 patients, 59 had a three-month follow-up of which 2 patients (3.4%) developed clinical lymphedema diagnosed via SOZO® who had undergone SLNB which resolved by 6-month follow-up. Additionally, compared to the historical incidence of BCRL which accounts for up to 40.4% in ethnic minorities, we found a significantly lower incidence of lymphedema ($p < 0.001$) in our patient population. Moreover, in our study, ALND and radiation therapy did not contribute to lymphedema rates.

Conclusion: ARM procedure can significantly lower BCRL even in ethnically minority groups. 3.4% of patients undergoing SLNB developed BCRL, which was significantly lower than historically reported data. Furthermore, in our study, no patients who underwent ALND developed lymphedema. Also, crossover nodes or radiation therapy did not contribute to the development of lymphedema after surgery demonstrating the effectiveness of ARM technique. Further studies with larger sample size and longer follow-up duration are necessary to better understand the utility of ARM technique in this population.

Background: The use of axillary marking before neoadjuvant systemic therapy (NST) is the standard of care in patients with positive lymph nodes (LN). Several methods have been tested leading to reduced false negative rate compared to sentinel lymph node biopsy (SLNB). With the increase in therapies in patients with residual disease, it is necessary to improve the accuracy of the axillary assessment. The aim of this study was to evaluate oncological

outcomes in patients undergoing targeted axillary dissection with positive LN pre-NST marked with 4% carbon marker, the secondary objective was to evaluate the association between SLNB and pre-NST marked lymph node. Methods: A prospective study was performed in patients with cT1-T4, cN1-N2 breast cancer who underwent NST. An ultrasound-guided 4% carbon marking was performed before proposed treatment. After NST, the carbon marked lymph node (CMLN) was identified and resected associated with SLNB. When at least one lymph node was positive, axillary dissection was performed. The oncological outcomes registered were overall survival (OS), specific survival (SS), disease-free survival (DFS), axillary recurrence (AR) and local recurrence (LR). Results: 176 patients operated between July 2014 and January 2019 were included in the analysis. The CMLN were identified in 168/176 (95.4%) and the SLNB 145/176 (82.3%) operations. SLNB and CMLN were coincident in 93/176 (52.8%) cases. The LNs were not coincident in 44/176 (25%) cases and at least one of the methods were not identified in 39/176 (22.1%). When condensing the lymph nodes not found as positive lymph node, the sample agreement was 148/176 (81.4%) [Kappa = 0.67 (95%CI: 0.56 – 0.78)], when separating the positive lymph nodes from the lymph nodes not found, the agreement was 133/176 (75.6%) [Kappa = 0.56 (95%CI: 0.46 – 0.66)] (Table 1). With a mean follow-up of 49 months, 168 patients were included in the analysis of oncologic outcomes. Among the patients analyzed, 7/168 (4,1%) had LR, 5/168 (2,9%) had AR, 28/168 (16.6%) had distant recurrences [DFS = 83.3%]. There were 10/168 (5,9%) deaths [OS = 94%], with 5 confirmed by breast cancer and 4 of undetermined cause. There was a significant association between axillary dissection and axillary recurrence (0 versus 6% p = 0.012). OS for clinical stages 2B, 3A and 3B were 97, 88 and 87.5% respectively. Conclusions: The use of 4% carbon marker is a feasible and cheap method for targeted axillary dissection. The oncological outcomes are compatible with the survival curves of the American Joint Committee on Cancer 8th edition, therefore, a safe tool to spare women cN+ from axillary dissection when there is a complete axillary response to NST. The concordance rate between the CMLN and the SLNB was moderate when we took into account the failure of some method, noting the need for a supplementary method to the SLNB after NST.

Frequency and percentages of anatomopathological results and methods of lymph node identification.

Positive SLNB	Positive CMLN			Total
	No	Yes	Not found	
No	91 51.7%	5 2.8%	5 2.8%	101
Yes	5 2.8%	39 22.2%	0 0.0%	44
Not found	13 7.4%	15 8.5%	3 1.7%	31
Total	109	59	8	176

SLNB = sentinel lymph node biopsy; CMLN = carbon marked lymph node

Occurrence of oncological outcomes

Oncological Outcome	No.	Outcome	No. (%)
Local Recurrence	168	No	161 (95.8)
		Yes	7 (4.1)
Axillary Recurrence	168	No	163 (97)
		Yes	5 (2.9)
Distant Recurrence	168	No	140 (83.3)
		Yes	28 (16.6)
Specific Death	164	No	159 (97)
		Yes	5 (3)
Death	168	No	158 (94)
		Yes	10 (6)

GILSOO SON, *n/a, Professor - Korea University College of Medicine*
Country: United States

Purpose : The purpose of this study is to introduce an early experience of endoscopic nipple-sparing mastectomy (NSM) combined with immediate breast reconstruction through simple single-port access that placed in axillary incision. **Methods and Materials :** Between November 2018 and June 2022, 48 female patients with breast cancer, total 50 cases of breast cancer (bilateral breast cancer in 2 patients) were treated with endoscopic NSM combined with immediate breast reconstruction through simple single-port access that placed in axillary incision. Forty-six patients, total forty-eight cases, underwent breast reconstruction with silicone implant, two patient underwent TRAM reconstruction. **Surgical procedures of endoscopic NSM :** Patients were placed in a supine position with both upper limbs on arm boards abducted 90 degree. An incision of 5 cm was made along the anterior axillary line from the inferior mammary fold. The sentinel lymph node was excised through the incision. A workspace for the insertion of a Glove Port (Nelis, Republic of Korea) was created within a radius of 3 cm from the incision, and the subcutaneous tissue flaps were raised. The Glove Port was inserted first into the retromammary space, carbon dioxide (CO₂) gas was insufflated, and the pressure was maintained at approximately 7 mmHg. The retromammary space dissection was performed with caution to avoid dissecting the interpectoral space, using an energy device and an endoscopic grasper guided by a flexible endoscope (ENDO EYE FLEX 10 mm, OLYMPUS, Japan). The breast was elevated to the edge of the latissimus dorsi muscle laterally, to the thoracoabdominal aponeurosis inferiorly, to the level of the clavicle superiorly, and to the edge of the sternum medially. After dissecting the retromammary fat plane, the Glove Port was relocated into the subcutaneous space. Skin flap was dissected using an energy device, and the duct beneath the nipple was cut off using endoscopic scissors. The subcutaneous flap was dissected completely along the boundaries of the breast, and the entire breast was removed. **Results :** The patients were 30-55 years old (mean, 43 years). The tumor located at the left breast in 26 cases and at the right breast in 23 cases. The diameter of tumor ranged from 1.5 to 5.2 cm (mean, 3.4 cm). Median operation time was 153 minutes. After operation, nipple necrosis or skin flap necrosis was not observed. No subcutaneous emphysema occurred. There is one tumor involvement to nipple in postoperative pathological examination. So, excision of nipple-areolar-complex was performed 2 weeks after first operation. All patients were followed up 1-43 months (median, 19 months). According to the Harris assessment criteria for appearance of reconstructed breast, there were 43 cases of excellent and 7 cases of good. No tumor recurrence or metastasis occurred during follow-up. **Conclusion :** It is a safe and feasible method of endoscopic NSM combined with immediate breast reconstruction

through simple single-port access that placed in axillary incision, and can obtain good cosmetic results. It is a new option to breast reconstruction.

Objective: With the development of the diagnosis and treatment of breast cancer, the pattern of multidisciplinary treatment has resulted a new tendency of breast conserving surgery and reconstruction. Nipple sparing mastectomy (NSM) preserves the aesthetically important nipple-areolar complex, improved appearance satisfaction and quality of life of patients after mastectomy , and had similar oncologic outcomes compared with traditional mastectomy techniques. The primary guiding principles of NSM are oncologic safety. Some studies have demonstrated its oncologic safety while others have demonstrated recurrent risk increasing because of the nipple-areolar complex. We sought to assess the overall survival and disease-free survival of NSM compared with breast-conserving surgery (BCS) and total mastectomy (TM). **Key words:** nipple sparing mastectomy, breast-conserving surgery, total mastectomy, the overall survival, the disease-free survival **Methods:** This retrospective matched-cohort study was conducted patients accepted breast surgery between January 2007 and December 2017 in the Department of Breast Surgery of Fudan University Shanghai Cancer Center. Cancer stages were identified depending on the American Joint Committee on Cancer [AJCC] TNM staging system. The inclusion criteria included (1) female breast cancer, (2) histopathology confirmed

invasive breast cancer without distant metastasis or local relapses, (3) had complete clinical and pathological T&N stages. The exclusion criteria included in situ carcinoma, phylloides tumor, recurrent or metastatic breast cancer and pregnancy. The primary outcome was the overall survival (OS), the secondary outcome was the disease-free survival (DFS). Statistical methods included Kaplan-Meier survival analysis and COX regression analysis, all of which were completed by SPSS 20.0. Results: A total of 2757 patients were evaluated for eligibility, of which 430 were included (86 NSM vs 172 BCS vs 172 TM) · the median follow-up is 61.57 months. Clinical T&N stage and other factors of the above three operations were balanced and comparable after matching. COX regression analysis reported that pT (pT3 vs pT1, P=0.00, HR 16.051, 95%CI:3.822-67.409) and pN (pN2 vs pN0, P=0.00, HR 16.626, 95%CI:4.581-60.337) were related factors for OS, and pT (pT3 vs pT1, P=0.021, HR 6.619, 95%CI:1.331-32.927) and pN (pN2 vs pN0, P=0.000; HR 13.320, 95%CI:3.250-54.591) are independent predictive factor of OS. In addition, pN (pN2 vs pN0, P=0.013; HR 3.448, 95%CI:1.304-9.118) was a related factor for DFS. Among 94.19% patients of the NSM group underwent breast reconstruction, 70 underwent implant-based breast reconstruction, 8 underwent autogenous flaps reconstruction, and 3 patients chose latissimus dorsi flap combined with prosthesis immediate breast reconstruction. Only 4 of 172 patients underwent autogenous flaps reconstruction in TM, and 1 chose implant-based breast reconstruction. Kaplan-Meier survival analysis found that the 5-year OS of NSM group, TM group and BCS group were respectively 100%, 95.8% and 99.2%. The 5-year DFS of three operations were respectively 95.2%, 92.1%, 93.5%. Patients who underwent NSM had no difference compared with BCS or TM regarding the OS (P=0.875, HR 0.938, 95%CI:0.421-2.090) and the DFS (P=0.882, HR 0.967, 95%CI:0.623-1.502). Conclusions: Patients undergoing NSM are not disadvantaged in terms of the OS and the DFS compared with patients who underwent BCS or TM. Patients with NSM tend to opt for breast reconstruction to keep good shape and it has the same prognostic outcome as patients with TM or BCS.

TITLE: Effect of intra-operative and post-operative topical tranexamic acid on early post-operative complications in patients undergoing axillary lymph node dissection for breast cancer. **Authors:** PACHIMATLA AKHIL GOUD¹, ISHITHA LAROIYA², SIDDHANT KHARE³, R N NAGA SANTHOSH IRRINKI², GURPREET SINGH⁴. **Affiliation:** 1. Junior Resident, Department of General Surgery, Post Graduate Institute of Medical Education & Research (P.G.I.M.E.R.), Chandigarh. 2. Assistant professor, Department of General Surgery, Post Graduate Institute of Medical Education & Research (P.G.I.M.E.R.), Chandigarh. 3. Associate professor, Department of General Surgery, Post Graduate Institute of Medical Education & Research (P.G.I.M.E.R.), Chandigarh. 4. Professor and Head (retired), Department of General Surgery, Post Graduate Institute of Medical Education & Research (P.G.I.M.E.R.), Chandigarh. **BACKGROUND:** Seroma formation after breast surgery has been a consistent problem with no established causes or risk factors. The role of topical tranexamic acid in reducing the incidence of seroma after axillary clearance in breast cancer is controversial. **AIMS & OBJECTIVES:** To study the effect of intra-operative and post-operative topical Tranexamic acid on the duration of drain and volume of seroma in patients undergoing axillary lymph node dissection (ALND) for breast cancer. **MATERIALS AND METHODS:** In this prospective, non-blinded, triple-arm randomized controlled trial conducted at the Department of General Surgery, PGIMER, 154 breast cancer patients were enrolled and studied from July 2020-July 2021. They were randomized into three

groups. Group A (n=51) received a single dose of diluted topical tranexamic acid intra-operatively, Group B (n=52) received intra-operative dose and daily post-operative doses till day-5 through the suction drain placed intra-operatively, and Group C(n=51) did not receive any topical tranexamic acid. The study groups were primarily compared for the total drain duration and total drainage volume. Daily drain volume for the first five days, complications like seroma, wound infection and severity of surgical site infections using Southampton score, and adverse reactions of the drug were compared. RESULTS Out of the 154 patients, four have failed to maintain appropriate records and analysis was done with 150 patients. The mean age of the study population was 52.17 ± 8.69 yrs, with a mean BMI of 26.20 ± 4.14 . The final analysis showed no significant difference in total drain volume across the three groups, but patients receiving multiple doses of topical tranexamic acid had the lowest total volume drained compared to patients receiving a single dose or no dose (1763ml Vs 1597 Vs 1773ml: $p=0.269$). There was no significant change in the duration of the post-operative drain (21.6 Vs 19.2 Vs 19.55 days: $p=0.54$). There was no statistically significant difference in complications between the groups. Seroma was seen in 6 vs 7 vs 4% ($p=0.629$) patients in groups A, B and C respectively. Wound site infection was noted in 11 vs 13 vs 10% of patients ($p= 0.766$). None of the patient characteristics like age, BMI, co-morbidities, previous lumpectomy, menopause, and length of history significantly correlated with seroma formation in the study population. CONCLUSION There was no significant reduction in drain volume or duration with either single or multiple doses of topical tranexamic acid after the axillary clearance for breast cancer. Even though not significant, an increasing trend in wound site infections was noted among the patients who received multiple doses of tranexamic acid was noted.

Country: Republic of Korea

Purpose We investigated the recurrence-free survival difference between limited axillary node surgery and axillary node dissection (ALND) in clinical N0 primary breast cancer patients with one to three sentinel node metastasis who underwent total mastectomy. **Method** We retrospectively analyzed clinical data of 579 primary breast cancer patients who underwent total mastectomy between 2014 and 2018 from Seoul National University Hospital and Asan Medical Center. All included patients had clinical T1-2, N0 disease at the time of diagnosis based on physical exam, radiologic evaluation, and pathologic assessment if needed. The patients had one to three metastatic sentinel node(s) at the time of surgery. The patients received sentinel lymph node biopsy (SLNB) with result of one to three metastatic node(s) and either proceeded to ALND or not. We performed propensity score matching between the SLNB and ALND group with baseline clinical factors including clinical T stage and number of metastatic sentinel node(s). Finally, 208 patients were matched 1:1 for each group respectively for further analysis. Also, we stratified the eligible patients based on radiation therapy for subgroup analysis. We examined disease-free survival, regional recurrence-free survival, distant metastasis-free survival and compared the results between the groups. **Result** The median follow-up period was 64.7 months. Among matched cohorts, mean number of metastatic nodes on final pathology result was 1.2 for SLNB group and 1.7 for ALND group. Also, mean number of total removed nodes was 8.3 for SLNB group and 17.4 for ALND group. The disease-free survival [DFS] at 7 years was 89.7% for SLNB group and 91.1% for ALND group with no statistically significant difference. (hazard ratio [HR] 1.43, 95% confidence interval [CI] 0.70 to 2.92, p=0.32) Among patients who were treated with radiation, the DFS was 94.1% in the SLNB group and 94.4% in the ALND group. (HR, 0.82, 95% CI 0.17 to 4.0, p=0.81) For the subgroup without radiation, the DFS was 87.7% in the SLNB group and 89.4% in the ALND group. (HR, 1.68,

95% CI 0.75 to 3.75, $p=0.19$) We observed no statistically significant differences in the regional recurrence-free survival at 7 years (95.8% in the SLNB vs. 95% in the ALND, HR 0.62, 95% CI 0.53-4.95, $p=0.39$), and in the distant metastasis-free survival at 7 years (95.8% in the SLNB vs. 95% in the ALND, HR 1.28, 95% CI 0.59 to 2.73, $p=0.52$) Conclusion Our results suggest that limited axillary surgery with sentinel node biopsy may be as effective as axillary node dissection in terms of recurrence-free survival, for clinically node negative, primary breast cancer patients with limited metastatic sentinel node(s) who are candidates for total mastectomy. Key words: Breast cancer, Total mastectomy, Axillary lymph node dissection, Sentinel lymph node biopsy.

Background Breast surgery is not standard treatment for metastatic disease, however several recent retrospective studies have suggested that breast surgery could increase survival. These studies have methodological limitations including selection bias. A systematic review mapping all randomized controlled trials addressing the benefits and potential harms of breast surgery is ideal to answer this question. **Objectives** To assess the effects of breast surgery on long term outcomes of women with metastatic breast cancer. **Search methods** We conducted searches using the MeSH terms 'breast neoplasms', 'mastectomy', and 'analysis, survival' in the following databases: the Cochrane Breast Cancer Specialised Register, CENTRAL, MEDLINE (by PubMed) and Embase (by OvidSP) on 08 December 2021. **Selection criteria** The inclusion criteria were randomized controlled trials of women with metastatic breast cancer at initial diagnosis comparing breast surgery plus systemic therapy versus systemic therapy alone. The primary outcomes were overall survival and quality of life. Secondary outcomes were progression-free survival (local and distant control), breast cancer-specific survival, and toxicity from local therapy. **Data collection and analysis** Two review authors independently conducted trial selection, data extraction, and 'Risk of bias' assessment (using Cochrane's 'Risk of bias'

tool), which a third review author checked. We used the GRADE tool to assess the quality of the body of evidence. We used the risk ratio (RR) to measure the effect of treatment for dichotomous outcomes and the hazard ratio (HR) for time-to-event outcomes. We calculated 95% confidence intervals (CI) for these measures. We used the random-effects model, as we expected clinical or methodological heterogeneity, or both, among the included studies. Main results We included four trials enrolling women with metastatic breast cancer in the review. These studies included 961 participants, 477 in the surgery group, and 485 in the control group. The evidence suggests that surgery does not improve overall survival as the quality of the evidence has been assessed as very low (HR 0.92, 95% CI 0.72 to 1.18; 4 studies; 961 women). The evidence suggests that surgery does not improve overall survival subgroup analysis according to the number of metastasis sites (HR 1.08, 95% CI 0.74 to 1.58; 3 studies, 320 women); bone metastasis only (HR 0.86, 95% CI 0.67 to 1.11; 3 studies, 253 women). According to the tumor subtype surgery seems not improve the overall survival in triple-negative (HR 1.10, 95% CI 0.53 to 2.28; 3 studies, 132 women) and HER 2 positive profile (HR 0.83, 95% CI 0.63 to 1.11; 3 studies, 262 women). However, for patients with luminal tumors surgery can significantly or marginally increase the survival (HR 0.81, 95% CI 0.67 to 0.98; 3 studies, 547 women). Breast surgery may improve local progression-free survival (HR 0.48, 95% CI 0.27 to 0.84; 3 studies; 686 women; low-quality evidence), while it does not change distant progression-free survival (HR 1.03, 95% CI 0.77 to 1.36; 3 studies; very low-quality evidence). Two studies reported quality of life outcomes, however it was not possible to perform a meta-analysis due to different tools used by these trials. Authors' conclusions Based on existing evidence from four randomized clinical trials, breast surgery does not to improve overall survival for women with metastatic breast cancer. However, in subgroup analysis, women with luminal tumors present increase in survival. The quality of evidence was very low and the decision to perform breast surgery on these women should be individualized and discussed by a multidisciplinary team considering the potential risks, benefits, and costs of each intervention.

Introduction:

Surgery is the mainstay treatment of breast cancer and has been improving in aesthetic outcomes even in locally advanced disease. Radical mastectomies are being replaced by less aggressive surgeries with immediate breast reconstruction. Nipple-Sparing Mastectomy (NSM) preserves Nipple Areolar Complex (NAC) along with the entire breast skin envelope and is associated with better aesthetic results and quality of life, improving patient satisfaction. Since NSM is a relatively recent technique and few studies have shown the feasibility of NSM after neoadjuvant chemotherapy (NACT), there are some concerns and controversies about its oncological safety, especially, with regard to the NAC recurrence due to the remaining tissue in the retroareolar area. This study compares the long-term oncological outcomes and correlated factors of NSM and skin-sparing mastectomy (SSM) after NACT.

Methods:

After approval by the institution's ethics committee a retrospective review was conducted to identify all patients who underwent NSM and SSM with immediate breast reconstruction after NACT between January 2011 and December 2018 at Centro de Doenças da Mama- Breast Unit Hospital Nossa Senhora das Graças. Metastatic disease, recurrent breast cancer, and other types of mastectomies were excluded. Clinicopathological and survival data, as well as recurrence events were collected from the electronic medical records. NSM was offered to the patients without involvement of the NAC and skin clinically and on imaging. All patients underwent ultrasonography, mammography and breast MRI in the preoperative period, as well as breast MRI after NACT. The decision to undergo adjuvant radiotherapy was determined by the treating radiation oncologists according to NCCN and ASTRO recommendation. A propensity score match was used to reduce the effect of selection bias on type of surgery and create well-balanced groups. The covariates included for matching were: anatomical stage, radiotherapy and molecular subtype.

Results:

A total of 188 patients underwent mastectomy in this period, 134 NSM and 54 SSM. After propensity score matching, 92 patients in the NSM group were matched to the 54 patients in the SSM group. The median follow up time was 44,7 months to NSM and 40,3 months to SSM. The characteristics of patients included in both groups after propensity score matching are described in Table 1. NAC recurrence was observed in 5 (5.4%) of 92 NSM patients, and median time of recurrence was 24.2 (11.7- 40.1) months. Ki67 showed a significant relationship with relapse in the NAC. The distance from the tumor to the NAC and other clinicopathologic variables were not correlated with NAC recurrence (Table 2). There were no significant differences between the groups in locoregional recurrence ($p=0.102$), distant metastasis ($p=0.223$) and death ($p=0.610$) (Table 3).

Conclusion:

In this matched control study, there was no difference in oncological outcomes in patients submitted to NSM and SSM after NACT, suggesting NSM with immediate breast reconstruction is a feasible option in this setting.

Targeted Axillary Lymph Node Dissections Using Radar Reflector Localization Can Reduce Unnecessary Axillary Lymph Node Dissections in Node Positive Patients Treated with Neoadjuvant Chemotherapy

Presenting Author(s) and Co-Author(s):

Background Targeted axillary dissection (TAD) is a surgical strategy that involves staging the axilla through sentinel lymph node biopsy (SLNB) combined with the removal of a biopsy-proven positive lymph node identified by a clip. TAD reduces the false negative rate of SLNB alone in patients with clinically detected nodal metastasis who receive neoadjuvant chemotherapy (NAC) while avoiding axillary lymph node dissections (ALND). Radar reflector-localization (RRL) can be used to identify previously positive nodes and safely and effectively guide dissection. **Methods** We performed an institutional retrospective chart review of breast cancer patients with clinical stage T1-3 and N1-3 disease treated with NAC from 2015 to 2020 who had a biopsy proven positive node and underwent TAD using RRL. The primary outcome was the retrieval of clipped node as documented by gross visualization or specimen radiography. Secondary outcomes included pathologic complete response rates and completion axillary lymph node dissections (cALND). **Results** 79 patients were identified who fulfilled inclusion criteria. 32 (40.5%) had RRL markers placed prior to chemotherapy (mean 187 days prior to surgery) and 47 (59.5%) had RRL markers placed following the completion of chemotherapy (mean 7 days prior to surgery). The clipped node was retrieved in 77 patients (97.5%). 32 of the 34 ypN0 (i+) patients avoided an ALND; 1 patient had a cALND for failure to localize the RRL and 1 patient had a cALND for a false-positive on frozen section. There was no significant difference in clip recovery rates in the pre vs post NAC RRL groups ($p=1.00$). **Conclusion** RRL systems are an effective way to guide TAD with a high success rate in identifying and removing previously biopsied nodes. These markers can be placed prior to NAC without migration or deactivation. This strategy allows surgeons to avoid unnecessary cALND.

Comparison of robot-assisted nipple sparing mastectomy with conventional nipple sparing mastectomy: a single-center experience.

Presenting Author(s) and Co-Author(s):

Ji Young You, MD, PhD, *Clinical Assistant Professor - Korea University Anam Hospital*
Country: United States

Haemin Lee, MD, *Clinical Assistant Professor - Korea University Anam Hospital*
Country: United States

Eun-Shin Lee, MD, *Clinical Assistant Professor - Korea University Anam Hospital*

Seung Pil Jung, MD, PhD, *Professor - Korea University Anam Hospital*
Country: United States

Purpose: Robot-assisted nipple-sparing mastectomy (RANSM) improves cosmetic outcomes compared to conventional nipple-sparing mastectomy (CNSM) since RANSM is performed with minimal incisions. However, there are few studies on the feasibility and surgical outcome of RANSM. The aim of this study was to compare the surgical outcomes of RANSM and CNSM in breast cancer patients. Method: A retrospective observational study was conducted at our institution between January 2021 and December 2021. A total of 54 patients diagnosed with breast malignancy that underwent either a robotic-assisted or conventional nipple-sparing mastectomy were included. The demographics of the patient's sex, age, body mass index (BMI), breast weight, and preoperative diagnosis were investigated. The surgical method, operation time (including docking time and console time in the case of robotic surgery), postoperative complications, length of hospital stay, pain score, and adjuvant therapy were analyzed. Result: A total of 57 breasts in 54 female patients were included in the study: 36 invasive ductal carcinoma patients, 11 ductal carcinoma cases, 6 invasive lobular carcinoma, 2 mucinous carcinoma, one solid papillary carcinoma and one lobular carcinoma in situ. A median age of 49(27-66), mean BMI of 22 (18.89-26.28), and mean breast weight was 246 g (120-305g). The mean operation time was 122 minutes (robotic 140 vs. conventional 118), and the average docking time was five minutes and console time 60 minutes in the robot-assisted surgery. There was only one postoperative complication in the robot group and ten cases in the conventional group. The mean hospital stay was 12.6 days (RANSM 10.75 vs. CNSM 12.92), and the average pain score was 3.53 (RANSM 3.50 vs. CNSM 3.54). None needed adjuvant therapy in the robot group. In the conventional surgical group, four patients underwent adjuvant radiotherapy and sixteen patients underwent chemotherapy including six neoadjuvant cases. Conclusion: Our results showed that RANSM had advantages of shorter hospitalization and lower pain scores although it had slightly longer operation time and could not be applicable in relatively large breasts. In the near future, RANSM may be considered as the surgery of choice over CNSM in breast cancer patients.

Introduction:

Targeted Axillary Dissection (TAD) is the combination of the sentinel lymph node biopsy

(SLNB) and retrieval of the clipped node that was proved positive before neoadjuvant treatment (NAT). Previous studies have demonstrated that this approach has a low false-negative rate in patients with cN+ before NAT. Current guidelines recommend axillary radiotherapy in cN+ despite a complete pathological response reported after NAT.

Aim:

To evaluate if TAD improves the quality of life and arm functionality compared to axillary lymph node dissection (ALND) in patients with cN+ before NAT.

Methods:

Prospective observational study. The study started in 2017 and ended in 2021. We included patients with one to three suspected lymph nodes and at least one confirmed by fine-needle aspiration. Suspicious lymph nodes were clipped before NAT. After NAT if a complete radiological response was achieved by axillary ultrasound, TAD was performed. During surgery, we used ultrasound-guided marked lymph node dissection and dual tracer SLNB. Clipped and SLN were assessed with intraoperative frozen section H&E, standard H&E, and IHC with CKAE1/AE3. After surgery, the breast tumor board analyzes the pathological findings and the surgical performance. When ITC, micro-metastases, or macro-metastases were found in the nodes, or when surgical performance is considered suboptimal, we proceed to ALND. We assessed QoL with standard forms and upper extremity mobility and lymphedema by physical examination.

Results:

We analyzed 44 women. Median age 53.9 years old. ALND was performed on 28 patients and TAD on 16 patients. Age and other confounding factors such as (BMI, type of surgery, and type of NAT) were similar in both groups. Median follow-up time: 24 months (5-60). No regional relapse in both groups. The axillary staging is shown in table 1. The surgical procedure and indications for ALND are shown in Table 2. Any patient with a Luminal-A-like profile had an axillary response to NAT and subsequent ALND was performed in all 4 patients. By contrast, patients with HER2 overexpression or triple negatives had better axillary responsiveness and 12/21 were stratified only with TAD. Two patients had a false positive finding on the post-NAT axillary ultrasound (one patient with LuminalB-Her2 positive tumor and one patient with HER2 positive not luminal) and ALND was performed, complete pathological response with only fibrosis was observed. Indications of ALND are shown in table 1. On the questionnaires, health status perception (84.9 TAD vs 65.77 ALND, $p=0.02$), QoL (83.33 TAD vs 64.29 ALND $p=0.03$), upper extremity symptoms (8.33% TAD vs 30.16% ALND, $p< 0.01$) and breast symptoms (14.06% TAD vs 31.25% ALND, $p=0.03$) are better on TAD than in ALND patients. On physical examination, 11 patients of the ALND group had some alteration in functionality (8 patients had limitation of abduction and 7 patients had lymphedema). By contrast, any alteration was found in the patients staged only with TAD.

Conclusions:

Targeted axillary dissection reduces posttreatment symptomatology and allows a better quality of life with no axillary relapses though follow-up is short. Patients with Luminal-A-like cancer probably are not good candidates for TAD because of a lack of responsiveness and perhaps another approach must be considered.

Objective :

Sentinel lymph node biopsy (SLNB) is currently used as a routine treatment for breast cancer patients. Many clinical studies, such as the NSABP B-32, have demonstrated that SLNB can safely replace axillary lymph node dissection (ALND) for patients with clinically node-negative breast cancer. However, it may not be applicable for male breast cancer (MBC) patients because they have notably different clinicopathological features from those occurring in females. There is a lack of evidence of SLNB application and safe exemption from ALND in MBC patients. This study aimed to evaluate the application of SLNB to provide information for the standardized treatment of MBC patients.

Methods :

The MBC patient records from four institutions ranging from January 2001 to November 2020 were retrospectively reviewed. Patients undergoing surgery as a primary treatment were included. Patients with stage IV and non-primary breast cancer were excluded. Patients were followed up postoperatively for survival analysis. The primary outcome was disease-free survival (DFS), and the secondary outcome was overall survival (OS).

Results :

There were 220 MBC patients with a median age of 60 (range 24-88) years and an average tumor size of 2.3 cm (range 0.5 cm - 6.5 cm). MBC patients were characterized by old age, advanced stage, and higher pathological grade. The median follow-up time was 5.0 (range, 1.0-17.3) years. Survival analysis showed the 5-year DFS and OS were 73.5% and 83.3%, respectively. 66 patients (30%) underwent SLNB and 39% of them showed positive results. 157 patients (71%) underwent ALND, while only half of them had positive nodes, causing unnecessary complications. For 92 patients at clinical early-stage (stage I or IIA), 28 patients only had SLNB as axillary treatment, 26 patients only had ALND and 38 patients underwent

SLNB and ALND. From Kaplan-Meier survival analysis, we found that the SLNB showed a non-inferiority to the ALND treatment in DFS ($p=0.18$) and OS ($p=0.055$).

Conclusion :

MBC patients are older at the time of diagnosis and present a higher pathological grade. There are certain obstacles to the broad application of SLNB due to the lower proportion of clinically-negative lymph node patients. However, it is undeniable that SLNB can safely and effectively exempt MBC patients at early-stage with clinically-negative nodes from ALND to reduce subsequent complications. It's still an ideal criterion for the axillary staging of MBC patients.

Clinicopathologic characteristics of MBC patients

The Omental Fat-Augmented Free-flap (O-FAFF) is being offered at our institution as an alternative method of breast reconstruction. This novel free-flap construct is ideal for underweight and normal weight women who lack abdominal or other donor tissue, desire to avoid donor site morbidity and/or are averse to implant-based reconstruction. We analyze omentum, mastectomy and final construct weights in women with BMI < 25 kg/m² who underwent nipple-sparing mastectomies and O-FAFF reconstruction. Methods Operative technical features of women undergoing nipple-sparing mastectomies with immediate O-FAFF breast reconstruction over a 34 month period are included. Steps of the operative procedure are as follows : laparoscopic omentectomy, liposuction and unilateral or bilateral mastectomy is performed. An acellular dermal matrix (ADM) shell is fashioned around a tissue expander. This mold is filled with the omentum and then engrafted with lipoaspirate followed by microsurgical anastomoses of gastroepiploic artery and vein to internal mammary artery and vein. Weight of biological construct is compared to native breast weight. Results 26 women with average BMI 21.2 kg/m² underwent unilateral (15) or bilateral (11) nipple-sparing mastectomies and O-FAFF reconstruction. Average omentum weight for 37 breasts was 149 gm (82- 262) and average mastectomy weighed 212.4 gm (85 – 396). The ratio of engrafted fat to omentum weight was 0.73 for unilateral versus 0.91 for bilateral cases. The ratio of omentum-fat graft construct to mastectomy weight was 1.24 for unilateral and 0.96 for bilateral cases. Conclusion O-FAFF is a novel procedure for autologous tissue breast reconstruction after nipple-sparing mastectomy in underweight and normal weight women. Comparable weight replacement for extirpated native breast is achieved.

Introduction: Post-mastectomy radiotherapy (PMRT) is an important component of breast cancer treatment and has been shown to improve overall survival for women with large cancers or node positive disease. The long-term effects of radiotherapy on the outcomes of immediate breast reconstruction (IBR) and how these are perceived from the patients' perspective, however, are largely unknown. The UK Brighter study aimed to evaluate the long-term impact of PMRT on the patient-reported outcomes of IBR to support informed decision-making.

Methods: Women who underwent unilateral mastectomy and/or breast reconstruction for invasive breast cancer or ductal carcinoma in situ (DCIS) in England between 1/4/2008 and 31/3/2009 were identified from National Health Service (NHS) Hospital Episode Statistics

(HES), and current contact information for the surviving cohort provided by the NHS Personal Demographic Service. Women were sent a letter inviting them to complete three validated patient-reported outcome questionnaires, the BREAST Q, EQ-5D-5L and ICECAP-A, electronically or by post at a minimum of 12 years following their index surgery. Questionnaires were scored according to developers' instructions and scores for women who had received PMRT following IBR compared with those who underwent IBR without radiotherapy, in the cohort as a whole and by reconstruction type. Results: 11,977 women were invited to participate of whom 4,207 (35.1%) completed the questionnaires. Some 1,236 (29.4%) underwent IBR with 343 (27.8%) expander/implant (EI) reconstructions, 629 (50.9%) latissimus dorsi (LD) flaps with or without (+/-) an implant, and 264 (21.4%) abdominal flap (AF) reconstructions. Of these, 388 (31.4%) (EI n=79 (20.4%); LD+/--implant n=222 (57.2%); AF n=87 (22.4%)) received PMRT. In the cohort overall, women who received PMRT following IBR reported significantly lower 'Satisfaction with Breasts' scores at 12 years compared with those who did not receive radiotherapy (PMRT mean 56.4, standard deviation (SD) 21.5 vs. no PMRT mean 61.3, SD 20.5), $p < 0.001$). However, this difference varied across procedure types. Specifically, the 'Satisfaction with Breasts' scores of women receiving PMRT following AF reconstruction were 10.5 points lower than those not receiving PMRT (PMRT mean 60.9, SD 20.2; no PMRT mean 71.4, SD 19.6, $p < 0.001$). This difference was lower in women undergoing LD reconstruction (mean with PMRT 54.3, SD 21.1; mean without PMRT 61.6, SD 20.7; $p < 0.001$). There were no significant differences in women undergoing EI reconstruction (PMRT mean 57.5, SD 23.6, no PMRT mean 53.9, SD 17.7). 'Physical Well-being' (chest) scores were also significantly lower in women receiving PMRT following IBR in the cohort overall (PMRT mean 78.7, SD 20.1, no PMRT 83.6, SD 18.6, $p < 0.001$) but women undergoing AF reconstruction showed the greatest difference in scores (PMRT mean 83.2, SD 17.0 vs No PMRT mean 90.1, SD 15.0, $p < 0.001$). There were no significant differences in 'Physical Well-being' scores for women who underwent EI reconstruction with or without PMRT. 'Psychosocial Well-being' scores were lower in women receiving PMRT after IBR (PMRT mean 70.8, SD 22.0, No PMRT 75.4, SD 21.0), but again, differential effects were seen by procedure type with no significant differences seen in the EI group but significant differences in scores seen in women receiving PMRT after flap-based procedures. Conclusions: Women undergoing PMRT report significantly lower long-term patient-reported outcomes of flap-based reconstruction, in particular 'Satisfaction with Breasts' and 'Physical Well-being' scores. This difference was not apparent in women undergoing EI procedures. This information should be shared with patients to help them make fully informed decisions about the type and timing of their reconstructive surgery.

Purpose: Since 2015, mastectomy with immediate implant-based reconstruction at our institution is an ambulatory "day surgery" procedure. Ambulatory criteria for surgery including ASA level, BMI and major comorbidities were used to screen patients. We aim to evaluate surgical outcomes for women who undergo ambulatory mastectomy with immediate alloplastic reconstruction for breast cancer or risk reduction. Our primary objective was to determine the impact of mastectomy type (nipple- or skin-sparing mastectomy) and device location (subpectoral versus prepectoral plane) on complication rates.

Methods: We performed a retrospective cohort study of women receiving immediate alloplastic reconstruction following mastectomy for either breast cancer or risk reduction at Women's College Hospital in Toronto, Ontario, Canada between 2015 and 2021. We collected demographic data on age, ethnicity, smoking status, and menopausal status. Clinical data collected included breast size, ptosis, surgical indications, laterality, location and type of implant, type of mesh used, and overall complication rate. We used a multivariable logistic regression model to determine the impact of mastectomy type and implant location on complication rates, with age, smoking status, breast size, ptosis, surgical indication, and use of mesh as covariates. Statistical analysis was performed using SAS® OnDemand for Academics and P values < 0.05 were considered statistically significant.

Results: 284 women underwent mastectomy with immediate alloplastic reconstruction for risk

reduction (130, 45.8%) and breast cancer (154, 54.2%). 134 (47%) underwent skin-sparing mastectomy (SSM) and 149 (53%) underwent nipple-sparing mastectomy (NSM). Demographic and clinical data are presented in Table 1. There was an overall complication rate of 19.4%; women having NSM had a higher crude complication rate compared with SSM (25.5% vs 12.6%, $P = 0.006$). In our multivariable logistic regression model, there was no interaction between mastectomy type and device location on complication rate ($P = 0.5$). There was also no difference in complication rates associated with SSM compared with NSM (OR 2.9, 95% CI 0.95 – 9.0, $P = .06$) or implant location ($P = 0.1$). Younger age (OR 0.93/year increase in age, 95% CI 0.89-0.98, $P = 0.005$) and having surgery for breast cancer (OR 3.4, 95% CI 1.1 – 10.2, $P = 0.03$) were associated with an increased likelihood of complications.

Conclusion: In women undergoing ambulatory mastectomy with immediate alloplastic reconstruction for breast cancer or risk reduction, there was no impact of mastectomy type (SSM vs NSM) or implant location (subpectoral vs prepectoral) on complication rates. Non-modifiable factors such as age and having surgery for breast cancer predicted having a complication. Our data suggest that with appropriate patient selection, there is no difference in surgical outcomes between mastectomy types and implant location in the ambulatory surgery setting.

Prepectoral versus subpectoral implant-based breast reconstruction: A systemic review and meta-analysis. Edvin Ostapenko, MD^{1,2}, Larissa Nixdorf, MD¹, Yelena Devyatko, MD¹, Ruth Exner, MD¹, Kerstin Wimmer, MD¹, Florian Fitzal, MD¹ ¹Department of General Surgery and Breast Health Center, Medical University of Vienna, Vienna, Austria. ²Faculty of Medicine, Vilnius University, Vilnius, Lithuania

Abstract Background Implant-based breast reconstruction (IBBR) is still standard and most popular option for women undergoing breast reconstruction after mastectomy worldwide. Recently, prepectoral IBBR has resurged in popularity, despite limited data comparing prepectoral with subpectoral IBBR. **Methods** A systematic search of PubMed and Cochrane Library from January 1, 2011, to December 31, 2021, was performed following the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) reporting guideline, data were extracted by independent reviewers. Random and fixed-effect models were applied to obtain pooled proportions and 95% CIs. The Risk of Bias in Nonrandomized Studies- of Interventions (ROBINS-I) tool was used for critical appraisal of cohorts and funnels plots, and the Egger bias test were used for evaluating the publication bias. Studies that compared prepectoral IBBR with subpectoral IBBR for breast cancer were included. **Results** Overall, 15 studies with 3101 patients were included in this meta-analysis. Our results showed that patients receiving prepectoral IBBR experienced fewer capsular contracture (odds ratio [OR], 0.54; 95% CI, 0.32-0.92; P=.02), animation deformity (OR, 0.02; 95% CI, 0.00-0.25; P=.002), and prosthesis failure (OR, 0.58; 95% CI, 0.42-0.80; P=.001). There was no significant difference between prepectoral and subpectoral IBBR in overall complications (OR, 0.83; 95% CI, 0.64-1.09; P=.19), seroma (OR, 1.21; 95% CI, 0.59-2.51; P=.60), hematoma (OR, 0.76 95% CI, 0.49-1.18; P=.22), infection (OR, 0.87; 95% CI, 0.63-1.20; P=.39), skin flap necrosis (OR, 0.70 95% CI, 0.45-1.08; P=.11), and recurrence (OR, 1.31; 95% CI, 0.52-3.39; P=.55). Similarly, no significant difference was found in Breast-Q scores between prepectoral and subpectoral IBBR groups. **Conclusion** The results of our

systematic review and meta-analysis demonstrated that prepectoral implant-based breast reconstruction is a safe modality and have similar outcomes with significantly lower rates of capsular contracture, prosthesis failure and animation deformity compared to subpectoral implant-based breast reconstruction. Future research should include randomized clinical trials or well-designed prospective matched studies with adequate follow-up to assess long-term as well as oncologic outcomes between comparative groups. Key Words: immediate implant-based breast reconstruction, breast cancer, outcomes, prepectoral, subpectoral;

Although multi-modal and ablative treatment strategies for breast cancer are becoming more popular, partial or full mastectomy is still a most common intervention. While proving to be effective in curing the cancer, it leaves the patient disfigured, which can pose a considerable psychological burden. Hence, reconstructive breast surgery is continuing to increase in importance as it offers the possibility to at least partially restore the original look of the breast. Autologous adipose tissue transfer techniques, amongst them the surgical gold standard flap surgery and liposuction-based fat grafting, present natural solutions with the patient's own tissue, but either produce a considerable secondary wound or are insufficient to address larger defects. Synthetic solutions like silicone implants on the other hand can also be used to fill large defects and only require minimal surgical intervention, but suffer from foreign body-associated complications like fibrosis. Tissue engineering biological breast implants of arbitrary size with no or minor insult to the patient's body and excellent biocompatibility, exclusively using biomaterials and patient-specific adipose cells, could open a new chapter for breast reconstruction. Such an approach has become an intriguing possibility through the rise of powerful biofabrication technologies in the last two decades, namely three-dimensional bioprinting. Bioprinting marries additive manufacturing with biomaterials and living cells with the aim to create life-mimicking tissues and organs, and while it is mainly focused on research today, current endeavors push for application in regenerative medicine. In our work we sought to fabricate adipose tissue constructs using light-based bioprinting to investigate the potential application of such technology for future reconstructive breast surgery. The engineered tissue blocks were designed to mimic native human adipose tissue by comprising fat, connective tissue and endothelial cells. Being specifically placed by the bioprinter within extracellular matrix-like hydrogels, the cells were cultured in vitro and differentiated within the cultivation time

of up to 4 weeks to form an adipose-like tissue. Live imaging showed high viability of bioprinted tissue blocks over the whole cultivation period and pronounced cellular reorganization. Confocal and histological analyses revealed a dynamic tissue maturation process with increasing proportions of differentiated adipocytes, ECM remodeling and formation of microvascular structures. In conclusion, the obtained results gave proof to the concept of engineering adipose tissue through bioprinting and could lay the groundwork for the development of all-natural biological breast implants.

Background: Asian women have relatively small breast sizes compared to European American women, so the latissimus dorsi flap (LDF) is the most commonly used autologous flap for breast reconstruction in Chinese patients with breast tumor. To explore the current status of LDF with or without implants (IMP) breast reconstruction in China, we conducted this study. Methods: This study was a single-center retrospective study that included breast tumor patients who underwent LDF breast reconstruction in Fudan University Shanghai Cancer Center (FUSCC) from 2000 to 2019. The basic clinicopathological information, the timing and type of reconstruction, postoperative hospitalization time and serious complications requiring surgical intervention were analyzed. Continuous variables were expressed as mean values or median values, while categorical variables were expressed as frequencies. Data were analyzed by using Chi-square and Kruskal-Wallis tests. All P values reported were two-sided and were calculated at a significance level of 0.05. Results: A total of 2868 patients who underwent breast reconstruction for breast tumor were analyzed in this study, 785 (27.4%) patients used LDF for breast reconstruction, and 397 (13.8%) patients underwent autologous breast

reconstruction utilizing abdominal flap. The number of breast reconstruction patients and the diversity of reconstruction procedures were increasing year by year. Breast reconstructions utilizing LDF have decreased as a percentage of breast reconstructions, but have increased in number in the past few years. Among patients with LDF breast reconstruction, the majority (97.3%) underwent immediate reconstruction, 11 patients underwent delay reconstruction, and 10 patients underwent immediate-delay reconstruction. 448 patients underwent expanded LDF breast reconstruction, and 337 (42.9%) patients underwent LDF combined with IMP breast reconstruction. 13 patients underwent restoration of reconstructed breast with LDF, 12 of which were changed to LDF±IMP reconstruction due to unsatisfactory outcome of expander reconstruction or failed implant reconstruction, and one patient was changed to LDF reconstruction from failed abdominal flap reconstruction. In terms of pathological type, 629 (80.1%) patients had invasive carcinoma, 129 (16.4%) had carcinoma in situ, 18 (2.3%) patients had phyllodes tumor and 9 (1.1%) patients had other malignancies. The median reconstruction age of the patients was 37 years old, the mean BMI was 21.76kg/cm², and the mean postoperative length of stay was 11.13 days. There were no significant differences in postoperative hospitalization time, reconstruction age, BMI, pT, ER, PR, HER2, Ki67, and radiotherapy between patients with expanded LDF and LDF combined with IMP breast reconstruction. Patients with neoadjuvant therapy (P=0.045), phyllodes tumors or other malignant tumors (P=0.023), and those with more metastatic lymph nodes (P=0.031) were tent to expanded latissimus dorsi flap reconstruction. Serious complications requiring surgical intervention occurred in 13 patients (1.65%), including 7 patients who underwent surgical debridement or scar repair due to wound infection and poor healing, and 3 patients who removed the implant due to implant infection. The reconstructed latissimus dorsi flaps necrosis occurred in 3 patients, and the reconstructed breasts were removed in these patients. There was no significant difference in the incidence of serious complications requiring surgical intervention between patients with expanded LDF and those with LDF combined with implant reconstruction, P=0.79. Conclusions: LDF±IMP breast reconstruction is a mature breast reconstruction procedure in our center with high safety. Whether combined with implant reconstruction did not affect the postoperative hospitalization time and the incidence of serious complications.

Introduction: Nipple-sparing mastectomy (NSM) is a surgical alternative for patients who are not candidates for breast-conserving therapy in early breast cancer or even for women who are candidates for risk-reducing mastectomies, facilitating immediate breast reconstruction. Aesthetic incisions such as through the inframammary fold (IMF) or periareolar (PA) are viable options for radial scars, with better cosmetic results and less visibility. Little is known about early surgical complications between these two techniques. Objectives and methods The aim of this study was to evaluate early complications (NAC necrosis [mild, partial or total], infection, seroma, hematoma, dehiscence and reconstruction failure) in patients undergoing NSM via esthetic incisions (IMF or PA) and immediate breast reconstruction in a unique Brazilian institution. A retrospective analysis was performed at Hospital Geral de Fortaleza (HGF) between 2015 and 2022, including patients with a minimum follow-up of 3 months and complete data in the medical records. The following demographic parameters were evaluated: age, body mass index, co-morbidities, use of direct implant or tissue expander, breast weight and pre-pectoral or submuscular reconstruction. Pearsons chi squared tests and t-test were performed and a p value of < 0.05 was considered statistically significant. Results A total of 180 NSM through IMF (n=106) or PA (n=74) incisions were included and 43 cases (23.9%) of complications were observed: 27 in the PA group (62.8%) and 16 in the IMF (37.2%), with this difference being significant (p=0.0002). Regarding NAC necrosis, 65.4% were observed in the PA incision (n=17; 22.4%), compared to 34.6% in the IMF (n=9; 8.7%) (p=0.0023). There was no significant difference in relation to other complications (n=7 [IMF] vs n=10 [PA]), just as there was no difference in relation to the demographic parameters evaluated, except for the pre-pectoral and direct-to-implant reconstruction, which were more frequently performed in the IMF group: 19 (18.3%) vs 3 (4%) and 52 (50%) vs 24 (31.6%) cases respectively. Only 2 patients had breast reconstruction failure, both in the PA cohort. Conclusions Both incisions are viable

options for accessing the NSM, with an acceptable rate of complications. The PA incision is related to a higher complication rate compared to IMF, based mainly on the NAC necrosis rate. More studies are needed for a better understanding of this scenario.

Background and Purpose In breast cancer patients receiving neoadjuvant chemotherapy (NAC), the use of immediate breast reconstruction (IBR) as a breast cancer treatment option remains controversial. The Japanese breast cancer society conducted retrospective multicenter

cohort study in the era of IBR, and we assessed the impact of NAC on surgical and oncological outcomes in patients underwent IBR. Methods Between January 2008 and December 2016, 473 (10.0%) breast cancer cases received NAC of 4726 cases underwent IBR after mastectomy. The clinicopathological and survival data of patients who received NAC (the NAC group) and those who did not receive NAC (the control group) were compared in terms of postoperative complications (infection, hemorrhage, seroma, dehiscence, tissue expander or implant loss, flap or skin necrosis) and oncologic safety. Results Eight-hundred forty cases had minor or major complications. NAC did not increase the risk of complications after IBR (OR 1.20; 95%CI 0.95 - 1.53; p = 0.13). Smoking (OR 1.35; 95%CI 1.14 - 1.62; p = 0.001), overweight (BMI \geq 25) (OR 1.94; 95%CI 1.61 - 2.35; p < 0.001), PMRT (OR 1.54; 95%CI 1.20 - 1.99; p = 0.01) increased risk of complications. At the median follow-up time of 76.5 months, 36 patient (7.6%) in the NAC group and 147 patients (3.5%) in the control group had local recurrence. 35 patient (7.4%) in the NAC group and 147 patients (2.0%) in the control group had regional recurrence. Conclusion Immediate breast reconstruction after NAC is a safe procedure with post-operative complication profile. It can be performed safely and therefore should be considered as a strategy preferred for patients with local advanced breast cancer.

Impact of the withdrawal of textured breast implants from the market on breast reconstruction practices

Presenting Author(s) and Co-Author(s):

CLEMENTINE JANKOWSKI, MD, *Surgeon - Centre Georges-François Leclerc, DIJON, FRANCE*

Country: United States

Maxime Martinez, *n/a, Surgeon - Centre Georges François Leclerc, Dijon*

CHARLES COUTANT, MD, PhD, *Surgeon - Centre Georges-François Leclerc, DIJON, FRANCE*

Country: United States

Background: In November 2018, the SOFCPRE (Société Française de chirurgie plastique, reconstructrice et esthétique) recommended that textured Biocell© implants should no longer be used because of a potential risk of anaplastic large cell lymphoma (ALCL). This decision was confirmed in April 2019 by the French Medicines Agency (ANSM, Agence nationale de sécurité du médicament), and the French Medical Regulatory Authority. In the Georges-François Leclerc Cancer Center (Dijon, France), we suspended the use of textured Biocell© implants from November 2018 onwards, in favour of smooth surface, round implants.

Objective: To assess the impact of textured implant withdrawal on surgical practices in breast reconstruction (BR) in a single French cancer center.

Methods: This is a retrospective, single-centre study in the Georges-François Leclerc Cancer Center (Dijon, France). Surgical practices of BR and complications were compared between 2 periods : before the withdrawal of textured implants from the market (Period 1 : September 2017-November 2017) and after (Period 2 : December 2018-March 2020). Patients were included if they were operated on for the first time for immediate or secondary BR in either period. Univariate analysis was performed to compare before vs after groups, and to analyse surgical practices (rates of autologous techniques and breast implant) of BR and complications ((defined as any complication grade IIIB or higher according to the Clavien Dindo classification) between the 2 periods.

Results: Data from 168 and 159 BR were collected from Periods 1 and 2 respectively. Characteristics were comparable between groups. The rate of BR with implants was significantly lower in period 2 compared with period 1 (23.9% vs 53.6% ; $p < 0.001$). Similarly, autologous BR increased significantly in period 2 for muscle sparing latissimus dorsi (2.4% vs 12.6% ; $p < 0.001$) and exclusive fat grafting (9.5% vs 21.5% ; $p < 0.01$). Others autologous techniques was comparable between the two periods (DIEP and latissimus dorsi). The number of complications decreased in period 2 (10% vs 18.4% in period 1, $p = 0.04$).

Conclusion : After the withdrawal of textured implants, we observed a significant change in surgical practices for BR in our center. The rate of reconstruction with implants decreased in favour of autologous techniques. This change in practice was accompanied by a decrease in

complications.

Surgical techniques for breast reconstruction between the two periods

	Period 1 (n=167)	Period 2 (n=159)	p
Breast reconstruction with implant	90 (53.9%)	38 (23.9%)	<0.001
Autologous reconstruction	77 (46.1%)	121 (76.1%)	<0.01
DIEP	27 (16.2%)	33 (20.8%)	0.36
Latissimus dorsi flap	30 (18%)	34 (21.4%)	0.52
Muscle sparing latissimus dorsi flap	4 (2.4%)	20 (12.6%)	<0.001
Exclusive lipofilling	16 (9.6%)	34 (21.4%)	<0.01
Timing of breast reconstruction			0.08
Immediate	81 (48.5%)	61 (38.4%)	
Secondary	86 (51.5%)	98 (61.6%)

The Kinesin-like protein Kif11 is essential for the Survival of TP53-mutant Triple Negative Breast Cancer Cells

Presenting Author(s) and Co-Author(s):

Background: Breast cancer is the most commonly diagnosed non-cutaneous malignancy in American women and one of the leading causes of cancer deaths. Breast cancer can be divided into several subtypes, the most aggressive of which is Triple-Negative Breast Cancer (TNBC), a disease with few targeted therapies. TP53 mutations are found in 80% or more of TNBCs. However, direct targeting of mutant TP53 has been difficult. To identify drugs that can specifically induce the death of TP53-mutant breast cancers, we conducted a drug screen in TP53-mutant and TP53-wild type breast cancer cells. Through this combined in silico and in vitro drug screen, we discovered that TP53 mutant TNBC cells have an increased sensitivity to KIF11 inhibition as compared to TP53 wild-type cells. Hypothesis: We hypothesize that TP53 mutational status confers sensitivity of triple-negative breast cancer cells to KIF11 inhibition. Methods: We obtained data on TP53 mutational status, KIF11 mRNA expression levels, and clinical characteristics from publicly-available TCGA, METABRIC, and CCLE datasets. To demonstrate the effect of KIF11 inhibition on cell growth, we treated TP53 mutant and wild-type breast cancer cell lines with the small molecule KIF11 inhibitor SB-743921 and KIF11 siRNAs. Cell counts were obtained through staining with DAPI or Hoechst nuclear stains and imaging on the MetaXpress PICO instrument. To determine protein expression of p53 and Kif11 across various cell lines, western blotting was performed. We then investigated the biological mechanisms of growth inhibition by DRAQ7 staining and flow cytometry analysis following Annexin V-PI staining. Results: Using cell growth assays we demonstrated that TP53 mutant cells are more sensitive to KIF11 inhibition. We next utilized cell lines in which TP53 mutations had been introduced into TP53 wild-type cells to show that overexpression of a TP53 mutant gene can sensitize cells to KIF11 inhibition. Using assays of proliferation and apoptosis, we showed that TP53 mutant breast cancer cells treated with a KIF11 inhibitor undergo cell death. Using publicly-available datasets of breast cancers, we showed that KIF11 is upregulated in TNBCs and TP53 mutant cancers, and that high expression of KIF11 in breast cancer is correlated with poorer clinical prognosis. Conclusions: Our results show that the Kif11 protein is essential for the survival of TP53 mutant TNBC cells. Inhibitors of Kif11 induce death of TP53 mutant TNBCs and thus, this kinesin-like protein involved in cell spindle mechanics is a potential target for the treatment of these aggressive cancers. Thioredoxin-interacting protein (TXNIP) plays a critical role in glucose metabolism and redox signaling through negatively regulating thioredoxin activity. Over the past decade, TXNIP has emerged as a novel tumor suppressor in various cancer models. In search of the molecular targets mediating the anticancer effect of an epigenetic drug UNC0642, we found TXNIP to be consistently upregulated by UNC0642, which was coupled with significant suppression of MDA-MB-231 breast cancer cell proliferation in vitro and tumor growth in vivo. TXNIP knockdown increased MDA-MB-231 cell proliferation and in vivo tumor growth and metastasis. In contrast, TXNIP-reconstitution in TXNIP-deficient HCC1954 breast cancer cells suppressed cell proliferation and migration that is coupled with increases in reactive oxygen species, strongly supporting TXNIP's potent antitumor function. TXNIP-reconstitution also decreased mitochondrial respiration and glycolysis in HCC-1954 cells as determined by using the Agilent Seahorse XF Cell Energy assays. To understand the molecular targets through which TXNIP exerted its antitumor activity, we performed co-immunoprecipitation studies and proteomic analyses to identify TXNIP-interacting proteins in UNC0642-treated MDA-MB-231 cells. Besides thioredoxin, we identified peroxiredoxin-6 (PRDX6), another modulator of cellular redox signaling, as a major TXNIP-interacting protein. While Prdx6-knockout mice develop normally, PRDX6 is frequently upregulated in breast cancer patients that is significantly associated with aggressive tumor subtypes and poor overall survival. The mechanism underlying the role of PRDX6 in breast oncogenesis remains elusive. Our findings suggest that TXNIP might exert its antitumor activity through binding and inhibiting PRDX6 activity in breast cancer cells to alter ROS signaling, thus providing novel therapeutic targets and potential prognostic biomarkers for breast cancer patients.

Epithelial-mesenchymal transition (EMT) inducing transcription factor TWIST1 plays a vital role in cancer metastasis. How the tumor-suppressive E3 ligase, Speckle-type POZ protein (SPOP), regulates TWIST1 in breast cancer remains unknown. In this study, we report that SPOP physically interacts with, ubiquitinates, and destabilizes TWIST1. SPOP promotes K63- and K48-linked ubiquitination of TWIST1, predominantly at K73, thereby suppressing cancer cell migration and invasion. Silencing SPOP significantly enhances EMT, which accelerates breast cancer cell migration and invasiveness in vitro and lung metastasis in vivo. Clinically, SPOP is negatively correlated with the levels of TWIST1 in highly invasive breast carcinomas. Reduced SPOP expression, along with elevated TWIST1 levels, is associated with poor prognosis in advanced breast cancer patients, particularly those with metastatic triple-negative breast cancer (TNBC). Taken together, we have disclosed a new mechanism linking SPOP to TWIST1 degradation. Thus SPOP may serve as a prognostic marker and a potential therapeutic target for advanced TNBC patients.

Background: Female breast cancer has been the world's leading cancer incidence among women. HER2-positive breast cancer accounts for about 15%~20% of all breast cancer, with a high degree of malignancy and easy metastasis and recurrence. With the development of medical technology and the continuous innovation of HER2 targeting drugs, patients with HER2-positive breast cancer have more treatment options and their prognosis had been greatly improved. However, there is still a lack of biomarkers for HER2-positive early breast cancer in clinical practice. Methods: This study prospectively collected single-center (Fudan University Shanghai Cancer Center, FUSCC) preoperative core needle biopsy samples of breast cancer patients from July 2017 to July 2018 who received neoadjuvant paclitaxel, carboplatin plus with trastuzumab (PCH). The patients were divided into pCR and non-pCR groups, and 81 patients were enrolled. The differential expression of genes was screened and validated by RNA-seq. The gene expression data for GSE181574 (this database has a total of 105 cases of breast cancer tissue samples were collected by core needle biopsy before neoadjuvant treatment. 52 cases underwent Ado-trastuzumab emtansine plus pertuzumab, 9 cases of paclitaxel plus trastuzumab, and 44 cases of paclitaxel plus trastuzumab and pertuzumab), GSE52707 (SK-BR-3 Lapatinib resistance cell group vs control group), and GSE15043 (BT474 Herceptin-resistant cell group vs control group), were downloaded from the Gene Expression Omnibus (GEO) database. Cell cloning formation, proliferation assay, and drug sensitivity experiments were conducted in MNX1 ectopic and knockdown cell lines. Co-IP assay, RNA-Seq, and ChIP-Seq analysis were used to explore the downstream pathways that MNX1 might be involved. Results: High-throughput sequencing results of core needle biopsy samples from 81 HER2-positive breast cancer patients were divided into pCR and non-pCR groups. Using DEseq2 packet analysis to screen differentially expressed genes, P-value < 0.05, | log2FoldChange | > 1 as the filter, there were 620 up-regulated genes and 715 down-regulated genes in the pCR group. The same method was used for the analysis of the GSE181574 data set. Combined the two datasets used P values and log2FoldChange (P-value < 0.05, | log2FoldChange | > 1.2) as selection criteria, we found the MNX1 and PNMT expressions were significantly higher in the pCR group. Subsequently, differential analysis of GSE52707 and GSE15043 datasets showed that MNX1 and PNMT expression levels were reduced in drug-resistant cell lines. Considering the P-value and | log2FoldChange |, we ultimately selected motor neuron and pancreatic homeobox 1(MNX1) gene as the target factors for follow-up studies. In the cloning formation and proliferation assay, overexpression of MNX1 inhibits proliferation and clonal formation of HER2-positive breast cancer cells. In the drug sensitivity experiments overexpression of MNX1 enhances the sensitivity of HER2-positive breast cancer cells to tyrosine kinase inhibitors (TKI)

such as lapatinib and pyrotinib. MNX1 knockdown reduces the sensitivity of HER2-positive breast cancer cells to TKI. Through RNA-seq and ChIP-seq, we found that CD-M6PR might be a downstream target gene regulated by MNX1. Verification by Dual-Luciferase Reporter Assay MNX1 was found to positively regulate CD-M6PR transcription. By Co-IP assay, it was found that MNX1 interacted with EEF1D, and EEF1D stabilized MNX1. MNX1 and CD-M6PR affect the proliferation and drug sensitivity of breast cancer cells by down-regulating the PI3K-AKT-mTOR pathway. Conclusion: Overexpression of MNX1 increases the sensitivity of HER-2 positive cells to TKI. MNX1 binds to EEF1D and is stabilized by EEF1D. MNX1 positively regulates M6PR and affects the proliferation of breast cancer cells and the sensitivity of breast cancer cells to TKI through the PI3K-AKT-mTOR pathway.

Objective: Triple Negative Breast Cancers (TNBC) are highly invasive and 46% of patients develop distant metastases, leading to higher mortality. Chemotherapy remains the most efficacious option, however, there is still a largely unmet need to identify novel therapeutic targets in TNBC to increase treatment options and improve patient outcomes, survival. Enhancer of zeste homologue 2 (EZH2), a member of the catalytic subunit of the polycomb repressive complex 2, is a histone methyltransferase and its canonical function is to methylate lysine 27 of histone 3. EZH2 is a potential driver of TNBC metastasis, and its high expression strongly associates with the TNBC phenotype as compared with other molecular subtypes of breast cancer. Despite the advancement in the discovery of inhibitors for EZH2 that attenuate its catalytic activity. Currently, several EZH2 inhibitors are under development and undergoing clinical trials and these compounds have been proved to be effective in the treatment of hematological malignancies, sarcomas and malignant rhabdoid tumors. However these inhibitors do not affect the intrinsic protein stability of EZH2, but typically competes with the cofactor S-adenosylmethionine (SAM) and binds to the SET domain of EZH2. Hence, the EZH2 inhibitors are only effective for some malignant blood tumors, and have poor efficacy for solid tumors, such as TNBC. Several studies have shown the involvement of neurotransmitter dopamine in proliferation, apoptosis, tumor angiogenesis, and drug resistance among different cancers, including the breast¹. Dopamine D1 receptor activation in TNBC cell line induces apoptosis, autophagy and phosphorylation of eukaryotic translation initiation factor 2-alpha (eIF2a)². Also, D1R agonists inhibits the invasion of breast cancer cell lines MDA-MB-231 and BT-20 and regress mammary tumors³. The oncogenic nature of EZH2 in driving aggressiveness in TNBC cells led us to simultaneously target dopamine D1 receptor and EZH2 to completely ablate tumor growth and metastasis. Methods: Schrodinger protein modeling software was employed for docking studies. TNBC cells MDA-MB-231 cells were treated with the EZH2 inhibitor GSK126 and/or D1R agonists A77636 and SKF38393 for assessing cell viability, migration. Immuno precipitation to investigate if the combination could disrupt the PRC2 complex in TNBC cells. To model tumor burden and the effects of combination therapy on tumor growth in vitro, we tested the combinatory effect of GSK126 and D1R agonists in a 3D culture system of MDA-MB-231 cells encapsulated in calcium-alginate microgels seeded from a microfluidic droplet generator. Cell death was determined by Yo-pro-Propidium Iodide staining. Result: In silico analysis confirmed that D1R agonists exhibited strong stabilization of protein structures upon binding to the EZH2 catalytic active site, albeit with slightly weaker affinity than GSK126. Combination treatment with GSK126 and dopamine agonists A77636 or SKF 38393 led to significant and synergistic inhibition of cell viability ($p < 0.01$), migration, invasion, and EZH2 activity ($p < 0.01$) in TNBC cells. In addition, MDA-MB-231 cells formed tumor spheroids that were subjected to the EZH2 inhibitor alongside dopamine agonists, indicating tumor reduction relative to single agent treatment in 3D culture ($p < 0.0001$). The combination also led to increased necrotic cell death ($p < 0.05$). Immunoprecipitation of EZH2 in the presence of GSK126 and SKF38393 and A77636 dissociated the physical interaction between EZH2, EED, and SUZ12 in MDA-MB-231 cells. Conclusion: Our data suggest that the combination of GSK126 and Dopamine D1 agonists synergistically inhibits TNBC proliferation by disrupting EZH2 functions leading to necrotic cell death. [Introduction] Breast cancer is the fifth leading cause of cancer-related death among women, and its prevalence is the highest in all cancers of Japanese women. To improve the prognosis of breast cancer patients, new diagnostic and therapeutic tools need to be developed. Adaptor protein complex-1 (AP-1) is one of the clathrin adaptor molecules regulating intracellular transport of specific cargos between the trans-Golgi network (TGN) and endosomes. Although the detailed mechanisms have been poorly elucidated, previous reports suggest that AP-1 expression is related with cell proliferation and cancer metastasis. The purpose of this study is to investigate the association between AP-1 expression in tumor tissue measured with immunohistological analyses and surrogate markers of cancer aggressiveness, such as Ki-67 labeling index and/or breast cancer subtypes. [Materials and methods] The records of 207 primary breast cancer patients surgically treated at Fukushima Medical University Hospital from 2011 to 2014 were reviewed. Paraffin embedded sections of these patients were processed for immunohistochemistry examination using antibody against γ -adaptin, a subunit of AP-1, and then its immunoreactivity was quantified. The staining patterns were also graded into 4 grade: Negative (Neg) = 1, Perinuclear (PN) = 2, Scattered (Sc) = 3, and Diffuse (Dif) = 4. The association of the stain characteristics, such as intensity and patterns, and clinicopathological factors, including Ki-67 labelling index and tumor subtypes, were assessed. In addition, the detailed intracellular localization of AP-1 was examined with double immunofluorescence microscopy using markers for the TGN and endosome. [Results] AP-1 intensity was associated with Ki-67 index ($p < 0.005$) and subtypes ($p < 0.0001$). Patients with high Ki-67 index showed significantly higher AP-1 intensity than those with low Ki-67 index ($p < 0.05$). Regarding the tumor subtypes, HER2 type ($p < 0.001$) and TNBC ($p < 0.05$) showed significantly higher AP-1 intensity than Luminal A. HER2 type also showed significantly higher AP-1 intensity than Luminal B ($p < 0.01$). In terms of the staining pattern, AP-1 distribution was also significantly associated with Ki-67 index ($p < 0.0001$) and subtype ($p < 0.0001$). The staining pattern grade of high Ki-67 index patients was significantly higher ($p < 0.0001$) than that of low Ki-67 index patients. Regarding the association with subtypes, the grades in Luminal B ($p < 0.0001$), HER2 type ($p < 0.0001$), and TNBC ($p < 0.005$) were significantly higher than that of Luminal A, and HER2 type also showed higher score than Luminal B ($p < 0.01$). In tumor cells with Sc pattern, AP-1 was mainly localized in EEA1-positive endosomes, but the localization in TGN was not apparent. [Conclusion] Although further confirmative studies are needed, these results suggest that the protein expression and the endosomal localization of AP-1 are likely related to the cellular proliferation activity in breast cancer tissues. Aberrant AP-1 distribution could be a predictive marker of the tumor growth potential.

Breast cancer is the most common cancer diagnosed in women worldwide and leads to 600,000+ deaths annually. The vast majority of breast cancer-related deaths are attributed to metastasis from the primary site in the breast to visceral organs or the brain. Therefore, understanding how these cells achieve metastasis is vital. Ion channels, such as the epithelial sodium channel (ENaC), are emerging as new targets for cancer research due to their role in regulating cell functions such as the process that allows cancer cells to undergo phenotypic changes necessary for metastasis. Ion channel dysregulation may be crucial in cancer development due to the ion channels' potential role in controlling cancer cell characteristics such as migration and proliferation. There is limited research investigating the role ENaC may have in breast cancer. We have shown that more migratory, mesenchymal breast cancer cell lines have reduced mRNA and protein expression of ENaC compared to more epithelial breast cancer cell lines. Importantly, higher expression levels of the pore-forming alpha-ENaC subunit is correlated with an increased breast cancer survival in patients (n=1705) included in the SCAN-B data set. Bioinformatic analysis, using the SCAN-B data set, showed an increase in the expression of alpha-ENaC mRNA correlated with lower expression levels of migration and proliferation markers, suggesting ENaC has a role in breast cancer cell proliferation and migration. Therefore, this research examines the influence of stably overexpressing the pore-forming subunit of ENaC, alpha-ENaC, in breast cancer cells on their cell migration and proliferation ability. We hypothesised that increasing the expression of ENaC will restore the cells to a more epithelial state, thus reducing cell migration and proliferation. MDAMB231 breast cancer cells were engineered via a stable transfection to overexpress alpha-ENaC or to express an empty vector control. Several clones were isolated and expanded and using RTqPCR, alpha-ENaC mRNA overexpression was confirmed to consistently have 200-fold

increased mRNA expression compared to control cells (n=9, p=0.0006). An increase in alpha-ENaC protein expression was also confirmed via western blotting. Using an EdU assay the alpha-ENaC overexpressing cells were shown to have a significant reduction in proliferation compared to the control cell line (n=3, p=0.0048). The alpha-ENaC overexpressing cells showed reduced migratory ability when examined in two established migration assays. In scratch wound assays, the alpha-ENaC overexpressing cells had a significant reduction in cell migration at 24 hours post scratch (n=4, p=0.0001). In Boyden chamber assays, the number of alpha-ENaC-overexpressing cells that migrated through the membrane was significantly reduced compared to the control cell line (n=4, p=0.02). Our results suggest that increased sodium entry into the cell through ENaC has a role in preventing the development of metastatic breast cancer cells, and highlights ENaC as a potential target for future breast cancer therapies.

Dual Specific Phosphatase-7 (DUSP7/PYST2) and its role in regulating vascular endothelial functions Wenxiao Ji, Wen G. Jiang, Lin Ye, Tracey A. Martin CCMRC, Cardiff University School of Medicine, Cardiff, Wales, UK Introduction. Dual specific phosphatases (DUSPs) are a large family of enzyme able to trigger tyrosine phosphorylation, and phosphorylation of serine and/or threonine. This feature of a dual phosphorylation pattern by DUSPs, renders them with diverse roles in cells, from cytoskeletal regulation of cell migration, regulation of multiple kinases in cell signalling, to regulation of proteins such as microtubules and cell growth. We have investigated DUSP family members, in particular DUSP-7 (otherwise known as PYST2), identified from our studies as being one of prominent DUSPs found to be highly aberrant in certain cancer types including gastric cancer and pancreatic cancer. In breast cancer cells, DUSP7 has been reported as a potential factor linked to drug sensitivity. The role played by DUSP7 in vascular endothelial cells has been poorly studied. Here, we present our findings on the role of DUSP-7 in the regulation of biological functions of vascular endothelial cells.

Methods. Human vascular endothelial cells were used in the present study. Cell sub-models were created by knock down of DUSP7. The cells were evaluated for their biological response to loss of DUSP7, including proliferation, migration, matrix adhesion and response to downstream signalling. DUSP7 responses to various exogenous factors were also evaluated by a protein kinase platform. Results. Knock down of DUSP7 in human endothelial cells rendered them manifesting significantly reduced matrix adhesiveness ($p < 0.05$) and most strikingly, reduced cellular migration ($P < 0.0001$, control versus DUSP7 knock down). Interestingly, there was little change with the rate of cell growth. When cells were tested by inhibiting a tight junctional molecule, HAVcr1, the endothelial cells responded with markedly reduced DUSP7 (reduction of 46%). Likewise, the cells were also exhibited reduced levels of DUSP7 after being challenged by exogenous metastasis related Kisspeptin, indicating that DUSP7 may participated the wide network of signalling and functional regulations shared with the tight junction regulator HAVcr1 and possibly utilising Mitogen-activated protein kinase 3 (MAPK3 or Extracellular signal regulated kinase-1). Conclusion. Dual specific phosphatase-7 has an

important role to play in vascular endothelial cells, primarily on cell matrix adhesion and cellular migration. A possible route of regulation is by targeting the extracellular signalling network.

APOBEC-catalyzed deamination of cytosine bases is the largest enzymatic and second largest overall source of mutation in cancer. One member from the APOBEC family of enzymes, APOBEC3B (A3B) is overexpressed and dysregulated in many different cancer types. In addition to hallmark C-to-T transitions and C-to-G transversions, APOBEC-catalyzed uracil lesions can be processed into single- and double-strand DNA breaks. Therefore, A3B-positive tumors are under continual stress to repair DNA breaks and may be vulnerable to DNA repair inhibition. Previous results from the Harris lab have identified UNG2, DNA uracil glycosylase 2 (UNG2), initiator of the base excision repair pathway, as synthetic lethal pair with A3B. The genetic disruption of UNG2 combined with high expression of A3B, causes cell death. This provides the rationale to hypothesize that also other DNA repair proteins could be putative synthetic lethal pairs with A3B, when its expression and activity are high. To test this hypothesis, CRISPR guide RNA library targeting 237 DNA damage repair and response genes was used in doxycycline-inducible TREX-293-A3Bi-eGFP cell line. Cells expressing or not A3B were harvested for DNA extraction and sequencing at different time points. Comparison of guide RNA abundance between doxycycline and H₂O treated cells revealed the dropout guides that disrupt genes and create putative synthetic lethal combinations with A3B. The screen design and overall results will be presented

Genetic instability commonly found in tumors may be a consequence of imbalance in homologous recombination (HR), a mechanism of DNA double-strand break (DSB) repair dependent on the formation and resolution of Holliday junctions' structures for genomic stability maintenance. The SMC6 is involved in DSB repair. The SMC6 gene is structurally located very close to the GEN1 gene in a head-to-head organization sharing a bi-directional promoter, and the encoded protein is also involved in HR. Herein, we explored the association between SMC6 expression, genomic instability, and prognosis of breast cancer (BC). SMC6 and GEN1 expression and Copy Number Variation (CNV) data measured by qRT-PCR and CGH array, respectively, were assessed in 33 BC of women non-carrier BRCA1/BRCA2-mutations. The SMC6 protein expression was evaluated on a Tissue Microarray containing 74 BC samples classified as low (negative/weak) or high (moderate/strong) according to SMC6 nuclear staining. SMC6 and GEN1 expressions were directly correlated ($p=0.821$). Moreover, SMC6-low tumors tend to show higher CNV. Yet, the SMC6-low group presented poorer disease-free survival (DFS) than the SMC6 high group ($\log\text{-rank}=0.008$). Further, SMC6 expression broke the DFS ER+ cohort in groups of distinct prognoses ($\log\text{-rank}=0.029$). By in silico data analysis,

SMC6 downregulation was also associated with worse prognosis in some BC subtypes. Our findings point to a possible association between SMC6 down-regulation and BC poor outcomes, suggesting that SMC6 may serve as an indicator of tumor genetic instability for BC patients. Supported by Fapesp and CNPq.

Background: Triple negative breast cancer (TNBC), defined by negative hormone receptor (HR) status and the lack of HER2 gene amplification, is a significant clinical challenge because of its aggressive clinical course and association with a poor prognosis. Recent studies demonstrated that approximately a third of TNBC has low expression of HER2, so called HER2-low TNBC, which could be targeted by the new generation HER2-directed antibody-drug conjugate (ADC). Trastuzumab deruxtecan (also known as T-Dxd, DS-8201a) is a novel HER2-directed ADC with a topoisomerase 1 inhibitor payload and a tetrapeptide-based cleavable linker, which has been FDA approved for patients with metastatic HER2-positive, or amplified breast cancer. T-Dxd has also shown to improve survival outcomes when compared to physicians' choice chemotherapy in patients with metastatic HR-negative/HER2-low breast cancer in the Phase 3 DESTINY-Breast04 trial. However, resistance is invariable. We hypothesize that small molecule inhibitors against DNA damage response (DDR) pathways could potentiate the DNA damaging effect of T-Dxd and improve its anti-tumor activity in HER2-low TNBC. Method: We conducted preclinical experiments to assess the anti-tumor activity of T-Dxd and each of the DDR pathway inhibitors, including the ATR inhibitor AZD6738, the ATM inhibitor AZD1390, and the PARP inhibitor olaparib, as well as the Wee 1 inhibitor AZD1775, either alone or in combination,

compared to the vehicle treatment, in a panel of HER2-low TNBC PDX models in vivo, as well as mechanistic studies using HER2-low TNBC cell lines in vitro. HER2-low was defined as 1+ or 2+ on HER2 immunohistochemistry. Results: Four HER2-low TNBC PDX models, including WHIM2 (TP53 mutated, basal-like), WHIM6 (TP53 WT, basal-like), WHIM12 (TP53, PIK3CA, and PTEN mutated, claudin-low), and WHIM30 (BRCA1 and TP53 mutated, basal-like), as well as a panel of 4 TNBC cell lines with variable HER2 expression were included in the study. We demonstrated that the addition of DDR pathway inhibitors to T-Dxd led to further tumor shrinkage and delayed tumor progression in HER2-low TNBC PDX models in vivo and induced synergistic anti-tumor effects in vitro. Enhanced DNA damaging effect and apoptosis induction were observed with combination therapies in vitro. Biomarker analysis on xenograft tumors harvested 3 days following treatment with either Vehicle, T-Dxd, olaparib, or T-Dxd plus olaparib in WHIM6, was also performed, which demonstrated that the addition of olaparib enhanced DNA damage (increased pH2AX), and promoted apoptosis (increased cleaved PARP). Further mechanistic studies in HER2-low TNBC cell lines demonstrated the formation of DNA topoisomerase 1 covalent complexes (Topolcc) following treatment with T-Dxd. Interestingly, while the formation of Topolcc was reduced with the addition of either ATR or ATM inhibitor, no reduction was observed with the addition of olaparib. Additionally, we observed that combination therapies reduced cell migration in vitro. The combination of olaparib with T-Dxd, in particular, reduced mammosphere formation and Epithelial Mesenchymal Transition (EMT) modulation markers, including SNAIL, SLUG and/or TWIST. Conclusion: Our study demonstrated that the combination of T-Dxd and DDR pathway inhibitors induced additive or synergistic anti-tumor effect in HER2-low TNBC. Our data from the studies of cell lines and PDX models provided preclinical rationale for the combination of T-Dxd and DDR pathway inhibitors in patients with HER2-low TNBC. The olaparib combination showed unique mechanistic characteristics compared with other DDR inhibitors, which are being further examined in additional HER2-low TNBC models.

ABSTRACT Increased expression of LY6K is significantly associated with poor survival outcomes in many solid cancers, including triple-negative and estrogen receptor-positive breast, ovarian, gastric, head and neck, neuroblastoma, bladder, and lung cancers. Inhibition of LY6K signaling is an ideal therapeutic approach for cancer, since the LY6K protein is not involved in vital organ function. Previously, we identified the small molecule NSC243928 as a binder of LY6K using surface plasmon resonance screening and showed that its activity was dependent on LY6K expression in triple-negative breast cancer cells. Here, we demonstrate the structural basis of the molecular interaction of NSC243928 with LY6K protein and the subsequent inhibition of LY6K function in mitosis and cell division via Aurora B-histone pathway. We observed that LY6K interacts with phosphorylated histones and Aurora B kinases during mitosis and that this interaction was disrupted in the presence of NSC243928. Disruption of LY6K function in mitosis/cytokinesis leads to DNA damage, senescence, and apoptosis of cancer cells. We observed that NSC243928 led to increased binding of LY6K to phosphorylated gammaH2X at S139, which was dependent on NSC243928 interaction with LY6K on phenylalanine 79. Furthermore, we observed increased levels of phosphorylated gammaH2X at S139 and increased caspase-3 activation in the tumor isografts of 4T1 and E0771 mammary tumors treated with NSC243928.

These data reveal that LY6K is a novel cell cycle target for therapeutic development in triple-negative breast cancer and other solid cancers with high expression of LY6K, such as bladder cancer, head and neck, and lung cancer.

Although male breast cancer accounts for less than 1% of all breast cancer cases, overall survival is worse for men compared to women. This is due, in part, to the older age of patients at the time of diagnosis and the increased presence of comorbidities in the male population. While male breast cancer presents with similarities to certain female breast cancers, the paucity of data available on male breast cancer makes it difficult to establish targeted therapies, and to date, most male breast cancers are treated according to the standards in place for female breast cancer. Thus, investigating the transcriptional and epigenetic landscape of male breast cancer with improved resolution is crucial for understanding the tumor heterogeneity of this rare cancer type and can lead to the discovery of new therapeutic targets. In this study, we present matched transcriptional (scRNA-seq) and epigenetic (scATAC-seq) profiles of two male breast cancer tumors at single-cell resolution. Using scRNA-seq, we determine differentially expressed genes between male and female breast cancer tumors, specifically in the malignant cell populations, and highlight several genes that may have therapeutic implications within male breast cancer. We then leverage the scATAC-seq data to link variation in chromatin accessibility to changes in gene expression and show that certain highly expressed genes in the tumor-epithelial cells of male breast tumors are linked to highly active enhancer elements that drive their expression. Finally, we examine transcription factor motifs in the tumor-epithelial regulatory regions of male breast cancer tumors to further investigate the regulatory logic of these cell types. Overall, this dataset exposes clinically relevant regulatory networks in male breast tumors, providing a useful resource to the field of breast oncology that expands on the current knowledge of male breast cancer genetics.

Background: Breast cancer in the recent years has accounted to be most frequently reported cancer across the globe. Nearly 11.7% of total cancer cases were of breast cancer and 6,84,996 deaths were reported in the year 2020. Multiple endocrine neoplasia type 1 gene that encodes for menin protein is known to be involved in numerous signaling pathways and is also reported to show its interactions with histone modifiers. MEN1 is frequently reported to be dysregulated in the cancer including neuroendocrine tumors, lung cancer and melanoma. However, the role of MEN1 in case of Breast cancer has not been well understood. Lifestyle, environmental conditions and ethnicity play crucial role in epigenetic modulation of gene expression. In the current scenario with high increase in number of cancer cases, there is need to develop more personalized course of treatment rather than generalized approach. Thus, discovery of new biomarkers will aid in designing better diagnostic and therapeutic strategy to treat cancer. Aims and Objective: In this study we aim to find MEN1 mRNA expression and its connection with the MEN1 promoter methylation in case of Indian breast cancer patients and to correlate our findings with the pathological parameters of the patients to understand the role of MEN1 gene in breast cancer progression. Material and methods: The ethical approval for the study was procured from Institutional ethical committee of AIIMS, New Delhi and Jamia Millia Islamia, New Delhi. The study comprises of 44 pair of Breast tissue samples including cancer

and adjacent normal tissue collected at department of surgical oncology AIIMS, New Delhi and were stored in RNA later and PBS at -80°C for RNA and DNA extraction respectively. DNA was extracted through PCI (Phenol-Chloroform-Isoamyl alcohol) method and was further confirmed by Agarose gel electrophoresis. TRIZOL method was used to extract RNA from tissue samples and was quantified using nanodrop. Moreover, cDNA synthesis was carried out using Verso cDNA synthesis kit. To investigate the MEN1 mRNA expression, RT-PCR was carried out with LightCycler96 SYBR Green I Master (Roche) using specific primers. To analyze the promoter methylation status of MEN1 promoter region, CT-conversion was done and MS-PCR was performed using Methylation and Unmethylation specific primers. Statistical analysis was done using Graph Pad and SPSS to correlate our findings with clinical parameters. Results: In our study we found 27 out of 44 patients to exhibit up-regulation of MEN1 mRNA in the breast cancer tissue as compared with the normal tissue. MEN1 promoter unmethylation was detected in 25 out of 44 cases, which revealed its significant correlation with the upregulated MEN1 gene. Further on correlation of our data with the clinical parameters, we found its significant association with the estrogen receptor status and age of menopause of the patients. Conclusion: Our results of the MEN1 mRNA expression study and its association with MEN1 promoter methylation in case of breast cancer suggests the tumorigenic role of MEN1 in breast cancer. Our findings thereby indicate the possible role of MEN1 gene in progression of the disease. Further study on large sample size will aid in better understanding the role of MEN1 gene in Breast carcinoma.

The human epidermal growth factor receptor (HER) family of receptors plays a significant role in the pathogenesis of several human cancers. Among them, HER2 is overexpressed in several cancers. In particular, overexpression with or without gene amplification occurs in 15-30% of breast cancers and this has both prognostic and predictive implications. HER2 overexpression and amplification is associated with shorter disease-free and overall survivals and with resistance to certain hormonal agents as well as increased risk of metastasis to the brain. Two types of treatment targeting HER2 biological activity have been developed: anti-Her2 monoclonal antibodies and small molecule tyrosine kinase inhibitors such as lapatinib and neratinib targeting HER2 and EGFR and Afatinib targeting all HER family members. Trastuzumab is a humanized anti-HER2 monoclonal antibody that binds to domain IV of HER2 extracellular segment and blocks its signaling. It is the first therapeutic antibody targeting Her2 overexpression approved by the FDA. It is administered in combination with standard of care chemotherapy. More recently, since it was shown that Trastuzumab was an internalizing antibody, two antibody drug conjugates using trastuzumab have been approved and used in the standard of care: Ado-Trastuzumab-Emtansine (Kadcyla) consisting of trastuzumab conjugated to the drug mertansine DM1 and fam-trastuzumab-deruxtecan-nhki (Enhertu). Enhertu is

another antibody drug conjugate using Trastuzumab to deliver a topoisomerase inhibitor deruxtecan. Our laboratory has been focused in developing fully human internalizing anti-Her2 antibodies that compete or not with trastuzumab for binding to Her2. These antibodies have been developed by immunizing fully human mice with recombinant Her2 protein. Human Ab producing Tc mice (TC-mAb mice) stably maintain a mouse-derived engineered chromosome containing the entire human Ig heavy and kappa chain loci in a mouse Ig knockout background. After production of hybridoma secreting fully human immunoglobulins, the screening process included inhibition of binding of trastuzumab to Her2 by enzyme linked immunoassay and by Octet epitope binning as well as internalization assay. Several internalizing antibodies with Kd ranging from 10⁻⁹ M to 10⁻¹² M were selected. They were stratified by their ability to compete or not with trastuzumab. They were further characterized for their ability to deliver a cytotoxic payload in Her2 overexpressing cells as well as for their efficacy to inhibit proliferation, signaling and migration of Her2 overexpressing breast cancer cells. Data related to these antibodies will be presented here. In conclusion, the use of fully human TC mice in our laboratory represents an attractive approach to develop fully human monoclonal antibodies to high value cancer targets that can by-pass the need for humanization and affinity maturation of antibodies.

Background: Epithelial-mesenchymal transition (EMT) phenotype is a complex process and plays a central role in tumor progression, aggression, invasion, metastasis, and resistance to therapy. Role of androgen receptor (AR) and androgens in inducing EMT has been well established in experimental systems of prostate cancer. AR is widely expressed in all subtypes of breast cancer (BC) and is considered to have context dependent role based on the steroid hormone microenvironment. Previous studies have shown AR as the only sex steroid receptor detectable in BC metastases and in metastatic lesion. We investigated the role of androgens in driving the EMT phenotype and association of AR induced genes with EMT in BC tumors using public dataset. Methods: We treated AR positive breast cancer cell line MDA-MB-453 with the androgen, dihydrotestosterone (DHT) followed by AR antagonist bicalutamide (Bic) and examined the expression levels of AR induced genes by quantitative real time PCR (qPCR) and AR induced protein GCDFP-15 by western blot. AR driven genes (SEC14L2, C1orf116, FKBP5, UGT2B11, UGT2B28, KCNMA1, PIP and ABCC11) were identified by bioinformatic pipeline using a systematic bioinformatic approach from public microarray data sets derived from AR positive breast cancer cell lines (S Rajarajan et al, SABCs 2021). Mesenchymal phenotype of the cell lines under DHT/ Bic was evaluated morphologically and expression levels of EMT markers (ZEB1, Slug, Vimentin) and E-cadherin was estimated by qPCR, western blot and

immunofluorescence. Migratory potential of the cell line under treatment was evaluated by wound healing assay and proliferation was examined by the MTT assay. Association of AR induced genes and levels of enzymes involved in intracrinial testosterone metabolism (SRD5A1 & SRD5A3) with EMT in breast tumors was evaluated using transcript data from METABRIC database. EMT scores were derived from previous publications (Byers et al, 2013, Mak et al, 2016) and correlation was tested with AR induced genes. Results: The MDAMB-453 cell line was treated with 10nM DHT for 72hrs and this increased the expression of AR downstream protein GCDP-15 by 31.47% ($p=0.022$) when compared to the control. Further, a significant increase in the expression levels of AR driven genes with a fold change >2 was observed in the DHT treated cells ($p < 0.05$). The expression of GCDP15 protein ($p=0.028$) and the AR downstream genes ($p < 0.05$) were significantly repressed upon treatment with bicalutamide. DHT treatment also showed a significant higher expression of EMT master regulator, SLUG (fold change >3 , $p=0.045$) and a wound healing assay showed a 22% increase in migration ($p=0.027$). The expression of SLUG was significantly repressed ($p=0.003$) and the migratory ability of the DHT treated cells reduced upon treatment with bicalutamide ($p=0.145$). We also observed a significant loss of E-cadherin protein (by 23.65%; $p=0.024$) with DHT treatment and this was completely reversed upon treatment with bicalutamide ($p=0.047$). No significant change in proliferation was observed among the different treatment conditions. A significant positive correlation was observed between AR induced genes and the EMT scores ($p < 0.05$). Expression level of SRD5A3 was also positively correlated with EMT score ($p=0.043$) and AR induced genes ($p < 0.05$), except SEC14L2. Conclusion: Androgen receptor plays an important role in the biology of breast cancer and is considered a useful marker for prognosis. However, antiandrogen therapies haven't seen the expected success in clinical trial settings. Our results support the controversial role played by AR in higher androgenic environment within breast cancer and warrant the consideration of the intratumoral levels of sex steroid hormones.

Background: In early-stage triple-negative breast cancer (TNBC), high glucocorticoid receptor (GR) expression correlates with worse relapse-free survival across TNBC subtypes, induces oncogenic gene expression and tumor cell survival, and potentiates anti-inflammatory or an anti-immunogenic phenotype. Immune checkpoint therapy has increased pathologic complete response rates in the neoadjuvant setting, however response to immunotherapy remains modest overall and the explanatory mechanisms for this phenomenon are incompletely understood. We sought a three-dimensional model of the TNBC immune microenvironment using patient-derived organoids (PDOs) that capture tumor heterogeneity, partially recapitulates tumor microenvironment, and can be established for longer-term in vitro/in-vivo translational study after exposure to immunotherapy. We hypothesize that during chemoimmunotherapy treatment of early-stage triple-negative breast cancer, high glucocorticoid receptor activity mediates an immunosuppressive phenotype and glucocorticoid receptor modulation can restore anti-tumor immunity. Methods and Results: We are successfully growing 5 PDOs out of 8 surgically resected samples tumors from patients with early-stage triple-negative breast cancer treated with chemotherapy vs. chemoimmunotherapy as per KEYNOTE-522.

Interrogation of complementary TNBC cell line data revealed that GR activation downregulates the expression of immune checkpoint genes (PD-L1, B7-H3, B7-H4), while GR knockdown or treatment with a selective GR modulator restores expression of these immune checkpoint genes. TNBC-intrinsic GR activation increases the proportion of regulatory T cells vs. CD8+ T cells. In a coculture system of TNBC spheroids and T cells, GR activation in TNBC results in decreased activated CD8+ CD137+ T cells and use of the selective GR modulator increases the proportion of activated CD8+ CD137+ T cells. Conclusions and Future Directions: In early-stage triple-negative breast cancer, GR activation downregulates expression of immune checkpoint genes and reduction of GR activity restores expression. In a coculture system that recapitulates T cell repertoire found in triple-negative breast cancer, tumor-intrinsic GR activation results in increased regulatory T cell population and reduction of GR activity increases activated CD8+ CD137+ T cells. Ongoing analyses of TNBC organoid-immune coculture systems modeling high GR states will be used to (i) define cooperativity amongst immune checkpoint proteins in costimulation vs. coinhibition of anti-tumor responses and (ii) define novel pairs of receptor-ligands amongst TNBC:CD8+ vs. TNBC:Treg vs. CD8+:Treg as discovery of potential new therapeutic targets.

Background: Humoral immune responses have previously been associated with improved outcomes, with B cell infiltrates able to independently predict pathologic complete response to neoadjuvant chemotherapy (NACT). B cells represent a diverse population of cells and the complex interplay between specific B cell subsets in the context of chemotherapy treated breast cancers remains unclear. Here, we investigate the dynamic changes in the B cell immune landscape before and after NACT treatment across different breast cancer subtypes. Methods: Treatment naïve, mid-treatment and post-NACT breast tumour tissue samples were dissociated into single cells, stained with two panels of B cell-specific antibodies recognising a total of 24 target proteins, and analysed by flow cytometry. In addition, PMBC before and after NACT were also profiled. B cell subsets were classified as either naïve (CD27—IgD+), class-switched memory (CD27+IgD—), unswitched memory (CD27+IgD+) or double negative (DN)(CD27—IgD—). DN B cells were further characterised into DN1 (CXCR5+CD21+) and DN2 (CXCR5—CD21—) subsets. In vitro co-cultures of breast cancer cell line spheroid and PBMC were carried out. Results: In both treatment naïve and chemotherapy treated samples, we observed a significant expansion in the DN B cell population within the TME compared to the periphery. DN B cells represented on average 40.96% of B cells in treatment naïve tumours vs 9.48% in PBMCs ($p < 0.0001$), and 71.80% vs 6.34% of B cells in post-NACT tumour vs PBMC samples respectively ($p < 0.05$). Interestingly, in treatment naïve PBMC and tumour tissue samples, the largest proportion of the DN subset consisted of DN1 cells, 69.35% and 64.11% respectively. In contrast, following NACT, DN2 cells constituted the majority of the DN population both within the TME (86.30%) and in the periphery (50.44%). Although the specific functions of these B cell subsets remain unclassified, deeper phenotyping suggests DN1 cells more closely resemble the phenotype of class-switched memory cells, whilst DN2 cells are thought to have antibody-secreting properties and more closely resemble the plasmablast phenotype. scRNA sequencing

of B cells pre- and post NACT is currently underway. Conclusion: To our knowledge, this work is the first to identify an expanded population of DN B cells in breast tumour tissue and highlights the requirement for further investigation into these cells to decipher their role in the context of chemotherapy treatment and resistance in breast cancer.

Background: Intrinsic resistance to immunotherapy observed in breast cancer is attributed to low neoantigen levels, defective antigen presentation, low mutational burden, reduced programmed death ligand (PD-L1) expression and the presence of immunosuppressive signals like transforming growth factor-beta (TGF β) in the tumor microenvironment (TME). These collectively attenuate the effector functions of T cells and natural killer cells (NK cells). NK cells are an important component of innate immunity. While generally TGF β dampens the NK cell response in the breast cancer TME, chronic stimulation in vivo with TGF β during the expansion process of donor NK cells produces TGF β imprinted NK cells which exhibit high cytotoxicity and resistance to suppression by TGF β due to down regulation of SMAD3 and hypersecretion of interferon gamma and tumor necrosis factor alpha. NK cell activation also promotes antibody dependent cellular cytotoxicity (ADCC) and augments monoclonal antibody directed killing. GD2 is a disialoganglioside and a tumor-associated antigen with limited expression in healthy tissues and overexpression in a variety of cancers, including breast cancer. Up to 60% of high grade breast cancers have GD2 expression with higher expression linked to worse overall survival. Given GD2 expression in aggressive BC subtypes and the role of NK cells in ADCC and antigen presentation, there is a strong rationale for evaluating an anti-GD2 antibody along with NK cells in the immunosuppressive breast TME. Based upon established preclinical data, we hypothesized that combining (1) an IgG1 anti-GD2 monoclonal antibody (anti-GD2), (2) TGF β imprinted, IL-21 expanded allogenic universal donor NK cells (TGF β iNK) and (3) the

standard chemotherapy agent gemcitabine (gem) which has immunomodulatory effects including improved NK cell function, will improve tumor control and survival in a TNBC mouse model. Methods: First, we evaluated if anti-GD2 treatment would increase ADCC against MD-MBA-231 tumor cells. To do this, tumor cells with or without anti-GD2 were cocultured with TGFβiNK + anti-GD2 and evaluated by real time cell analysis (RTCA). Next we evaluated the effect of gem on both tumor and immune cells. Finally to evaluate the effect of our novel combination therapy, female NSG mice were injected with 1x10e6 MDA-MB-231 cells into the mammary fat on day 0 and tumor burden was followed for 83 days. On day 21, mice were divided into 4 groups: control, gem only (standard of care), TGFβiNK+anti-GD2 (NK-GD2), and gem+TGFβiNK+anti-GD2 (G-NK-GD2) and tumor growth was measured weekly. Mice were observed for toxicity and bioluminescence evaluation for NK cells were performed prior to each cycle. Results: RTCA data confirmed anti-GD2 treatment increased ADCC mediated cell lysis by TGFβiNK. Furthermore, at clinically relevant doses, gem did not alter GD2 expression by flow cytometry on MDA-MB-231 tumor cells but induced MICA expression which suggests potential improved NK cell activity. In the mouse model, monitoring of mouse weights showed greater weight stability in the G-NK-GD2 group, suggesting a tolerable regimen. Serial measurement of tumors showed a significant reduction in tumor growth in NK-GD2 and G-NK-GD2 arms when compared to Gem or control. Additionally, mice who received G-NK-GD2 or NK-GD2 had significantly improved survival. Histological evaluation and immune assessment of the mice are ongoing. Conclusion: Our data showed no significant toxicities in the murine model and improved efficacy of G-NK-GD2 over the standard of care gemcitabine. Our preclinical data supports moving forward with a phase 1b/2 Bench-To-Bedside clinical trial, that will evaluate this combination in patients with aggressive subtypes of metastatic breast cancer where there is a great clinical need for effective treatments.

Human Epidermal growth factor Receptor 2 (HER2) is overexpressed in 20% to 30% of breast cancers and is associated with poor prognosis. Patients with advanced HER2-type breast cancer are treated with HER2-directed tyrosine kinase inhibitors as well as antibodies, but many patients finally acquire therapeutic resistance. Therefore, it is important to develop new treatment strategies that circumvent HER2 positive resistant breast cancer. Among the suggested mechanisms of resistance to HER2-targeted therapeutics, tumor hypoxia and relevant biological factors are known as important players. In this study, we aimed to explore the role of tumor hypoxia in the development of resistance to HER2-targeted therapeutics, and whether the role of an immunological therapy targeting this could contribute to overcoming resistance. To this end, we established lapatinib-resistant HER2 positive breast cancer cells in vitro (SKBR3, BT-474 for human and MMC for murine cells). First, we examined if lapatinib-sensitivity is different according to oxygen concentration using lapatinib-resistant cell lines (LR-SKBT3, LR-BT-474, LR-MMC) compared with parent cell lines. Resistant cells were resistant both in normoxic and hypoxic conditions, but parent cells were highly sensitive in both of the oxygen concentration. In the Western blot analysis, HIF1 α and c-MET were overexpressed in the resistant cells compared with parent cell lines in both normoxic and hypoxic condition. Interestingly, treatment with lapatinib had reduced HIF1 α and c-MET expression at normoxia in parent cell lines but not in resistant cell lines. Under the hypoxic conditions, the difference in expression of HIF1 α and c-MET was more pronounced between parent cell lines and resistant cell lines treated with lapatinib. These results indicate that the expression of HIF1 α and c-MET was involved in lapatinib-resistant. In a previous study, we have identified epitopes from HIF1 α /c-MET and demonstrated effect of delayed bone metastasis in triple negative breast cancer model when used as peptide vaccine. Herein, we evaluated whether the immunization using HIF1 α /c-MET peptide vaccine is effective in inhibition of lapatinib-resistant HER2 positive breast cancer growth in vivo. MMTVneu-transgenic mouse model was used and 6- 8 weeks old mice were injected with LR-MMC subcutaneously. Immunization using the HIF1 α /c-MET

peptide vaccine significantly inhibited growth of LR-MMC cells in MMTVneu-transgenic mice compared with controls. HIF1 α /c-MET specific IFN- γ -secreting T cell responses in the splenocytes were significantly higher in the immunized group than controls. Immunohistochemical staining of T cells revealed that expression of tumor HIF1 α and c-MET was significantly decreased, while the number of CD8+ T cell was increased in the tumors from immunized animals compared with control tumors. In conclusion, our study demonstrated that the vaccine targeting HIF1 α /c-MET might be a promising cancer immunotherapy in lapatinib-resistant HER2 positive breast cancer. In vivo study to evaluate efficacy of combination therapy (lapatinib and HIF1 α /c-MET vaccine) is ongoing.

Objective Immunotherapy using the tumor-specific antigens (TSAs) is a promising strategy in breast cancer. Studies have suggested that the in vivo exposures to certain tumors can induce adaptive anti-tumor immunity in syngeneic tumor models. In this study, we show the efficacy of the tumor lysate vaccine and peptide-based vaccine against tumor neoantigen in suppressing tumor growth and metastasis in 4T1 syngeneic tumor models. Method We used BALB/c mice and its syngeneic tumor cell lines to evaluate the anti-tumor effect induced by the transient exposure to the tumor cells. For tumor vaccines, we synthesized the tumor lysate vaccine by the freeze-thaw method or synthetic peptide against the selected tumor neoantigens identified by exome sequencing. We systemic and local immune remodeling was investigated by using immunohistochemistry, flow cytometry, and single cell RNA sequencing. Results We observed a significant reduction of tumor growth and metastasis in 4T1 syngeneic tumors when the mice were previously exposed to the same cells (pre-exposure group). This anti-tumor effect induced by the exposures to the tumor was cell line-specific. The 4T1 tumor lysate vaccines administered prior to the tumor cell injection also showed significant inhibitory effect on tumor

growth and metastasis. T lymphocytes, isolated from the tumor tissues of the 4T1 pre-exposure mice and lysate vaccine-treated mice, showed higher levels of TNF- α and IFN- γ when compared to the control those from the control tumors. The lysate vaccine treatment resulted in a substantial remodeling of tumor microenvironment including reduction of myeloid-derived suppressor cells and M2 tumor-associated macrophages. On the other hand, the numbers of M1 tumor-associated macrophages and effector memory CD8+ T cells were increased by the lysate vaccine. While the peptide vaccine showed no inhibitory effect on the primary tumor growth, it also suppressed spontaneous lung metastasis. Finally, we administered lysate tumor vaccine after the tumor establishment to determine the therapeutic effect. The lysate vaccine significantly suppressed the tumor growth and lung metastasis of the syngeneic 4T1 tumors. Conclusion Tumor lysate vaccine can suppress the tumor growth and metastasis in the 4T1 syngeneic mouse models by inducing substantial remodeling of tumor immune microenvironment. Additionally, tumor lysate vaccine can elicit similar anti-tumor immune response when administered after the establishment of the primary tumor suggesting a potential therapeutic value.

Anti-B7-H3 Antibody (T-1A5) Blocks Immunomodulatory Function of B7-H3 and Enhances NK and T Cell–Mediated Cytotoxicity against Breast Cancer Cells

Presenting Author(s) and Co-Author(s):

One of the main factors contributing to breast cancer (BC) initiation and metastasis is immune suppression by tumor cells. Immune checkpoint blockade has recently been shown to overcome tumor-induced immune suppression, but a significant proportion of patients do not respond, implying that more effective cancer immunotherapies are required. B7-H3 belongs to B7 family of immune checkpoint proteins that is overexpressed in various human malignancies. Here, we hypothesize that blocking B7-H3 using monoclonal antibodies (mAbs) enhances immune cell proliferation and function. To test our hypothesis, B7-H3 expression was determined using RNA-seq data from primary and metastatic breast tumors, and adjacent normal tissues, from the TCGA and METABRIC databases. To assess B7-H3 protein expression in BC, we performed immunohistochemistry (IHC) on frozen primary tumor tissues (n=50) and adjacent normal tissues (n=23) from TNBC patients. In addition, to investigate the immunomodulatory effect of B7-H3 in BC, we performed IHC for T-cell markers in subsets of patient tissues with high and low levels of B7-H3 expression. Next, we assessed B7-H3 expression in over 13 BC cell lines, including TNBC and ER+, PR+, and HER2+ cell lines, as well as TNBC PDX-derived cells. Moreover, to determine the effect of B7-H3 knockdown on NK- and T-cell activity, we co-cultured control and B7H3-KD BC cells in the presence and absence of NK and T cells and measured the induction of apoptosis in BC cells through IncuCyte live-cell imaging system. The effect of a novel B7H3-blocking mAb (clone T-1A5, isotype IgG1) on NK-cell and T-cell-mediated cytotoxicity in BC cell lines was examined using live-cell imaging. In the TCGA and METABRIC databases, B7-H3 was found to be significantly overexpressed ($P < 0.0001$) in tumor tissues than in adjacent normal tissues of BC patients. A survival analysis by the log-rank test indicated that patients with B7-H3^{high} tumors had significantly lower progression-free ($P=0.01$) and relapse-free ($P=0.0026$) survival than patients with B7-H3^{low} tumors. Moreover, B7-H3 is significantly upregulated in all the BC subtypes including basal, luminal A, luminal B and Her2-enriched with highest expression in basal type BC. Relative mRNA quantification and flow cytometry analysis demonstrated strong B7-H3 expression in most of the BC cell lines including TNBC and ER+, PR+, and HER2+ cell lines, as well as TNBC PDX-derived cells. Furthermore, IHC analysis revealed that compared to the matched normal tissue, B7-H3 expression was substantially higher in tumor tissue ($N=16$, $P < 0.001$). Also, patients with high B7-H3 expression had significantly lower numbers of CD3+, CD4+, and CD8+ T-cell, compared to patients with low B7-H3 expression ($P < 0.001$), indicating immunosuppressive role of B7-H3. Furthermore, NK cell and T cell mediated killing was significantly higher in B7H3-KD BC cell lines compared to control cells. We observed a significant increase in the killing of BC cells by NK cells and T cells in the presence of anti-

B7H3 mAb T-1A5 in a concentration dependent manner ($P < 0.001$), suggesting that anti-B7H3 antibodies suppress the immunomodulatory function of B7-H3 and enhance NK and T cell-mediated ADCC in BC. To determine the antibody-dependent cell-mediated cytotoxicity, we developed a human-mouse chimera of T-1A5 (chT-1A5) and tested in combination with NK cells. Interestingly, we found a concentration and time dependent increase in ADCC in BC cells in the presence of chT-1A5 antibody. Our data suggests that B7-H3 is overexpressed in primary BC and inhibits immune-cell infiltration. Moreover, blocking the immunomodulatory functions of B7-H3 using anti-B7H3 antibody T-1A5 enhances NK and T cell-mediated killing of BC cells.

Background: Most breast cancers are not inherently immunogenic, and as a result are difficult to treat with immunotherapy. However, recent research has shown that triple-negative breast cancer (TNBC) and HER-2 positive (HER2) breast cancers can stimulate some level of an immune response. In contrast, the most common form of breast cancer, the luminal A (hormone receptor-positive (HR+)/HER-2 negative), has shown low involvement of tumor-infiltrating lymphocytes (TILs) and low expression of immune checkpoint inhibitors specifically programmed death-ligand-1 (PD-L1). Cryoablation, the destruction of cells using ultra-low temperatures, has been used as a primary treatment method for benign breast tumors and is in clinical trials to evaluate its use for invasive breast cancer. A secondary effect of cryoablation is the release of cellular proteins that can function as neoantigens and are in their native folded state. We hypothesize that release of these native neoantigens might trigger an immune response capable of preventing/reducing metastasis and local relapse. In this pilot study, we evaluated biopsy material, cryoablated specimens and sentinel lymph nodes (SLN) from patients enrolled in the ACOSOG Z1072 trial at Lankenau Medical Center (LMC) [N=18] with cancers < 2 cm. Responses were compared to patients treated with surgical resection. Methods: After obtaining IRB approval for retrospective analyses of specimens from the ACOSOG Z1072 trial, these samples were evaluated with immunohistochemistry (IHC) using commercially available antibodies and standard techniques to determine changes in CD4, CD8, CD20, CD21, CD1c levels, as well as the immune checkpoint regulators PD-1, PD-L1 and CTLA-4, and the immune modulator IDO1. Patient samples included biopsy, surgical material,

and SLN collected from the patients and were compared with patients of similar age, tumor characteristics and time to surgery. Per the ACOSOG trial protocol, tumors had to be surgically removed within 28 days of cryoablation, but the exact time was left to the surgeon's discretion. Participating surgeons at LMC preferred to remove tumors on average 24.7 days after ablation resulting in an average time from diagnosis to surgical removal of 43.3 days. Results: Cryoablation of the tumors resulted in coagulative necrosis presenting as a gelatinous mass surrounded by a fibrous capsule. The ACOSOG trial demonstrated effective cryoablation-induced destruction of ER+ invasive ductal carcinoma lesions in 92% of patients (N=86). On IHC staining of the cryoablated samples, more CD8+ lymphocytes were identified compared to CD4+, which was consistent with pattern among non-cryoablated tumors, albeit to a lesser degree. Though no difference in percentage of PD-1 positive cells were observed between treatment modalities, positive cells in cryoablated tumors had mostly moderate-to-strong staining. We observed a 20% increase in cells positive for PD-L1 after cryoablation with predominantly strong staining. Though IDO1 had fewer positive cells in the tumor mass, the expression in SLN was higher with nearly all cells exhibiting strong staining. Compared to the patients who were treated with surgery alone, the SLNs of cryo patients had higher levels of CD20+ B cells as well as CD21+ follicular dendritic cells. CTLA-4 was seen sporadically, but with a slight preference for the surgery patients. Conclusion: We show that cryoablation of breast cancer lesions in vivo can induce an immune response in HR+ tumors, turning an immunogenically cold tumor into an immunogenically hot, tumor potentially responsive to check-point inhibitors and immune modulators. Possibly providing less toxic treatment options for elderly patients and/or patients with comorbidities All local cryo patients in the clinical trial are currently disease-free (F/U 5 - 13years), while 1 surgical patient is alive with late recurrence (11 years post-surgery).

The activin-like kinase receptor 1 (ALK1, encoded by ACVRL1) is a member of the transforming growth factor β (TGF- β) superfamily. Expression of ALK1 has been historically associated with endothelial cells, thus serving as a potential target for antiangiogenic therapy in cancer. Despite promising preclinical results with a ligand trap (RAP-041/dalantercept), clinical trials did not show additional benefit of dalantercept when combined or contrasted with the standard of care.

This outcome raises the question about patient selection and optimal combination partner in the clinical setting. Moreover, from the biological perspective, how ALK1 signaling shapes the features of a tumor is still largely uncharted. Based on our previous observations, we confirmed that the genetic network correlated with ACVRL1 expression is associated with immune processes in human breast cancer. Next, we validated that inhibition of ALK1 altered the immune landscape in experimental primary breast cancer (MMTV-PyMT model), providing a rationale for a combined regimen with immunotherapy. After developing and validating a murine model of adjuvant therapy with RAP-041 (syngeneic E0771 and 4T1 cell lines), we discovered that ALK1 blockade potentiated immune checkpoint inhibitors. Based on bulk RNA-sequencing and a multicolor FACS approach, addition of RAP-041 to immunotherapy significantly reduced the number of intratumoral macrophages compared with either treatment alone. Notably, these changes were coupled with systemic alterations in peripheral blood cell composition, with the combined administration suppressing circulating monocytes. Interestingly, ALK1 signaling appears to be a pivotal contributor to this phenotype, as fewer circulating monocytes were also detected in the RAP-041 cohort. Based on our in vitro characterization, we revealed that ALK1 expression is not limited to endothelial cells, as different myeloid populations readily expressed *Acvrl1*, suggesting a direct functional role of ALK1. Stimulation of ALK1 did not alter macrophage polarization, even though different levels of mediators downstream of ALK1 characterized the M1/M2 states. Furthermore, apoptosis and necrosis did not seem to be affected upon activation of ALK1, while the effect on the cell cycle awaits confirmation. In vitro genetic modulation of ALK1 activity is ongoing, with co-culture systems, transendothelial adhesion and migration being currently assessed. Inspection of several human sc-RNA-sequencing datasets confirmed the existence of ACVRL1-positive monocytes in human PBMCs from healthy individuals as well as in human solid cancers, including breast cancer. Focusing on the immune compartment, ACVRL1 expression characterized recruited tumor-associated macrophages (TAMs) and their cycling counterpart. In light of this feature, longitudinal follow-up of patients exposed to chemotherapy and/or anti-PD-1/PD-L1 revealed that expression of ACVRL1 decreased following exposure to chemotherapy. Notably, high ACVRL1 expression and an increased proportion of ACVRL1-positive TAMs were found at progression with anti-PD-1 treatment. In agreement with our preclinical data, ACVRL1-positive cells were depleted from circulation upon recurrence, indicating a migration from blood to tumors. Finally, survival analysis determined that ACVRL1^{hi} signature in macrophages correlated with a significantly lower survival in a 5-year follow-up in breast cancer. In conclusion, our work sheds light on the value of ALK1 as a promising dual antiangiogenic and immunomodulatory target for precision medicine in cancer.

Breast cancer is one of the most commonly diagnosed cancer types and a leading cause of cancer death in women in the United States. However, it is difficult to treat with immunotherapy because of its immunological “cold” status. This underscores the importance of a novel clinical approach to increase efficacy of immunotherapy including acute upregulation of Type I Interferon (IFN) response. One strategy to enhance Type I IFN response is by release of damage-associated molecular patterns (DAMPs) from mitochondria, including mitochondrial DNA, RNA and oxidized proteins that are recognized by pattern recognition receptors (PRRs) in cytoplasm and activate downstream IFN signaling. Because many cancers including breast cancer experience increased and dysregulated mitochondrial biogenesis at baseline, they contain significantly higher levels of DAMPs compared to normal cells, but these substrates are sequestered in mitochondria and not accessible to PRRs. We set out to develop a strategy to exploit increased levels of DAMPs in cancer cell mitochondria to enhance Type I IFN response. While DAMPs are released from mitochondria upon apoptosis caused by mitochondrial outer membrane permeabilization (MOMP), Type I IFN response is still silenced due to cleavage of PRRs by activated caspases. One way to induce MOMP is by inhibition of Myeloid Cell Leukemia-1 (Mcl-1), an anti-apoptotic family protein that is frequently upregulated in breast cancer. Interestingly, breast cancer cell lines showed the highest dependency on Mcl-1 among solid cancers and inhibitors of Mcl-1 have shown efficacy in breast cancer early clinical trials. Based on our preliminary observations showing that Mcl-1 inhibition activates a robust Type I IFN response in MCF7 breast cancer cells deficient for caspase 3, we hypothesized that combining Mcl-1 inhibitors with caspase inhibitors would greatly enhance Type I IFN response in a robust and specific manner by facilitating release of DAMPs into the cytoplasm while preventing inactivation of PRRs. Strikingly, in contrast with Mcl-1 inhibitor treatment alone, combination treatment led to dramatic increase in expression levels of IFN- β and interferon-stimulated genes (ISGs) in MCF7 and ZR-75-1 ER+ breast cancer cell lines with minimal effects on cytotoxicity. In addition, T47d, a breast cancer line highly resistant to Mcl-1 inhibition due to compensation by other Bcl-2 family proteins, showed greatly enhanced Type I IFN response upon combined Mcl-1, Bcl-2 and caspase inhibition. Because reduced expression of MHC class I molecules on cell surface is one of the most important immune escape mechanisms in tumors including breast cancer, we examined whether the proposed combinatorial treatment would overcome this by enhancing expression of MHC class I. Immunofluorescence (IF) staining confirmed that the combination treatment dramatically increased total HLA-ABC protein expression on plasma membrane of ZR-75-1. Furthermore, combinatorial treatment upregulated transcription of most genes responsible for antigen presentation, a multistep process consisting of antigen peptide generation and loading of MHC class I molecules. Lastly, we sought to examine how elevated chemokine expression may impact patients with breast cancer. We examined association of cytokines highly upregulated by the combination treatment with immune cell infiltration using a TCGA dataset that included

over a thousand breast cancer samples. This analysis was performed by xCell algorithm and demonstrated strong association of that cytokine expression with CD8+ T, B and DC infiltrate. Our results demonstrate that the combination of Mcl-1 and caspase inhibitors greatly enhances Type I IFN response and may improve anti-tumor immunity. We plan to further test this drug combination in immunocompetent mouse models, laying the foundation for a clinical trial assessing the combination treatment in patients with metastatic ER+ breast cancer.

Introduction Recent advances in breast cancer treatment strategies have improved survival outcomes in metastatic breast cancer (mBC). Targeting immune checkpoint, especially programmed death 1 (PD-1)/programmed death ligand 1 (PD-L1), has made a breakthrough in treating advanced malignancies including breast cancer. Immune checkpoint inhibitors (ICIs), such as pembrolizumab and atezolizumab, in combination with chemotherapy have prolonged survival outcomes in mBC with triple negative subtype. However, the low response rate and resistance of ICIs with anti-PD 1/PDL-1 antibodies is a major limitation and a challenge. Lymphocyte Activation Gene-3 (LAG3; CD223) is a potential cancer immunotherapeutic target due to its negative regulatory role on T cells and cytokines, thereby ensuring immune homeostasis. Several studies suggested that combination immunotherapy of anti-LAG-3 and anti-PD-1 has shown promising efficacy in fighting PD-1 resistance. Therefore, we evaluated the prognostic role of LAG3 in metastatic TNBC (mTNBC) treated with ICIs to figure out resistance mechanism of ICIs. **Methods** mTNBC patients with available archival tumor tissues, who has received ICIs in Samsung Medical Center, were enrolled in this study. For the evaluation of LAG3 expression in tumor microenvironment, Vectra Polaris Multispectral Imaging and Whole Slide Scanning technique (PerkinElmer, Inc. Hopkinton, MA) was used. **Results** In total, 64 mTNBC patients were treated with ICI's with or without cytotoxic chemotherapy between 2019.02- 2021.11. Of 70 mTNBC patients, 41 patients had archival tissues and finally 40 patients were included in this study. Median age was 43.0 years of age (range: 24.5 ~ 64.5). Recurrent mTNBC was 92.5% and only 7.5% was de novo mTNBC. Geremline BRCA1 pathogenic variants were detected in 4 (10.0%) patients. Among 37 recurrent mTNBC patients, 72.5% were treated with neoadjuvant chemotherapy with anthracycline (97.3%) and taxane(97.3%). Among ICI's, 52.5% were treated with pembrolizumab and 47.5% of

atezolizumab. LAG3 expression varies among mTNBC tissues (median cell density: 366, range: 48, 2861 cells/mm²). Among cells expressing LAG3, LAG3 was expressed more in CK+ cells compared with CK- cells (median:150 (20, 2503) cells/mm² in CK+ cells, median: 88 (2, 806) cells/mm² in CK- cells, p=0.005). Patients with high LAG3 expression in CK+ cells showed short progression free survival(PFS) compared to those with low LAG3 expression in CK+ cells (median PFS of high vs. low LAG3 expression [months]:1.9 vs. 4.2, p=0.01). On the contrary, patients with high LAG3 expression in CK- cells had 9.1 months of PFS compared to 3.1 months of PFS in patients with low LAG3 expression in CK- cells (p=0.10). In addition, patients with high LAG3 in CK- cells had longer overall survival(OS) compared to those with low LAG3 expression in CK- cells (median OS of high vs. low LAG3 expression [months]: not reached, 15.7, p=0.05). Conclusion LAG3 expression was associated with PFS in patients with mTNBC treated with ICI's independent of PDL-1 expression. And the prognostic significance of LAG3 expression was different between CK+ cells and CK- cells. These findings need to be proved in large scale clinical trials.

Clinical studies have linked usage of progestins (synthetic progesterone) to breast cancer risk. However, little is understood regarding the role of native progesterone (P4), signaling through the progesterone receptor (PR), in breast tumor formation. Recently, we demonstrated that P4 treatment or PR overexpression can drive changes in immune cell populations in the murine mammary gland and that PR overexpression leads to increased development of mammary gland tumors in mice. Given these findings, we sought to investigate whether P4 impacts tumor growth and immune cell infiltration of mammary gland tumors. We utilized syngeneic mammary gland tumor models to evaluate the effect of P4 on PR+ mammary gland tumor growth, which

revealed that P4 promoted tumor growth and impacted immune cell infiltration of PR+ mammary gland tumors. Of note, numbers of tumor-infiltrating dendritic cells were decreased and exhausted T cells and regulatory T cells were increased with P4 treatment in PR+ tumors. To determine if anti-progestin therapies could reverse the growth-promoting effect of P4 on mammary gland tumors, mice bearing PR+ mammary gland tumors were treated with the anti-progestin onapristone. Onapristone treatment led to significantly decreased tumor volumes in two syngeneic mammary gland tumor models and reversed the effect that P4 had on tumor-infiltrating regulatory T cells. To determine if inhibition of tumor growth by onapristone was immunologically mediated, SCID mice bearing PR+ mammary gland tumors were treated with onapristone. Results revealed a decreased ability of onapristone to inhibit tumor growth in SCID mice compared to immunocompetent mice, suggesting that inhibition of tumor growth is, in part, immunologically mediated. These findings offer a novel mechanism of P4-driven mammary gland tumor development and provide rationale in investigating the usage of anti-progestin therapies to promote immune-mediated elimination of mammary gland tumors.

Abundance of tumor-infiltrating lymphocytes is associated with pathologic complete response to neoadjuvant chemotherapy but not with survival in ER-positive/HER2-negative breast cancer

INTRODUCTION: Abundance of tumor infiltrating lymphocytes (TILs) is well known to be associated with achievement of pathologic complete response (pCR) after neoadjuvant chemotherapy and is a surrogate of better survival in triple negative breast cancer (TNBC). However, the association remains unclear in ER-positive/HER2-negative, which is the most common subtype in breast cancer. Further, pathological quantification of TILs is known for its ambiguity. We hypothesized that abundance of TILs, quantified by transcriptomic signatures, in ER-positive/HER2-negative is associated with different biology and is not a surrogate of survival unlike in TNBC. **METHODS:** A total of 6035 primary breast cancer patients from three cohorts (TCGA, METABRIC, and SCAN-B) with full transcriptome and clinical data were analyzed. Lymphocyte fractionation in the tumor microenvironment of a bulk tumor was estimated from the transcriptome using two different deconvolution tools, CIBERSORTx and xCell. **RESULTS:** First, the correlation between TIL score measured histologically on TCGA patients and gene expression of CD3D, CD3E, CD3G, CD8A, CD4, and total lymphocytes, and total T-cells measured by xCell or CIBERSORTx were analyzed. Total sum of lymphocytes by xCell correlated the strongest, thus it was adopted as the TIL score. The TIL score strongly correlated with CD3G, CD3E, CD3D, CD8A, and CD4 gene expressions in both TCGA and GSE96058 cohorts (all $r > 0.48$). Among the infiltrated cells; M1 and M2 macrophages, dendritic cells, mast cells and monocytes were all higher, and microvascular endothelial cells and pericytes were lower in TIL score high tumors in ER-positive/HER2-negative (all $p < 0.01$) where M2 and mast cells were not in HER2+ and TNBC in both 2 cohorts. Enrichment of immune related gene sets IL2/Stat5 signaling, IL6/Jak/Stat3 signaling, inflammatory response, and Complement were less in high TIL group of ER-positive/HER2-negative than HER2 and TNBC. In agreement, cytolytic activity was lower in TIL high of ER-positive/HER2-negative

compared from TNBC. On the other hand, high TIL group in ER-positive/HER2-negative had significantly higher intratumor heterogeneity, homologous recombination deficiency, mutation burden, and neoantigens, which were not the case in the other subtypes. In agreement, all the cell proliferation-related gene sets; E2F targets, G2M checkpoint, mitotic spindle, Myc targets v1 and v2, were more strongly enriched in high TIL group of ER-positive/HER2-negative compared from HER2+ and TNBC. MKI67 gene expression and Nottingham histological Grade were uniformly elevated with high TIL regardless of subtypes. In three independent neoadjuvant cohorts, we found that pathologic complete response rates of high TIL group. On the other hand, high TIL group did not show any survival benefit compared with low TIL group in ER-positive/HER2-negative, unlike in HER2+ or TNBC. CONCLUSION: High tumor-infiltrating lymphocytes in ER-positive/HER2-negative breast cancer was associated with less immune response and higher genetic alteration and cell proliferation compared to the other subtypes, leading to better response of neoadjuvant chemotherapy, but no benefit in survival outcome.

Title: Relationship of HIF-1 α and tumor infiltrating lymphocytes in patients with HER2-negative early-stage breast cancer treated with neoadjuvant chemotherapy Authors: Grabinski VF, Oza HH, Gilkes DM, Shah MY, Cimino-Mathews A, Gabrielson E, Zhi I, Pipa Z, Lehman J, Ibanez HE, Ke S, Tsai HL, Stearns V, Santa-Maria CA Introduction: Hypoxia inducible factor 1 α (HIF-1 α) is an oxygen-dependent transcription factor expressed in areas of hypoxia associated with

regulation of immune escape mechanisms, metabolism (CAIX), and results in cancer treatment resistance. High stromal tumor infiltrating lymphocytes (sTILs) are associated with pathologic complete response (pCR) to neoadjuvant chemotherapy (NACT) in breast cancer. We investigated associations between HIF-1 α , sTILs and their relationship with pCR after NACT in patients with HER2-negative early-stage breast cancer. Methods: We identified patients with early-stage HER2-negative breast cancer at the Johns Hopkins Sidney Kimmel Comprehensive Cancer Center from 2000-2009 who received NACT, and had accessible breast tissue from biopsy and/or surgery. A pathologist scored nuclear HIF-1 α (0, 1, 2, or 3), membranous CAIX (0, 1, 2, or 3), sTILs (0-100) from baseline (ie pre-NACT) and surgical tissue (if non-pCR). Statistical analysis considered the following variables: age, histology, race, menopausal status, tumor size, and node status. Chemotherapy regimens were divided into either anthracycline AND taxane versus anthracycline OR taxane. Wilcoxon rank-sum, Fisher exact, and Jonckheere trends tests were utilized to assess differences between groups. Results: 43 patients met the predefined criteria and were included in the analysis, 16% (n=7) obtained a pCR. Patient race, ethnicity, clinical tumor size, histology, clinical subtype (estrogen receptor positive (ER+) vs. triple negative (TN)), and NACT regimen were not associated with pCR. Older age (p=0.019), postmenopausal status (p=0.009), smaller surgical tumor size (p < 0.001), and surgical node-negative status (p < 0.001) were associated with pCR. Mean TILs score was 32.5% in patients achieving pCR versus 20% in those with non-pCR (p=0.46); mean HIF-1 α was 2.42 in pCR group versus 2.57 in non-pCR (p=0.84). There was a trend of lower baseline sTILs with increasing nuclear HIF-1 α score (p=0.085). Membranous CAIX was not associated with nuclear HIF-1 α or baseline TILs, however, in the small proportion of patients (n=11) with CAIX scoring, higher membranous CAIX score at baseline (1 vs. 0) was associated with pCR (p=0.024). Conclusions: We observed that patients with pCR had a numerically higher sTILs level at baseline consistent with other studies, but did not find a correlation of HIF-1 α and pCR. Patients with higher HIF-1 α scores tended to have lower sTILs, suggesting that hypoxia may be leading to an immunosuppressive tumor microenvironment. Further characterizing the HIF-1 α pathway and its effects on the immune microenvironment may help identify resistance mechanisms to chemotherapy and immunotherapy.

Here, we report that uncontrolled elevation of CD73 levels due to its aberrant turnover is tightly correlated with poor prognosis in immune-cold triple negative breast cancers (TNBCs), which impedes the efficacy for chemotherapy and immunotherapy. We have identified TRIM21 as a E3 ligase that governs CD73 destruction. Disruption of TRIM21 stabilizes CD73 that in turn enhances CD73-catalyzed production of adenosine, resulting in the suppression of CD8+ T cell function. The immunostaining demonstrated the cytosolic colocalization between TRIM21 and CD73. Molecular mapping further identified the amino acid stretches from 340-476 on TRIM21 and residues from 176-224 on CD73 mediated the interaction between TRIM21 and CD73. Replacement of lysine 133, 208, 262 and 321 by arginine on CD73 attenuated CD73 ubiquitylation and degradation. Moreover, TRIM21 is upregulated but CD73 is downregulated in response to IFN- γ secreted from activated CD8+ T cells in a feedback manner. Importantly, in preclinical animal models, diminishing of CD73 ubiquitylation remarkably promotes tumor growth and impedes antitumor immunity. In addition, a TRIM21^{high}/CD73^{low} signature in a subgroup of human breast malignancies was associated with a favorable immune profile. Collectively, our findings uncover a novel mechanism that governs CD73 proteolysis and point to a new therapeutic strategy by modulating CD73 ubiquitylation.

Purpose: Elucidating the unique immunomodulatory mechanisms in breast cancer microenvironment should provide useful insights to aid the development of new therapeutic strategies for this disease. Some studies suggested the immune regulatory function of hormone

receptor such as estrogen receptor- α (ER) and androgen receptor (AR), but their mechanism has not been fully understood because of the complexity of immune milieu in breast cancer microenvironment. In this study, we systematically analyzed the relationships between ER, progesterone receptor (PgR), and AR expression and the immunological profile in breast cancer tissue. Methods: Gene set enrichment analysis (GSEA) was used to screen the biological processes associated with the expression of human sex hormone receptor genes (ESR1, PGR, and AR), using a gene expression profile dataset of the Molecular Taxonomy of Breast Cancer International Consortium (METABRIC). Then, using METABRIC and a gene expression profile dataset of The Sweden Cancerome Analysis Network - Breast (SCAN-B), the correlation between the immune cell composition in breast cancer tissue (estimated with the CIBERSORTx) and hormone receptor expression was analyzed. In our previous study of 45 breast cancer tissues, we evaluated the level of human tumor infiltrating lymphocytes (hTILs), expression of human programmed death-ligand 1 (hPD-L1), and infiltration of 11 types of immune cells, using hematoxylin–eosin staining, immunohistochemistry (IHC), and multicolor flow cytometry, respectively. In this study, the levels of ER, PgR, and AR expression were further evaluated using IHC, and their relationship with the immunological profile of breast cancer tissues was analyzed. Results: GSEA showed that the expression levels of the ESR1, PGR, and AR genes were negatively correlated with multiple immunological processes, including “INFLAMMATORY RESPONSE.” Analysis of the correlations between the immune cell composition and hormone receptor gene expression showed that ESR1 expression was inversely correlated with Macrophage M1, CD4 memory activated T cells, Macrophage M0, CD8 T cells, and CD4 memory resting T cells; PGR expression was inversely correlated with Macrophage M1, CD4 memory activated T cells, and Macrophage M0; and AR expression was inversely correlated with Macrophage M0 and Macrophage M1. Immunohistochemical evaluation of ER and AR expression revealed both receptors to be inversely associated with hTIL, hPD-L1 expression, and leukocyte infiltration in breast cancer tissue. Analysis of the immune cell composition in these tissues revealed that ER expression was associated with the decreased infiltration of total T cells, CD4+ T cells, monocytes/macrophages, myeloid-derived suppressor cells, dendritic cells, and myeloid dendritic cells; PgR expression was associated with the decreased infiltration of dendritic cells; and AR expression was associated with the decreased infiltration of CD4+ T cells, monocytes/macrophages, nonclassical monocytes, myeloid-derived suppressor cells, dendritic cells, myeloid dendritic cells, and minor natural killer cells. Conclusion: The correlation of hormone receptor expression with specific immunological profiles in the breast cancer microenvironment both at the genetic and protein levels strongly suggests that hormonal signals may preferentially affect certain subsets of immune cells.

Background: Eribulin, an anticancer drug that increases the overall survival (OS) of patients with metastatic recurrent breast cancer, inhibits microtubule polymerization, although the mechanism is different from that of other microtubule inhibitors (taxanes). A subgroup analysis revealed a low neutrophil-to-lymphocyte ratio (NLR) (< 3) to be a prognostic factor of eribulin treatment. NLR has also been reported to be a predictive marker for cancer immunotherapy. Checkpoint inhibitor-based cancer immunotherapy is currently available for breast cancer. We hypothesized that eribulin improves breast cancer cell immune response. Immunological effector cytotoxic T lymphocytes (CTLs) recognize antigenic peptides presented by human leukocyte antigen (HLA) class I; HLA class I downregulation is frequently observed in breast cancer. Here, we evaluated the CTL response in eribulin-treated breast cancer cells. Materials and Methods: HLA class I expression before and after eribulin treatment was evaluated using immunohistochemistry in tumors from patients, and by immunofluorescence, flow cytometry, western blotting, and quantitative RT-PCR (qRT-PCR) in breast cancer cells (MDA-MB231 and MCF7). Factors that upregulate HLA class I were screened using RNA-seq. To evaluate T cell recognition, we generated cancer testis antigen (NY-ESO-1)-specific T cell receptor transduced-T cells (TCR-T cells). NY-ESO-1 cDNA was stably transduced into MCF7 and

MDA-MB-231 cells. TCR-T cell reactivity with MCF7/NY-ESO-1 cells was analyzed using an ELISPOT assay. A combinatorial therapy model was established using eribulin and TCR-T. Results: HLA class I was upregulated after eribulin treatment in clinical samples. To confirm this, we treated breast cancer cells with eribulin and evaluated HLA class I expression. Eribulin increased HLA class I expression, as evidenced by immunofluorescence, flow cytometry, western blotting, and qRT-PCR. RNA-seq results on eribulin-treated cells showed that eribulin upregulated NLRC5, a master regulator of HLA class I. IFN γ ELISPOT assay revealed that eribulin increased IFN γ secretion by TCR-T cells ($p < 0.01$), indicating that eribulin enhanced the immune response. These results suggest that eribulin and immunotherapy had a synergistic effect. Therefore, we established an eribulin and NY-ESO-1 combinatorial therapy model and showed that the combination group had a significantly lower number of viable cancer cells than the eribulin- and TCR-T-only groups ($p < 0.01$). Conclusions: Eribulin increased the expression of HLA class I, probably by upregulating NLRC5 in breast cancer cells. It also enhanced TCR-T recognition in breast cancer cells. The combinatorial therapy model revealed the synergistic effect of eribulin and TCR-T. These results indicate that eribulin might be an immune potentiator and that combination therapy with immunotherapy can be effective for the treatment of breast cancer.

Background: Invasive lobular breast carcinoma (ILC) represents 5 to 15% of all invasive breast cancers. Recent studies showed the importance of tumor microenvironment (TME) heterogeneity on patient outcome. Here, we aim to characterize TME spatial heterogeneity by performing clustering analysis on spatial transcriptomics (ST) data. Methods: Frozen tumor samples from 43 primary estrogen receptor positive, HER2-negative ILCs were characterized using ST (Visium, 10x Genomics), each ST slide containing 4992 spots. Hematoxylin/eosin (H&E) stained ST slides were annotated (QuPath software) reaching single cell resolution. After performing normalization, hierarchical clustering (STUtility R package) across all samples was carried out on principal components computed using highly variable genes. Clusters were characterized using morphological annotation and gene set enrichment analysis for hallmark gene sets from MSigDB (FGSEA R package). A cluster of spots was defined as tumoral or stromal if the average proportion of pixels annotated as tumor or stroma across its constitutive spots was higher than the average proportion of tumor or stroma pixels across all spots of our cohort. Spatial heterogeneity was assessed by comparing the number of contacts between spots belonging to the same cluster (homo-contacts) and the number of contacts between spots belonging to different clusters (hetero-contacts). Comparisons between groups were assessed using Wilcoxon test. Results: Out of the 43 ILC samples, 19 were T2 or T3, 13 were node-positive and 34 were grade 2. Of note, 9 patients experienced disease relapse. Morphological annotation revealed that an average of 20.4%, 61.12%, 11.5%, 0.45%, 3% of the tissues in our dataset corresponded to tumor, stroma, adipose tissue, immune infiltrate and normal structures (vessels, normal breast), respectively. Bioinformatics analysis revealed 7 tumor, 11 stroma, and 6 normal structures clusters, as well as 8 mixed clusters with no predominant morphological structure, with a median of 22 clusters per sample. Tumor and stroma clusters were either shared across all samples or present only in specific samples. Overall, tumor clusters were characterized by an enrichment in estrogen and androgen response related pathways. Moreover, tumor clusters enriched in oxidative phosphorylation, G2M checkpoint and MYC targets were more present in samples with higher histopathological grade ($p=0.016$), whereas tumor clusters enriched in interferon alpha/gamma response related pathway were associated with a higher tumor stage ($p=0.007$). A higher number of hetero-contacts among tumor spots were associated with disease relapse ($p=0.02$). Similarly, a higher number of hetero-contacts among stroma spots including immune and adipose related clusters was also found in samples from patients who experienced disease relapse ($p=0.01$). Overall, these findings suggest a role of both tumor and stroma spatial disorganization and heterogeneity in tumor progression. Furthermore, clusters capturing the presence of normal breast and in situ carcinoma were enriched in samples from patients who did not relapse ($p<0.001$). Conclusion: Our results revealed the substantial inter- and intra-patient heterogeneity of ILC both at the tumor and microenvironment levels. Different tumor and stroma clusters characterized by specific hallmarks were associated to specific clinical features and disease outcome, unraveling potential new targets for optimizing ILC care. Further validation is needed.

Introduction: The use of preoperative CDK4/6 inhibitors combined with endocrine treatment remains investigational in breast cancer (BC), while their effect on tumor-immune microenvironment (TIME) in luminal BC is the subject of few published studies. The aim of this study was to characterize the treatment-induced changes of TIME at a spatial proteomic and bulk tumor transcriptomic level in clinical luminal A BC patients treated with neoadjuvant palbociclib and endocrine treatment. **Methods:** The PREDIX Luminal A phase II randomized clinical trial (NCT02592083) included patients with stage 2-3 BC and IHC-defined luminal A biology (ER+ and PR+, HER2-, low proliferation) treated with preoperative ET (tamoxifen or aromatase inhibitor) with or without the addition of CDK4/6i palbociclib, based on the early change of Ki67 levels. A core biopsy was obtained at baseline, after 10 weeks of treatment (on-treatment) and at surgery. The study was closed after the inclusion of 10 patients due to slow accrual. By using formalin-fixed paraffin-embedded tissue from all timepoints, we performed the GeoMx® Digital Spatial Profiling (DSP, NanoString, Seattle, WA, USA) for the spatial profiling of 27 immune cell and tumor markers (immune cell profiling core and pan-tumor panels) both at intra-epithelial and stromal tissue segments. Upon data normalization, a linear mixed model was adopted for differential marker expression assessment between the different timepoints and treatment arms, using the DSP Suite® software. RNA was also extracted from fresh-frozen biopsies and the nCounter® Breast Cancer 360™ panel (NanoString) was used for gene expression profiling of 776 targets and data analysis was performed using the nSolver® software. **Results:** A total of 7 patients received palbociclib + ET and 3 were treated with ET only. All patients experienced an on-treatment radiological partial response while no patient achieved pathological complete response. While ET suppressed the ER axis in both palbociclib-treated and untreated patients, treatment with palbociclib additionally led to cell-cycle arrest as evidenced by a decrease in proliferation and downregulation of cell-cycle gene pathways. Immune-related protein markers were enriched in the stroma segments and pan-tumor markers were enriched in the intra-epithelial segments at all timepoints. In palbociclib-treated patients, immune cell markers (e.g. CD45, CD68, CD20, CD4, HLA-DR) were significantly enriched in on-treatment samples (n=3) both in tumor and stromal segments, while these expression changes were reversed between on-treatment and surgery. In the ET-treated patients immune markers reflecting e.g. T-, B- and/or antigen-presenting-cells were significantly enriched at the operation samples (n=2), in the intra-epithelial but not in the stromal areas. This finding was confirmed also at the gene level, where immune-related pathways (e.g. chemokine and cytokine activity and receptor binding) were upregulated in the palbociclib-treated patients on-treatment but they were partially abrogated at surgery. The ET-only treated patients presented with enhanced immune activation gene sets at both on- and post-treatment timepoints **Conclusion:** The findings of this small hypothesis-generating study indicate an upregulation of immune function during treatment with palbociclib and ET and an altered tumor microenvironment. The prognostic and potential therapeutic implications of sensitizing tumors to subsequent chemotherapy and immunotherapy need to be further investigated in larger studies.

Ductal carcinoma in situ (DCIS) is characterized by inter-tumor heterogeneity that poses a therapeutic challenge due to its unpredictable recurrence and progression to invasive breast cancer (IBC). Recent publications have implicated the crucial role of the tumor microenvironment particularly stromal differences between DCIS patients who progress to IBC (progressors) and those that do not (non-progressors). However, spatial regulation of the collagen proteome has yet to be investigated in the context of disease progression in DCIS. In this study, we hypothesized that the collagen proteome was significantly altered between DCIS

and IBC and that differentiating collagen peptide signatures could be related to clinical outcomes. Our initial studies investigated collagen peptide signatures in lumpectomies (n=13) annotated as DCIS, DCIS and invasive ductal carcinoma (IDC), or IDC only. We leveraged our previously published method for spatial imaging of collagen proteomics on tissue to report collagen types and collagen post-translational modifications including 40 other extracellular matrix (ECM) proteins involved in the regulation of collagen fibers. Over 1000 peaks were found to be linked to annotated pathologies or adjacent regions. Initial comparison of DCIS to IDC lesions demonstrated 63 differentially expressed peaks between these regions by unpaired, two-tailed t-test ($p < 0.001$). Image segmentation of the 315,541 pixels demonstrated 16 high-level hierarchical groups designating unique spatially localized ECM proteomic groups. Notably, these groups overlaid with histopathological features and pathological annotations. Next, we investigated collagen peptide signatures in a subset of DCIS samples from the Resource of Archival Breast Tissue (RAHBT) (n=37). Samples were histologically diverse within the tissue microarrays, with cribriform, micropapillary, papillary, solid, and comedo necrosis architectural patterns. In our preliminary analysis, we found two peptide peaks that could distinguish the solid subtype (n=22) from comedo necrosis (n=4) and one peak that could discriminate between the cribriform (n=8) and solid subtype (n=22) by area under the receiver operating curve (AUROC) ≥ 0.75 and Wilson/Brown t-test ($p < 0.05$). Evaluated per clinical outcome, four ECM peptides showed significantly different peak intensities in progressors with IBC recurrence (n=7) compared to non-progressors (n=26) (AUROC ≥ 0.75 ; Wilson/Brown t-test $p < 0.05$). One peptide had significantly different peak intensities between progressors with contralateral IBC recurrence and DCIS recurrence (n=5) and non-progressors (n=26) (AUROC ≥ 0.75 ; Wilson/Brown t-test $p < 0.05$). Overall, the data suggest that unique collagen signatures in DCIS could be useful for understanding recurrence and progression to IBC. Further investigation of the spatial distribution of the collagen proteome within DCIS pathologies and relative to clinical outcome is warranted.

Introduction: Breast cancer (BC) during pregnancy (PrBC) is an uncommon malignancy characterized by a more aggressive clinical course compared to pregnancy-unrelated BC. Specific patterns of tumor-infiltrating lymphocytes (TILs) subpopulations have been observed in these patients, with significant prognostic roles. Previous studies demonstrated the varying histopathologic and prognostic profiles of PrBC by gestational age. However, the underlying immune landscape dynamics has never been investigated. Here, we sought to provide comprehensive insights into the association between gestational age at breast cancer diagnosis and tumor immune microenvironment (TIME) composition. **Materials and Methods:** A total of 110 PrBC were selected from our Institutional registry and categorized based on the trimester in which they were diagnosed. All cases were subjected to TILs profiling according to the International TILs Working Group recommendations. Immunohistochemistry for CD4, CD8, forkhead box P3 (FOXP3), and PD-L1 (clone 22C3) on a Dako Omnis platform was performed. Fisher's and Chi-squared tests, multinomial logistic regression models, ROC curve, and survival analyses were performed. **Results:** The proportion of patients with high histologic grades incremented with the increase in gestational age (1st, n=24, 53%; 2nd, n=27, 69.2%; 3rd trimester, n=20, 87.0%; p=0.02). Neither breast cancer subtypes nor the hormone receptor (HR) and HER2 status changed significantly according to the pregnancy trimester. In HR+/HER2- subtype, the proportion of TILs+ tumors were higher in the early phases of pregnancy (1st, n=29, 100%; 2nd, n=17, 89.5%; 3rd trimester, n=9, 81.8%; p=0.04) imprinted by FOXP3 positivity where more FOXP3+ TILs were seen in the first months and decreased progressively (1st, n=10, 55.6%; 2nd, n=2, 11.8%; 3rd trimester, n=0, 0%; p< 0.01). While in the triple negative breast cancer (TNBC) population, the proportion of PD-L1+ tumors (i.e. CPS>1) was significantly higher in the later stages of pregnancy (1st, n=2, 16.7%; 2nd, n=2, 18.2%; 3rd trimester, n=5, 71.4%; p=0.03). Patients who relapsed after a BC diagnosis during the 1st and 2nd trimesters lacked more frequently FOXP3+ and CD8+ cells, unlike those with no disease recurrence (n=21, 77.8% vs. n=17, 48.6%; p=0.02 and n=18, 66.7% vs. n=10, 28.6%; p< 0.01, respectively). **Conclusions:** TIME dynamics of PrBC are different according to the gestational age in both HR+ and TNBC PrBC. Our results suggest that immune tolerance events are likely to involve PrBC at later gestational age. Specific escape mechanisms (i.e., TILs and FOXP3 decrease in HR+ and PD-L1 expression in TNBC) might explain the aggressiveness of PrBC diagnosed during the later gestational age.

Brain metastases are associated with shortened survival and poorer quality of life in breast cancer patients. Recently, the importance of platelet-derived growth factor-B (PDGFB) and its stromally localized cognate receptor, platelet-derived growth factor receptor-beta (PDGFR β) in promoting breast cancer metastasis to the brain was identified by our group. Historically, PDGFB-to-PDGFR β signaling is known to promote angiogenesis and vessel maturation both in normal physiology and in cancer, but the mechanism(s) behind this tumor stromal interplay in brain metastasis is poorly understood. Based on our previous work and the work of others, we hypothesized that breast tumor-derived PDGFB directly modulates both brain endothelial and blood brain barrier (BBB) function by altering angiogenesis and endothelial permeability. To test this directly, we over-expressed PDGFB ligand in MDA-MB-231 and HCC1187 triple negative

breast cancer cell lines and compared the angiogenic potential of the conditioned medium (CM) from these cells. We utilized both a 3D in vitro (human brain microvascular endothelial cell, HBMEC) spheroid angiogenesis model and a tri-culture BBB system (HBMECs in direct interaction with human astrocytes and human pericytes) to test the BBB vasculature. CM harvested from PDGFB overexpressing cells significantly increased the sprouting angiogenesis potential of 3D HBMECs and the migration of 3D tri-culture BBB spheroids compared to CM obtained from parental cells. In addition, CM from PDGFB overexpressing cells caused the surface of BBB spheroids to exhibit significantly increased permeability to high molecular weight dextran compared to CM from parental cells. In agreement with these findings, the tight junction protein ZO1 was diminished. Importantly, in vivo BBB permeability was also tested upon intracardiac injection of MDA-MB-231 cells with and without PDGFB overexpression. These studies revealed that Evans blue dye fluorescence intensity was significantly higher in the brains of mice injected with PDGFB overexpressing cells compared to parental cells. Overall, these studies reveal a previously unrecognized role for PDGFB-to-PDGFR β signaling in brain vascular remodeling and BBB permeability, which has clinical implications for women with PDGFB-positive breast cancer.

Background Triple negative breast cancer (TNBC) is a breast cancer subtype with increased risk of distant metastasis, especially to lung and liver. In addition to the intrinsic characteristics of tumor cells, the molecular features of the tumor microenvironment cells can also regulate the metastasis process of TNBC. In this study, we tried to characterize the transcriptomic features of microenvironment fibroblasts associated with the distant metastasis of TNBC. Method We established PDX models by obtaining tumor tissues from 26 triple-negative breast cancer patients and transplanting them into the mammary fat pads of immunodeficient mice. When the PDX tumors grew sufficiently in the fat pads, we excised them and saved the mice to assess whether each PDX tumor was capable of developing spontaneous distant metastasis. We used bulk RNA sequencing and single cell RNA sequencing to determine the transcriptomic features associated with the distant metastasis. Results We classified the 26 TNBC PDX models based on their in vivo metastasis capacity and the clinical outcomes of the corresponding patients. Non-metastatic PDX models were defined as the lack of developing distant metastasis in either mouse experiment or clinical follow-up data (n=5). PDX models were defined as metastatic models when they developed distant metastasis in both mouse and human (n=4). We performed single cell RNA sequencing using the nine PDX tumors and observed a substantial gene expression differences of fibroblasts in the tumor microenvironment between the metastatic and non-metastatic PDX models. The fibroblasts of the metastatic PDX models showed up-regulation of genes involved in the response to hypoxia, inflammatory response, neutrophil chemotaxis, cellular response to IL-1, positive regulation of cell proliferation, and negative regulation of apoptotic process. Moreover, this difference of gene expression between metastatic and non-metastatic TNBC PDX models were not identified by the bulk RNA sequencing data. Conclusion By using the single cell RNA sequencing using the TNBC PDX models, we identified key features of fibroblasts in the tumor microenvironment that contributes to the metastasis capacity of TNBC. Further studies are on-going to elucidate the underlying mechanisms.

Background:

Recent advances in immunotherapy led to development of new technologies to identify topographical distributions and correlations in the tumor microenvironment, enabling a better understanding of the tumor immune landscape.

Based on the 2019 WHO classification Invasive lobular carcinoma (ILC) has various histological presentations. The pleomorphic variant has been reported to be biologically different to the classical counterpart.

Cancer associated fibroblasts (CAFs) secrete cytokines and growth factors aiding in tumor growth. CAFs have been shown to express alpha-smooth muscle actin (α -SMA), Thy1, fibroblast activation protein (FAP), S-100. IHC based studies have shown differences in CAFs subpopulation between ILC and IDC. Here, we explored different CAFs subpopulations between Pleomorphic and Classical ILC using multiplex immunofluorescence (mIF).

Study design:

Multiplex immunofluorescence (mIF) was performed on formalin-fixed paraffin-embedded (FFPE) tissue sections [(n=6, classic ILC; n=6 pleomorphic ILC)] stained with Opal 7-color Kit using an automated system. Sections were stained consecutively with Pancytokeratin, CD45, A-SMA, FAP, S100, Thy-1. Slides were scanned using the Vectra 3.0 spectral imaging system (PerkinElmer). Five tumor ROIs were examined with Phenochart (Akoya/PerkinElmer) viewer and subsequent images were analyzed to explore spatial distances of CK+ cells to the CAFs. Data was generated using InForm and Phenoptr softwares (Akoya Labs) as a median value. Statistical analysis data correlation was performed using SPSS version 24.0 (IBM Corp)

Results:

Twelve invasive lobular carcinomas cases were evaluated. All cases with classical features were nuclear grade 2 and all pleomorphic cases (n=6) were nuclear grade 3. Six were Luminal B, five were Luminal A and one case was triple negative invasive lobular carcinoma. We studied nineteen different phenotypes of CAFs in the tumor, stroma, and overall tissue compartments. We found statistically significant differences (p -value < 0.05) between the distances of CAFs from the tumor cells in classic and pleomorphic ILC in three phenotypes. The A-SMA+, A-SMA+/S100+ phenotypes were closer to the tumor cells in classic subtype and the S100 only phenotype was closer to the tumor cells in pleomorphic carcinomas. In addition, there were two other phenotypes namely A-SMA+/Thy-1+(closer to tumor cells in classic ILC) and FAP+/S-100+ (closer to tumor cells in pleomorphic ILC), which showed a trend of significance (Table 1)

Discussion:

TME studies in invasive breast lobular carcinoma have been primarily based on chromogenic IHC. Multiplex immunofluorescence quantifies cell phenotype's densities and positions in different tissue compartments (tumor vs stroma vs total tissue). Knowing the proximity of an individual TME cells to the tumor cells, aids in pinpointing possible therapeutic targets. Fibroblast dysregulation in cancers, enhances their pro-tumorigenic and anti-tumorigenic potential. Due to their heterogeneity, they can express a wide array of markers. Identifying the full possibility of CAF subsets is one of the keys to discovering actionable targets. Our results showed Alpha- SMA positive, Alpha-SMA/S-100 positive, Alpha SMA/ Thy-1 positive CAFs in closer proximity to the classic ILC tumor cells as compared to pleomorphic ILC. Additionally, S-100 positive and FAP/S-100 positive CAFs showed a closer proximity to tumor cells in the pleomorphic subtype. Based on these results we hypothesize that pleomorphic ILCs are closely associated with pro-tumorigenic CAFs as compared to classic ILCs. Larger datasets are needed to confirm this.

In conclusion we utilized an objective approach to quantify, phenotype and spatially correlate each cell in the tumor microenvironment. This has helped identifying CAFs subsets that differs in the spatial correlation to tumor cells in ILC subtypes, which can be potential actionable targets.

Table 1

Distance of CK+ cells from CAF subtype	p-value
Total FAP	0.093
Total Alpha-SMA	0.026
Total Thy1	0.132
Total S100	0.310
Alpha-SMA/FAP	0.132
Alpha-SMA/FAP/Thy1	0.400
Alpha-SMA/FAP/S100	0.093
Alpha-SMA/FAP/S100/Thy1	1.000
Alpha SMA only	0.699
Alpha-SMA/Thy1	0.067
Alpha-SMA/S100	0.02
Alpha-SMA/S100/Thy1	1.000

Invasive lobular breast cancer (ILC) is an understudied subtype of breast cancer with late recurrence, metastasis to serosal surfaces, such as the peritoneum, and dismal long-term outcome. We previously reported better patient outcome in ER+ breast cancers with high glucocorticoid receptor (GR) expression (Pan et al 2011). Preliminary data suggests more favorable patient outlook in the ILC subtype when tumors express higher levels of GR. The dynamic interaction between a tumor and its microenvironment leads to phenotypic changes in stromal cells and the extracellular matrix to promote growth or invasion of malignant cells. ILC is histologically distinct from invasive ductal carcinoma and is characterized by discohesive tumor cells that grow as "Indian files" due to lack of the cell adhesion molecule E-cadherin. Because of these differences we expect the tumor microenvironment (TME) to be quite unique in ILC compared to other breast cancer subtypes. We hypothesized that differing levels of expression of nuclear receptors by tumor cells would impact cells residing within the stroma, presumably through paracrine signaling. Immunohistochemistry for 25 ILC biopsies revealed a wide variation in GR expression, ranging from completely negative to strongly positive. Our goal was to gain insight into how GR presence or absence in ILC cells might impact gene and

protein expression in malignant cells and their TME. We were inspired to examine how crosstalk between the GR-positive or GR-negative cancer cells and their respective tumor microenvironment (TME) differentially impact stromal cell gene expression as well as the immune cell milieu. Bulk expression profiling is inadequate to examine molecular profiles of the tumor and stroma separately. Therefore, we used nanoString GeoMx® high-plex digital spatial profiling of RNA and protein expression in GR-positive and GR-negative primary ILC. We first performed spatial gene expression using the Whole Transcriptome Atlas (WTA) for six primary ILC, two of which were strongly positive for GR, two GR-negative and 2 tumors harboring both GR-positive and GR-negative regions. To examine the tumor cells and the stroma independently we segmented regions into panCK-positive and panCK-negative segments and analyzed those separately. Intriguing differences were observed between GR-positive and negative ILC, for the tumor cells as well as for the TME. Implementation of the Spatial Deconvolution script embedded within the GeoMx® software revealed striking differences in the abundance of immune cells, endothelial cells and fibroblasts in the stroma of GR-positive vs GR-negative ILC. Macrophages and other myeloid subsets were present in significantly higher numbers in the TME of GR-positive compared to GR-negative ILC. The contribution of B- and T-cell subsets as well as endothelial cells and fibroblasts were also notably different. To more precisely define the spatial distribution and abundance of various cell subtypes and their association with tumor cells, we are including protein DSP as an added layer to complement the WTA. We are also performing RNA and protein DSP for an additional ten GR-positive and ten GR-negative ILC. Thus, we will test our initial observations and expand our investigation to generate comprehensive molecular profiles of ILC tumors and stromal cells and acquire a deeper understanding of how GR expression/activation influences the crosstalk between ILC cells and their TME. We anticipate that differences in gene and protein expression will provide clues as to how GR activation affects proliferative and adhesive properties of ILC through modification of the TME.

Despite the advances in early diagnostics and therapeutics, women with metastatic breast cancer have limited treatment options. Women with TNBC, who constitute 15-20% of breast cancer patients, are often diagnosed with aggressive/metastatic disease. Advanced studies implicated immunosuppressive tumor microenvironment (TME) in aggressive/metastatic properties of TNBC subtype. Alternatively activated immature myeloid cells including tumor-associated macrophages (TAM), tumor-associated neutrophils (TAN), tumor-associated dendritic cells (TADC) and myeloid derived suppressor cells (MDSC) constitute a major component of TME. However, anti-tumorigenic microenvironment is also reported and that may have clinical relevance in early TNBC patients. Therefore, our hypothesis is that myeloid cells polarize to become immunosuppressive and infiltrate tumors and pre-metastatic niches in patients with advanced disease, while patients with early TNBCs may elicit anti-tumor immune response eliminating disseminated tumor cells (DTC). The utilization of syngeneic immunocompetent mouse models has contributed to our current understanding of immunosuppressive or immunomodulatory TME. Using these models, we have demonstrated that tumor dissemination and growth at metastatic sites is facilitated by MDSC's. Emerging technologies; single cell RNA sequencing (scRNA-Seq), mass cytometry (CyTOF) or cellular

indexing of transcriptomes and epitopes sequencing (CITE-Seq) has been powerful platforms for detailed characterization of tumors and TME compartments. We performed scRNA-Seq and CyTOF analyses of the myeloid cell populations of tumors and spleens from metastatic 4T1 and non-invasive EMT6 tumor-bearing mice. Tumors and spleens from 4T1 tumor-bearing mice exhibited a marked expansion of myeloid cell subsets that are characterized by the expression of immunosuppressive as well as progenitor markers. On the contrary, indicated tissues from EMT6 mice were enriched in NK cells, T and B lymphocytes and they were lacking immunosuppressive myeloid cell subsets. Furthermore, we identified a distinct differentiation pattern of immature myeloid cell subsets from neutrophil progenitors (NP) in 4T1 tumor-bearing mice. Using the murine TNBC models in syngeneic mice, we provide evidence that early TNBC tumors may elicit anti-tumor immune responses and thus the survival outcome in those patients is substantially increased after complete surgical resection of the primary tumors. Whereas immunosuppressive tumor microenvironment contributes to the poor overall survival in patients with advanced TNBCs. Therefore, identifying an anti-tumor immune signature in early TNBC patients may be utilized as a clinical biomarker before surgical intervention as well as improve the survival outcome.

Background Breast Cancer (BC) patients who do not obtain pathologic complete response (pCR) after neoadjuvant chemotherapy (NACT) present higher rate of relapse and worse overall survival. Recent evidence suggests that chemotherapy (CT) efficacy relies on the capacity of chemotherapeutic agents to interact with the immune system. BC features a unique tumor microenvironment (TME) comprising of multiple immune cell types including Macrophages that share a double-edged relationship with cancer as they get polarised from M1 (anti-tumour) to M2 (Pro-tumour). Pro-tumour M2 macrophages are referred to as tumor-associated macrophages (TAMs) and are implicated extensively in angiogenesis, metastasis and therapy resistance. Establishing role of TAMs, facilitates the emergence of novel strategies that exploit them as theranostic targets/tools of interest for treating cancer. Utility of using Drugs like Zoledronic Acid, Trabectedin, Rebastinib in combination with 5-fu have shown promising anti-TAM activity and improved response to CT in clinical trials. In this study, we have characterized presence of M2-TAM and its correlation to NACT response in matched primary

and residual tumours by examining expression of several biomarkers . Methods Treatment naïve primary and their matched residual tumour specimens from 45 women treated at a single center were accessed through IERB approved protocols. The study included locally advanced HR+HER2-ve and TNBC tumours treated with standard NACT regimes between 2018 to 2020. To determine the association of TAM population with response to NACT, expression levels of CD68 (pan macrophage marker) & CD163 (marker of M2 macrophages), were detected by immunohistochemistry (IHC) and represented as combined H score. We also performed gene expression of chemokines, inflammatory cytokines and interleukins involved in M1-M2 polarization by q-RT-PCR. Residual Cancer Burden Scoring was used to assess response and patients were divided into three groups (complete responders, partial responders and non-responders). Univariate and multi variate analysis were performed between gene expression groups and IHC groups with clinicopathological parameters. Findings from this study was validated on public data bases like TCGA, METABRIC and GEO. Results: 20% of all patients included in the study were complete responders. We arrived at a Macrophage Polarisation Score (MPS) by Gene expression and also a combined H score by IHC. MPS and H-score had a positive correlation ($p=0.083$) overall. Interestingly, Combined analysis of H-Score and MPS with response to treatment showed a greater and statistically significant correlation with residual tumours as compared to treatment naïve tumours ($p=0.009$). We also observed that high MPS and high combined H score in residual tumours were associated with increased tumour size and LVI ($p=0.055$ and $p=0.03$). Other clinicopathological parameters like receptor status, grade and stage at diagnosis were not significantly associated with H score or MPS. Taken together we found that 11% of patients who exhibited high TAM score by both H sascore and MPS fell into the non-responders category. We therefore report TAMs in residual tumours being more indicative for response to therapy compared to primary tumours. Conclusion Although primary tumours are useful for building predictive models to therapy response, we have demonstrated that there is utility in examining residual tumours as well for choice to adjuvant chemotherapy, since the tumour is constantly evolving through the NACT period. More work to arrive at a “TAM score” that could aid in choice of additional adjuvant treatment strategies is underway. We believe our work is helping us to move one step closer to Precision Medicine in a low and middle income country like India that has a higher burden of locally advanced disease. Our analysis also lends itself to becoming a clinical test since it is performed on an FFPE specimen

The desired effect of cancer therapeutics can only be conceived when applied to complex multicellular structures with different cell types and extracellular matrix (ECM) in three-dimensional (3D) space. Therefore, 3D cell culture systems have become very popular in drug screening and discovery. There is an immense demand for highly efficient and easy methods to produce 3D spheroids in any cell format. However, heterogeneity in size, extended cultivation times, and reproducibility for high throughput assays are limiting factors in the generation of spheroids. Recently we have established a naturally transformed breast cancer cell line, KAIMRC1 (1), from ductal breast carcinoma. We have developed a novel and easy method to produce spheroids (2) from KAIMRC1 cells in vitro, which can be used as a 3D model to study proliferation, differentiation, metabolism, cell death, and drug response of cells in the tumor microenvironment. We developed an in-vitro high content imaging (HCI) based cellular assay using commercially available compound panels to perform initial drug screening in the KAIMRC1 spheroids model. Our approach allows rapid screening of a panel of drugs to assess inhibitory effects on the growth of tumor cells in 3D cultures. To mimic the actual in-vivo tumor microenvironment, we are now developing an HCI-based assay utilizing 3D KAIMRC1 spheroids co-cultured with patient-derived fibroblast cells. 1. Ali, Rizwan, et al. Background: Cancer associated fibroblasts (CAFs) regulate breast cancer growth, differentiation and metastasis. Targeting the signaling pathways between myofibroblast CAFs (myCAF) and cancer cells required for myCAF maintenance provides a mechanism to reverse engineer the tumor microenvironment to inhibit cancer growth and metastasis.

Methods and Results: We co-cultured human triple negative breast cancer (MDA-MB-231) with human mesenchymal stem cells (MSC). After 72h, MSC mRNA expression of the myCAF markers, alpha-smooth muscle actin (α -SMA) / vimentin (Vim) / tenascin C (Ten-C) are all significantly increased. In parallel, MB-231 mRNA expression of stemness markers, SRY-Box Transcription factor 2 (Sox2) / Octamer-binding transcription factor 4 (Oct4) / Nanog, are also significantly increased. Migration assay and morphology imaging confirm the induction of the myCAF phenotype to promote MB-231 cancer stemness. shRNA lentivirus was used to knock down Sox2 gene expression in MB-231. We performed RNA-seq in MB-231 first comparing MB-231 vs. MB-231+MSC and then MB-231(-/-sox2)+MSC vs. MB-231+MSC. There are 104 overlapping genes in MB-231+MSC from the two analyses indicating upregulation with myCAF differentiation and cancer stemness. Using the Human Cancer Secretome Database, 9 genes are either membrane or secreted proteins. Using antibody blockade in co-culture, antibody depleted co-culture medium, and adding activated proteins to culture, A Disintegrin And Metalloprotease 8 (Adam8) gene was found to be required for myCAF maintenance. Using SELEX, we isolated 5 RNA aptamers targeting the human Adam8 soluble MP domain. Using in vitro quantification of Adam8 MP activity with human Adam8 fluorogenic peptide substrate and recombinant human Adam8 protein, Adam8 Apt-1 with IC₅₀=33nM and K_d=29nM was selected. APt-1 does not inhibit human Adam 10 or 17 MP activity and remains extracellular. The core inhibitory domain of Apt-1 aptamer contains 23nt. Following induction of the myCAF phenotype and cancer stemness in MB-231+MSC coculture, addition of Apt-1 significantly decreased myCAF and cancer stemness markers. In murine NOD/scid xenograft model, 10⁶ luciferase-MB-231 and 10⁶ MSC were implanted in the R3 position at week 0. Apt1 was administered (10mg/kg via tail vein every 2 days) from week 3 to week 6. MB-231 volume (bioluminescence) was significantly decreased following Apt1. (Table)

Conclusion: Adam8 is expressed in MB-231 breast cancer cells in the context of MSC/myCAF coculture and MB231 stemness and is required for MB-231 cancer growth. Aptamer ablation of Adam8 extracellular activity reverses MB-231 growth.

MB-231 and MSC Murine Xenograft Model

	MB-231 and MSC Xenograft Model

Late-stage relapse also known as late recurrence breast cancer is a metastatic disease that occurs more than five years after initial adjuvant endocrine therapy treatment. The 5-year relative survival rate is less than 30% and there are limited treatment options for patients with late-stage relapse because of poor performance status. We hypothesize that long non-coding RNA (lncRNA) protein interactions regulate genes to promote late-stage relapse and these interactions can be targeted using RNA therapeutics. To address this, we used RNA-sequencing to identify LINC00355 to be up-regulated in 24 late-stage relapse samples compared to a unique cohort of 72 primary breast cancer samples. Analysis of 480 primary breast cancer samples from The Cancer Genome Atlas (TCGA) also shows decrease expression of LINC00355 compared to late-stage relapse. To better assess LINC00355 cell type expression, we analyzed 26 publicly available primary breast cancer single cell sequencing data samples and detected 0.90% or less of cells expressing LINC00355, which was restricted to cancer epithelial cells. Due to cellular localization playing an important role in lncRNA function, we isolated nuclear and cytoplasmic lysates and orthogonally validated with RNAscope in situ hybridization (RNA-ISH) to show that LINC00355 is located in the nucleus of MCF7 long-term estrogen deprived (MCF7 LTED) cells. LTED cells are deprived of estrogen for longer than three years meant to recapitulate the acquired resistance to aromatase inhibitors.

Next, we determined that LINC00355 binds to MENIN protein to regulate p27KIP expression to promote proliferation with UV crosslinking immunoprecipitation and chromatin immunoprecipitation qPCR of LINC00355 overexpression and mutant constructs. Furthermore, RNA-ISH assays validated high nuclear expression of LINC00355 and RNA-ISH protein co-detection assays showed co-localization of LINC00355-MENIN interaction in a panel of late-stage relapse breast cancer patient tissues compared to primary tissues. Lastly to determine clinical significance, we treated MCF7 LTED cells with two locked nucleic acid antisense oligos (ASOs) targeting LINC00355 to observe a significant decrease in proliferation, cell viability, and invasion. Overall, this is the first study to show the importance of lncRNA-protein interactions and therapeutically target lncRNAs with ASOs in late-stage relapse breast cancer. Moving forward, we intend to further understand how LINC00355 contributes to the progression of late-stage relapse with the intent of creating novel cancer diagnostics and therapies.

Background: Breast cancer is the most commonly diagnosed cancer and the leading cause of cancer-related death among women worldwide. Triple-negative breast cancer (TNBC) is an aggressive subtype representing 15-20% of all breast cancers. TNBC often ends with a poor clinical outcome due to high histological grade and recurrence rates with few treatment options. Chemotherapy remains the standard of care for TNBC treatment, but unfortunately, patients frequently develop resistance, and alternative treatment strategies for the chemoresistant disease remain a major unmet need. circRNAs are newly identified non-coding RNA molecules with covalently closed circular structures. Recently, an increasing number of studies have indicated that circRNAs play crucial roles in regulating tumor development and chemoresistance. However, the role of circRNAs in the process of TNBC chemotherapy resistance is not yet fully clear. Materials and methods: To study the molecular functions of circRNAs in TNBC chemoresistance, identify alternative biomarkers for chemotherapy-resistant disease, and elucidate novel therapeutic targets, doxorubicin-resistant (Doxo-R) and paclitaxel-resistant (Taxol-R) cell lines were generated using TNBC models. Results: Doxo-R and Taxol-R cells exhibited a 3- and 12-fold decrease in sensitivity to their respective chemotherapeutic agents. We identified a large spectrum of gene expression changes that were acquired in Doxo-R and Taxol-R cells. The expression of circRNAs was profiled using circRNA microarrays, and top hits were validated using RT-PCR. We identified 429 and 310 circRNAs that were differentially expressed in Doxo-R and Taxol-R resistant cells respectively compared to the parental chemosensitive cell line ($|FC| \geq 1.5$; p value < 0.05). Of these, 66 were commonly differentially expressed between the two chemotherapy resistant models. Conclusions: These results revealed that Doxo-R and Taxol-R TNBC cell lines were successfully established and serve as good models for studying the mechanisms of chemotherapy resistance and the regulatory roles of circRNAs in the development of chemoresistance in TNBC. Increasing knowledge of the important functions of circRNAs underlying drug resistance will provide new opportunities for developing efficacious therapeutic strategies and prognostic/predictive biomarkers for TNBC.

Background: Breast cancer (BC) is the most diagnosed cancer in women worldwide. MicroRNAs (miRNAs) are involved in different processes of BC and their deregulation can cause them to act as oncogenes or tumor suppressors, participating in cancer progression or also as therapeutic target. Using The Cancer Genome Atlas (TCGA) database, we found that miR-660-5p is significantly overexpressed and associated with poor survival in patients with this pathology. Moreover, it is reported that miR-660-5p can induce BC progression through transcription factor CP2 (TFCP2) and the down regulation of tet-eleven translocation 2 (TET2). In this project, we propose to identify the role of miR-660-5p in proliferation, migration, invasion, angiogenesis, and possible targets involved in these processes in BC cell lines. Methods: Basal levels of miR-660-5p were determined in BC cells MDA-MB-231 and MCF-7, and in human epithelial breast cells MCF-10A by RT-qPCR. The effect of miR-660-5p was evaluated on proliferation, migration, and invasion processes using MDA-MB-231 and MCF-7 cells. HUVEC cells were used to assess angiogenesis. All cell lines were transfected with miR-660-5p inhibitor. Analysis of nine miRNA-target prediction databases was made to identify targets of

miR-660-5p. We selected the target genes predicted by at least three of these programs, and their expression was evaluated by RT-qPCR in a customized 384-well plate. Results: We found that miR-660-5p is significantly upregulated in MDA-MB-231 and MCF-7, compared to MCF-10A cells. In addition, we observed a significant decrease in proliferation, migration, and invasion of BC cells transfected with miR-660-5p inhibitor, compared to non-treated cells and miRNA inhibitor negative control treated cells. Similarly, we observed a significant decrease in angiogenesis of HUVEC cells transfected with miR-660-5p inhibitor. Furthermore, of all the miR-660-5p targets identified by prediction databases 21 were selected, and of these, 7 were observed upregulated and 1 downregulated. Conclusions: The results show that miR-660-5p is upregulated and involved in proliferation, migration, invasion, and angiogenesis of BC, which may lead us to suggest that this miRNA act as an onco-miRNA. In addition, seven potential miR-660-5p target genes were identified, but further validation assays are needed to clarify their implication in this disease.

Background: MiRNAs are non-coding RNA molecules and its function is the regulation of gene expression. In cancer, the deregulation of miRNAs allows them to act as oncogenes or tumor suppressors. From an analysis of the expression of miRNAs in breast cancer (BC) in The Cancer Genome Atlas (TCGA), it was identified that miR-1307-3p is significantly overexpressed in the tumor tissue compared to healthy tissue from patients. So far, in BC, it has only been reported that this miRNA inhibits SMYD4 and that it is involved in resistance to cisplatin through its effect on Mdm4. In this project we propose to identify the role of miR-1307-3p in proliferation, migration, invasion, angiogenesis, and possible targets involved in these processes in BC cells. Methods: RT-qPCR was used to evaluate basal levels of miR-1307-3p in the BC cell lines MDA-MB-231 and MCF-7, and the human epithelial breast MCF-10A cells. Later, we determined the effect of miR-1307-3p on proliferation, migration, and invasion in MDA-MB-231

and MCF-7, and angiogenesis in the HUVEC endothelial cells. All assays were carried out using the miR-1307-3p inhibitor. Finally, nine miRNA-target prediction databases were analyzed to identify potential miR-1307-3p target genes, and their expression was analyzed by RT-qPCR in a designed 384-well plate. Results: We found that miR-1307-3p is overexpressed in MDA-MB-231 and MCF-7, compared to MCF-10A cells. We also identified that transfection with the miR-1307-3p inhibitor causes a significant decrease in the processes of proliferation, migration, invasion, and angiogenesis, when compared with untreated or negative control transfected cells. For its part, prediction databases analysis allowed us to identify 19 potential targets of miR-1307-3p. Finally, by RT-qPCR, the overexpression of 3 and the downregulation of 2 genes were confirmed. Conclusions: MiR-1307-3p is overexpressed in BC cells. Furthermore, miR-1307-3p induces the processes of proliferation, migration and invasion in BC cells, and angiogenesis in HUVEC cells. These observations suggest that miR-1307-3p can acts as an onco-miRNA. In addition, the expression of 5 of the predicted target genes were altered by miR-1307-3p inhibitor. Further analysis to validate the implication of this miR-1307-3p targets are needed to understand its importance in BC.

Background: Triple-negative breast cancer (TNBC) patients frequently receive combination chemotherapy treatment, but a direct comparison of response to carboplatin, docetaxel, and their combination in 50 TNBC patient-derived xenografts (PDXs) showed that combination treatment was largely ineffective at generating enhanced responses over the best single agent. This suggests de-escalation of chemotherapy may be possible if molecular mechanisms and biomarkers underlying response to individual treatments can be identified. To this end, we performed multi-omics profiling for the 50 TNBC PDXs. Methods: Orthotopic TNBC PDXs were treated with four weekly cycles of docetaxel, carboplatin, or the combination. Changes in tumor volume after 4 weeks of treatment were assessed quantitatively and by modified RECIST criteria. Genomic, transcriptomic, and mass-spectrometry-based proteomic profiling were performed on baseline tumors prior to treatments to identify associations with chemotherapy response at the gene and pathway level. ProMS was used to integrate both RNA and protein data to select a 5 RNA feature combination for optimized prediction of carboplatin response in a logistic regression model. Publicly available neoadjuvant chemotherapy clinical datasets with transcriptomic data and response information used for validation/testing included TNBC samples from: GSE18864, I-SPY2 (GSE194040), and BrighTNess (GSE164458). Results: Proteogenomic profiles revealed distinct genes associated with response to each agent and their combination, respectively, suggesting distinct molecular mechanisms underlying response to each treatment. A substantial number of genes associated with single agent and combination treatment were validated in multiple independent patient cohorts receiving platinum and taxane containing neoadjuvant therapy, confirming clinical relevance of our PDX panel. For the same treatment, different types of molecular data identified distinct sets of associated genes,

providing highly complementary information. At the pathway level, RNA and protein data converged to metabolic and E2F/G2M related pathways which were upregulated in PDXs resistant or responsive to all treatment types, respectively, while variable levels of MYC-related proliferation pathways were observed across all treatments suggesting pathways that are common across and unique to different treatments. Several individual genes found to be higher in PDXs with better response to either single-agent had discriminatory power in external clinical TNBC datasets treated with similar neoadjuvant chemotherapy regimens. In addition, a logistic regression-based carboplatin response prediction model trained to select a group of 5 RNA markers (TKT, MAGI2, ATF6B, MCM7, LRP6) using both RNA and protein data performed the best in predicting response to cisplatin in a clinical TNBC dataset vs predicting response to other datasets with taxane and platinum + taxane combination containing chemotherapy regimens, demonstrating specificity of the prediction model. These results suggest potential individual biomarkers or biomarker combinations to select TNBC tumors that may respond to either single agent carboplatin, docetaxel, or their combination. PDXs refractory to all treatment arms had higher levels of proteostasis-related pathways including proteasome degradation and the unfolded protein response (UPR) related to endoplasmic reticulum stress and altered levels of chromatin regulation. Subsequent pharmacological targeting of the UPR pathway and targeting HDACs enhanced chemotherapy response. Conclusion: Proteogenomic characterization identifies molecular mechanisms and putative biomarkers for stratifying TNBC tumors for single or combination chemotherapy treatments, suggests targeted therapies to augment chemotherapy response, and provides a valuable resource for researchers and clinicians.

Background: Malignant phyllodes tumors (MPT) are rare fibroepithelial breast tumors that disproportionately affect young women. Despite high local and distant recurrence rates, treatment is almost exclusively surgical. With no known effective chemotherapy or targeted systemic therapy options, metastatic progression portends dismal prognosis. Current national guidelines do not recommend biomarker testing in the non-metastatic setting. Management of metastatic disease follows principles of soft tissue sarcoma recommending Next-Generation Sequencing on an individual basis for patients who may qualify for clinical trials or are refractory to standard therapies. In the largest genomic profiling effort of MPT to date, we sought to describe the genomic landscape of MPTs through comprehensive genomic profiling (CGP) and immunotherapeutic biomarker analysis.

Methods: Cases of sequenced MPT were identified from a CLIA-certified, CAP-accredited laboratory database (Foundation Medicine, Cambridge, MA). Cases were categorized as localized/locally recurrent or metastatic. All cases underwent CGP by DNA extraction from FFPE samples using a hybrid capture, adaptor ligation-based next generation sequencing assay, and all classes of genomic alterations, microsatellite instability (MSI), and tumor mutational burden (TMB) were evaluated. PD-L1 expression by IHC was measured by the DAKO 22C3 assay (scored CPS) or the Ventana SP142 assay (scored as IC). Patient

characteristics and results of CGP of MPT were summarized by either N (%) or median (range). Factors from MPT were compared to all cases of breast carcinoma in the lab database. Fisher's Exact Tests were used to test for differences between groups and analysis of variance was used to test for differences for continuous variables.

Results: Of 135 MPT cases identified; 94 (69.6%) were localized/locally recurrent (breast, chest wall, soft tissue, skin, or lymph node) and 41 (30.4%) were metastatic (73% lung, followed by bone, liver, other intraabdominal). All patients were female with a median age of 54 years (range 14-86). The median TMB across samples was 2.5 mut/Mb and only 3 were TMB-high tumors (>10mut/Mb). Over 1/3 (36.8%) of samples were PD-L1+ via Ventana SP142 assay (≥ 1) and 21.4% were PD-L1+ via Dako 22C3 assay (CPS ≥ 10). All evaluable cases (N=132) were microsatellite stable. The ten most commonly altered genes included TERT-promoter (69.7%), CDKN2A (45.9%), TP53 (37.8%), NF1 (35.6%), CDKN2B (33.3%), MED12 (28.9%), MTAP (27.7%), KMT2D (22.2%), PIK3CA (20.0%), PTEN (18.5%), and RB1 (18.5%); notably distinct in frequency from the breast carcinoma cohort (Table 1). Alterations in genes affecting cell cycle regulation (i.e. CDKN2A/B and TP53) were mutually exclusive from one another ($p < 0.001$). Several tumors harbored genomic alterations with FDA-approved indications in other tumor types were found including: NF1, PIK3CA, EGFR Exon 19/20 insertions, and BRAF V600E mutations. There were no statistically significant differences between alterations in localized/locally recurrent versus metastatic specimens.

Conclusions: In the largest genomic evaluation of localized/locally recurrent or metastatic MPTs to date, multiple clinically actionable mutations for further exploration were found. TERT-promoter was altered in the majority of cases. PDL-1 was expressed in over 1/3 of cases suggesting that clinical investigation of immunotherapeutic strategies is warranted. Routine sequencing of metastatic MPT may provide additional information to guide treatment decisions and clinical trial enrollment.

Country: United States

Background Trastuzumab (H) is a critical component of therapy (tx) for HER2+ breast cancers (BCs) and can induce anti-tumor immune responses that as part of its mechanism of action. Pre-clinical studies have suggested that antibody-dependent cell-mediated cytotoxicity (ADCC) through NK cells is a major driver of the immune response. However, there is also evidence that macrophages and dendritic cells (DCs) can play an important role in H immune response through antibody-dependent cellular phagocytosis (ADCP). Here, we present pre- and post-tx gene expression and immunohistochemistry (IHC) data to characterize the tumor microenvironment (TME) changes in response to a single dose of H in patients (pts) with early HER2+ BC. Methods Pts with Stage I-III HER2+ BC with minimum 1 cm tumors were eligible. Pts received 8 mg/kg IV H followed by tissue collection. There was a minimum of 14 days between (btw) H and post-tx tissue collection. Pre- and post-tx tissues were assessed for tumor-infiltrating lymphocytes (TILs), immune-related gene expression, and AE1/3, CD31, CD4, CD8, CD11b, CD68, and CD56 expression through IHC. Results Thirteen pts were enrolled and evaluable. 5/13 were estrogen-receptor positive (ER+). TILs were assessed independently by two pathologists and the results averaged. Tx with H resulted in an increase in TILs in the post-tx tissue ($p < 0.01$). Pre-tx TILs ranged from 2-80% (median 6%) and post-tx TILs ranged from 2-80% (median 20%). 6/13 pts had immune infiltration (Inf), defined as a TIL increase of greater than 1 decile btw pre- and post-tx samples. 2/6 pts with Inf were ER+. Pts with Inf had a significantly higher DC immune signature (ISS) compared to pts without Inf ($p < 0.01$, univariate analysis). No other ISS reached significance. 6 pts had paired pre- and post-tx samples evaluated by IHC. 4/6 pts had Inf per prior definition. Pts with Inf had an increase in CD11b+ (includes macrophages and some DCs) and CD56+ cells (includes NK cells) after H tx within the tumor compartment ($p < 0.05$). Pts with Inf had an increase in CD11b+, CD56+, and CD44+ cells in the stromal compartment ($p < 0.05$). Conclusions Innate immune cells such as macrophages and DCs are key players in H-induced immune response in the early HER2+ BC TME. This data is consistent with prior pre-clinical findings.

Background: Single hormone receptor-positive breast cancers (BCs) display two distinct phenotypes: ER+/PgR- and ER-/PgR+ further stratified by their HER2 status. Their molecular features are not well defined. Our study aimed to identify differentially expressed genes in ER-/PgR+ BCs compared to other phenotypes. Methods: Our cohort comprised 15 ER+/PgR-/HER2-, 11 ER+/PgR-/HER2+, 17 ER-/PgR+/HER2-, 9 ER-/PgR+/HER2+, 5 ER+/PgR+/HER2-, and 5 ER-/PgR-/HER2- invasive BCs collected from 9 Polish and 2 Hungarian centers. The cases were selected from a larger cohort after being matched according to grade, HER2 status, lymph nodes, and distant metastasis status. ER-/PgR+ group was thoroughly validated via immunohistochemistry [Kunc et al. 2022]. The expression of 776 genes was profiled with nCounter® Breast Cancer 360™ Panel in archival formalin-fixed paraffin-embedded tissue samples. A gene was defined as differentially expressed between groups if it met the following criteria: the log2 fold-change in the expression of >1 or <-1 and the p-value < 0.05 (Mann-Whitney U test). Additionally, weighted correlation network analysis (WGCNA) was performed to identify modules of at least 15 highly correlated genes. Subsequently, the association between gene modules and PgR status in ER- subgroup was performed. Identified mRNAs were subjected to functional annotation analysis to determine the top enriched pathways. Results: ER-/PgR+ BCs were characterized by significantly lower expression of ESR1 compared to double-positive (p< 0.001) and ER+/PgR- tumors (p< 0.001), whereas PGR expression was higher compared to ER+/PgR- (p< 0.001), and no significantly different from ER+/PgR+ BCs (p=0.14). Triple-negative BCs had no detectable PGR mRNA. Four genes (MIA, ID4, FOXC1, CDC20) were consistently up-regulated and six genes (FAM214A, MLPH, NFKBIZ, FOS, SLC44A4, SPDEF) were down-regulated in ER-/PgR+/HER2- tumors compared to other HER2- subgroups. Compared to ER+/HER2- BCs, ER-/PgR+/HER2- cases showed up-regulation of 15 genes associated with response to vitamin D, response to ketone, and regulation of transcription, and downregulation of 33 genes

involved in response to estrogen, negative regulation of cell population proliferation, regulation of epithelial-mesenchymal transition, and controlled by ESR1 and SUZ12. In WGCNA analysis of the ER⁻ subgroup, PgR status was negatively correlated with 4 gene modules and positively correlated with 1 gene module. In line with differential gene expression analysis, genes negatively correlated with ER⁻/PgR⁺ status are regulated by ESR1 and SUZ12 and are involved in the regulation of cell proliferation, extracellular matrix organization, and NOTCH1 signaling. Genes positively correlated with ER⁻/PgR⁺ status are regulated by E2F4, FOXM1, SIN3A, NFYB, E2F1, FOS, IRF1, ZMIZ1, and UBTF and participate in cell cycle, regulation of mitosis, and microtubule cytoskeleton regulation. Conclusions: ER⁻/PgR⁺ BCs display a distinct mRNA expression profile characterized by the down-regulation of genes controlled by ESR1 and SUZ12. The latter as a part of Polycomb Repressive Complex 2 contributes to chromatin silencing, and some previous studies suggested its role in the regulation of steroid hormone receptors expression. Additionally, ER⁻/PgR⁺ BCs overexpress FOXC1 which is linked to more aggressive, high-grade, and treatment-resistant breast cancers. Our data indicate the need to unravel the mechanism of epigenetic regulation of PGR expression, especially its methylation status, in ER⁻/PgR⁺ breast cancer.

Background: Triple negative breast cancers (TNBC) are characterized by the absence of estrogen receptors, progesterone receptors, and HER2 receptors on immunohistochemical analysis (IHC). This subtype of breast cancer has been traditionally associated with unfavorable prognosis. TNBC includes morphologically diverse mammary carcinomas including apocrine, metaplastic, medullary and other less common variants with heterogeneous clinical behavior and outcome. Despite previous efforts to further characterize TNBC with genomic and transcriptomic techniques, there is no specific targeted therapy for TNBC. Cytotoxic chemotherapy remains the mainstay of systemic treatment for these patients. DNA methylation has proved to be a promising tool in classifying a variety of cancers. In this study, we aim to analyze TNBC using comprehensive DNA methylation profiling. Method: DNA methylation profiling was performed in TNBC cases from a single academic institution using Illumina Infinium MethylationEPIC Kit. The tumors were obtained from formalin-fixed paraffin-embedded tissue from surgical specimens. Unsupervised clustering analysis based on the methylation profile was performed. Clinical, pathological, and genetic features were analyzed between the clusters. Results: We analyzed 44 cases (all female; median age 61 years) with treatment naïve TNBC diagnosed from March 2011 to April 2018. Median follow-up time was 58 months. Thirty-four (77%) patients were identified as white with the remaining 10 (23%) as non-white. Thirty-four tumors (77%) were classified as invasive ductal carcinoma of no special type, six

(14%) as apocrine carcinoma, and four (9%) as metaplastic carcinoma. Six tumors (14%) were grade 2 and 38 (86%) were grade 3. Lymphovascular invasion was noted in 7 patients (16%). Tumor size ranged from 4 to 45 mm (median: 20 mm). Lymph node involvement was identified in 8 (18%) patients. Eleven (25%) patients harbored germline BRCA1/2 mutations. During the follow up period, 7 patients developed recurrent disease: 3 had local recurrences, 4 patients were found to have metastatic disease, and 1 patient had both local and distant recurrence. At last follow-up, 34 patients (77%) showed no evidence of disease, while 4 (9%) were alive with disease and 5 (11%) had died of disease. In this cohort, we identified three distinct DNA methylation clusters. In Cluster 1 (n=9), the patients were significantly older (mean age: 72 years; p=0.008) and tumors were more likely to be of apocrine morphology (56%, p= 0.001), of lower grade (55% were grade 3; p=0.009), and showed lower proliferation index (mean ki-67: 32%; p= 0.002). Cluster 3 (n=28) included younger patients (mean: 55 years) and tumors with higher grade (92% were grade 3) and proliferation index (mean ki-67: 75%). Cluster 2 (n=7) represented cases with intermediate features between Clusters 1 and 3. All patients in Cluster 1 were white, while Clusters 2 and 3 included non-white women. Cluster 1 included a significantly higher percentage of HER2-low tumors (HER2 1+ or 2+ by IHC and negative fluorescence in situ hybridization) (p=0.03; cluster 1: 89%, cluster 2: 28%, cluster 3: 46%). The vast majority of patients with germline BRCA1/2 mutation were found in Cluster 3 (67% of patients with genetic testing in Cluster 3 had germline BRCA1/2 mutation). There was no difference between the clusters in relation to stage, recurrence, and outcome. Conclusion: DNA methylation profiling is a promising tool to classify TNBC patients into clinicopathologically relevant groups, and we are continuing to expand this cohort. Classification by DNA methylation profile may result in better risk stratification for TNBC patients, which can inform their system therapy. In addition, specific methylation profiles have the potential to lead to the development of specific targeted therapies to improve the prognosis and survival for these patients.

Concordance of Targeted Sequencing from Circulating Tumor DNA and Paired Tumor Tissue

Presenting Author(s) and Co-Author(s):

Chi-Cheng Huang, MD, PhD, *Professor - Taipei Veterans General Hospital*

Country: United States

Ling-Ming Tseng, MD, *Professor - Taipei Veterans General Hospital*

Country: United States

Purpose

In this study, we evaluated the concordance of targeted sequencing results between paired ctDNA and tumor samples from early breast cancers scheduled for curative surgery with or without adjuvant therapy. If high concordance was observed, pre-operative ctDNA testing could serve as a non-invasive surrogate for variants meant to be revealed after definite surgery. On the other hand, poor concordance may hamper wide clinical absorption of liquid biopsy early breast cancer.

Materials and Methods

The study VGH-TAYLOR: Comprehensive precision medicine research on the heterogeneity of Taiwanese breast cancer patients, consisted of three years enrollment and approximately four years follow-up after enrollment. Individual subject was assigned into Group 1 [planned to receive surgery as first-line treatment and followed by adjuvant therapy, Group 2 [planned to receive neoadjuvant therapy as the first-line treatment and followed by surgery], and Group 3 [diagnosed with de novo and treatment naïve stage IV breast cancer, or stage IV breast cancer with recurrence beyond three years after surgery]. Molecular profiling and potential biomarkers were determined using OncoPrint Comprehensive Assay v3 from FFPE tissues and OncoPrint Breast cfDNA Assay v2 from plasma. OncoPrint Comprehensive Assay is a targeted sequencing of NGS experiments were performed with TMO comprehensive using FFPE tissues, included 161 cancer-relevant genes and types of mutation detected such as frameshift, missense, synonymous, SNV, Indel, and CNV. OncoPrint Breast cfDNA Assay detects breast-derived cfDNA including hotspot genes: AKT1, EGFR, ERBB2, ERBB3, ESR1, FBXW7, KRAS, PIK3CA, SF3B1, TP53 (~152 hotspots), CNVs: CCND1, ERBB2, FGFR1, and full length TP53 (~80% coverage). Common genes interrogated by both ctDNA and TMO assay were identified, and concordance between paired targeted sequencing results from the same individuals were reported.

Results

We reported the mutational landscape of initial 612 patients interrogated with the OncoPrint Breast cfDNA assay; 239 out of 612 patients reported at least one mutation (39%). Among 246 patients assayed for both ctDNA and tumor tissue, cfDNA assay detected 73 (29.6%) and TMO comprehensive assay detected 201 (81.7%) breast cancers with at least one variant (c2 test, $p=0.001$). Sixty-seven (25.6%) were tested positive for both liquid and tissue assays, while cfDNA and TMO comprehensive assay detected additional 10 (4%) and 138 (56%) cases, which were not identified by the other platform. Table 1 details the distributions of called variants among common targeted genes.

Conclusion

In current study, we evaluated the concordance of called variants between targeted sequencing from ctDNA and tumor tissue among an early breast cancer cohort in Taiwan. Only one-quarter of patients were positive for both cfDNA and TMO comprehensive assays from the same

subject, indicating assay-specific sensitivity inevitably resulting in diagnostic discrepancy. Another plausible explanation came from the early stage nature of interrogated patients, which may inherit fewer ctDNA spillage from tumor and compromise detectability from liquid biopsy. The most prevalent mutant genes from both platforms were TP53 (68.3%) and KRAS (53.5%), both were well-known drivers in cancers. From breast cancer actionability, PIK3CA (39.4%) mutation is a biomarker for the FDA-approved PI3Ka inhibitor such as alpelisib, AKT1 (45.9%) mutation for agents such as capivasertib (AZD5363) and ipatasertib, and ERBB2 mutation for tyrosine kinase inhibitor such as neratinib. Our study showed that tumor should be the preferred source for targeted sequencing, and additional 4% of variants would be revealed from liquid biopsy.

Table 1. Distributions of variants from common targeted genes (n=6) from cfDNA and TMO comprehensive assay.

	ctDNA	Tumor tissue	Both detectable	Both non-detectable	Total affected
AKT1	1	113	1	133	113(45.9%)
ERBB2	0	42	0	204	42(17.1%)
KRAS	4	130	3	115	131(53.5%)
PIK3CA	15	93	11	149	97(39.4%)
SF3B1	3	14	1	230	16(6.5%)
TP53	65	146	43	78	168(68.3%)

Background: High (HTMB) tumor mutation burden (TMB) defined as ≥ 10 mutations/megabase (Mb) identifies breast cancer patients who could benefit from pembrolizumab. The higher the TMB the greater the likelihood of benefit. The goal of this analysis was to determine the frequency and genomic landscape of MBC with ultra-high TMB (UHTMB) defined as a TMB > 20 mutations/Mb. Design 2,049 MBC patients (pts) underwent hybrid capture based comprehensive genomic profiling for genomic alterations (GA) in at least 324 genes including determination of TMB to guide therapy decisions using the FoundationOne@CDx assay. ER, PR and HER2 expression were abstracted from submitted pathology reports. Results: 165 of 2049 MBC (8.1%) had HTMB > 10 mutations/Mb, among these 45 (2.2% of all cases) had UHTMB. When compared with the 2,004 non-UHTMB MBC pts with TMB < 20 mutations/Mb, the 45 UHTMB pts were older (mean 64.6 yrs vs 58.2 yrs; $p < .0001$), more often had lobular histology (40.00% vs 14.5%; $p < .0001$) and ER+ disease (86.6% vs 70.0%), had higher average driver GA/tumor (9.84 vs 5.7; $p < .0001$), and less often had TNBC (13.3% vs 27.0%; $p = .041$) compared to non-UHTMB high cancers. There were no significant differences in ancestry. Mutation signature analysis revealed that APOBEC was predominant in UHTMB samples (82.5%) with a minor portion with an MMR signature (10%), however, MSI-H status was significantly higher in UHTMB high cases (11.6% vs 0.40%; $p < .0001$). GA more frequently identified in UHTMB cases included CDH1 (45.50% vs 14.32%; $p < .0001$), PIK3CA (81.80% vs 37.86%; $p < .0001$), CDKN2A (11.40% vs 3.19%; $p = .017$), ARID1A (25.00% vs 5.01%; $p < .0001$) and NF1 (20.50% vs 5.94%; $p = .0014$). PD-L1 (CD274) gene amplification (2.3% vs 1.3%) or protein expression by the Ventana SP142 assay (57.14% vs 51.10%) were not significantly different. Conclusions: UHTMB MBC is a rare but clinically important subset in breast cancer that could have high response rates to single agent pembrolizumab. This phenotype is driven by APOBEC mutagenesis, more often seen in ER+ lobular cancers, and have higher frequencies of MSI-high status and mutations in CDH1 and PIK3CA.

Background: HER2 activating mutations occur in 2-5% of metastatic breast cancer (MBC) patients. These mutations cluster in the kinase domains and at amino acids 309-310 in the extracellular domain. The MutHER, SUMMIT, and PlasmaMATCH clinical trials have shown neratinib monotherapy or neratinib plus fulvestrant combination produce clinical benefit in 28% to 46% in HER2-mutated MBC patients, but median progression-free survival was only 3.6 to 5.4 months. In order to improve the knowledge and outcomes for patients with HER2-mutated MBC, we compared the mutational landscape and gene expression of HER2-mutated MBC patients to HER2-amplified and HER2-wild type MBC patients. Methods: De-identified data from a cohort of stage 4 breast cancer patients (n=1,834) sequenced with the Tempus xT (DNA-seq of 595-648 genes, whole exome-capture RNA-seq) solid tumor assay was retrospectively analyzed. The most recent sample of the patient was used for analyses. Patients were stratified by HER2 mutational status: HER2-wild type (HER2-wt), HER2-amplifications (HER2-amps), or HER2-mutants (HER2-muts). Additionally, a sub-analysis was conducted among HER2-mutants to compare kinase domain mutations to other HER2 mutations. Patient demographic characteristics were compared between groups along with the prevalence of individual gene alterations (pathogenic/likely pathogenic short variants and copy number alterations), adjusted for false-discovery. Results: Within the cohort, 62 (3.4%) patients harbored HER2-muts tumors and 125 (6.8%) patients had HER2-amps tumors. Three patients, whose tumors had both HER2 mutation and amplification, were classified among the HER2-

mutants. Relative to the HER2-wt cohort (median = 53 yo), HER2-mutants patients were older (median = 55 yo) while HER2-amps patients were younger (median = 49 yo) ($P < 0.001$). Significant differences were observed in genomic alterations co-occurring with HER2-mutants compared to HER2-wt and HER2-amps, including CDK12 (4.8% vs 0.2% vs 74%), CDH1 (44% vs 11% vs 4.8%), ESR1 (4.8% vs 21% vs 8.8%), TOP2A (3.2% vs 0.5% vs 14%), and ERBB3 (11% vs 0.9% vs 0.8%). Of note, the majority of CDK12 mutations are amplifications (96%). Median HER2 mRNA log₁₀ gene expression differed among the three cohorts (HER2-mutants (3.79), HER2-wt (3.56), HER2-amps (4.54); $P < 0.001$). Among HER2-mutants patients, 46 (74.2%) patients had HER2 kinase domain mutations (HER2-kinase). Relative to other HER2-mutants patients, HER2-kinase patients displayed a lower prevalence of CDH1 mutations (35% vs 69%; $P = 0.018$). No significant differences were noted in ERBB3 co-mutations, however all 7 were missense variants (5 of which are p.E928G variants) and occurred among HER2-kinase patients. Conclusions: Real-world data show increased HER2 mRNA expression in both HER2-mut and HER2-amps MBC patients. Co-occurring genomic alterations were different among all three groups. Notably, ERBB3 and CDH1 alterations co-occurred commonly in HER2-mut MBC patients, while ESR1 alterations co-occurred in only 4.8%. All ERBB3 co-mutations occurred with HER2 kinase domain mutations, while CDH1 co-mutations were less prevalent in the HER2-kinase group. Understanding the frequency and spectrum of HER2 mutations in MBC, as well as co-mutations, will help to guide combination treatment strategies and improve the clinical benefit of targeted therapy in HER2-mutated MBC.

Background: Invasive ductal carcinoma (IDC) accounts for ~80% of all invasive breast carcinomas (IBC) with several histologic subtypes comprising the remainder of cases. Some histologic subtypes of IDC (such as tubular carcinoma) have been associated with better prognosis, while other subtypes (such as metaplastic and micropapillary) have been associated with poorer prognosis. Prior studies have shown patients with early stage, hormone-receptor positive IBC that have low Recurrence Score® (RS), as measured by the 21-gene Oncotype DX® (ODX) assay, have little benefit from chemotherapy. Here, we report our experience with the histologic subtypes of IDC and associated patterns of observed gene expression using ODX.

Methods: All US samples submitted for IBC ODX between 2005 to 2021 were reviewed. Ductal carcinoma NOS (DC), tubular carcinoma (TC), cribriform carcinoma (CC), mucinous carcinoma (MUC), lobular carcinoma classic, solid or alveolar type (ILC), pleomorphic lobular carcinoma (PL), medullary/medullary-like carcinoma (MED), metaplastic carcinoma (MET), micropapillary carcinoma (MP), papillary carcinoma (PC) and solid papillary carcinoma (SPC) were included. Quantitative expression of 16 cancer-related genes was measured on a scale from 2 to 15 (relative to reference genes) where 1 unit increment is associated with ~2-fold change in expression. RS was calculated as published. Descriptive statistics for the RS, individual genes (ER, PR, HER2), and gene groups [invasion gene group (IGG) and proliferation gene group (PGG)] were obtained.

Results: A total of 957,624 samples were included in this analysis with 85.4% DC, 9.7% ILC, 2.8% MUC, 0.5% TC, 0.4% PL, 0.4% PC, 0.3% MP, 0.2% CC, 0.2% MED, 0.1% SPC, and

0.02% MET. For all types, a wide continuous range of RS was noted. MET had the highest median RS, followed in decreasing order by MED, PL, DC & ILC, TC, MUC, MP, CC, SPC, and PC. ER and PR were highest among PC and SPC. ER and PR were lowest among MED and MET. HER2 was highest among PC and TC and lowest among MED and MET. IGG was highest in MET and lowest in SPC. PGG was lowest for TC and highest for MED and MET. ER+/PR-/HER2- phenotype occurred more often in MED and PL. ER-/PR+/HER2- phenotype rarely occurred, but was most frequent in MED and MET. ER+/PR+/HER2+ accounted for 0.4% of our total sample.

Conclusions: Here, we demonstrate histologic subtypes of IDC have a wide continuous range of RS. ODX assay may be used to further stratify patients with IDC and its histologic subtypes; however, further studies are needed to better understand the predictive capability of ODX in the histologic subtypes.

Table 1. Quantitative gene expression by RT-PCR in histologic subtypes of invasive breast carcinoma

Histologic subtype	N	RS [median (IQR)]	RS<25	RS 26-100	ER [median]	PR [median]	HER2 [median]	IGG [median]	PGG [median]
Ductal carcinoma, NOS (DC)	81797	16 (0-100)	675040 (82.6%)	142757 (17.4%)	10.2	7.6	9.2	7.1	5.5
Lobular carcinoma (classic, solid or alveolar) (LC)	92472	16 (0-82)	64939 (70.1%)	7533 (8.1%)	9.8	7.2	9.3	6.5	5.1

Background:

Recent studies suggest differences in outcomes among patients (pts) with metastatic breast cancer (MBC) treated with abemaciclib, ribociclib, or palbociclib, but whether these differences have a genomic basis is unknown. Here, we utilize a large real-world dataset to compare the mutational landscapes of HR+/HER2- MBC samples in which CDK4/6 inhibitor (CDK4/6i) treatment was initiated ≥ 6 months prior to biopsy to describe variations in tumor biology associated with exposure to each CDK4/6i. We also compare mutations detected by solid tumor sequencing and liquid biopsy to better understand each assay's ability to identify relevant alterations in this population.

Methods:

De-identified data from a cohort of pts with HR+/HER2- MBC (n=1172) sequenced with the Tempus xT (DNA-seq of 595-648 genes, whole exome-capture RNA-seq) solid tumor and xF (105-gene panel focused on detecting oncogenic and resistance mutations from cell-free DNA) liquid biopsy assays were retrospectively analyzed. For pts with multiple samples sequenced, the most recent sample was analyzed. Pts were selected based on receipt of CDK4/6i between metastatic diagnosis date and biopsy collection and excluded if < 6 months elapsed between CDK4/6i initiation and biopsy collection.

Demographics, clinical characteristics, and NGS findings were compared between groups by Chi-squared/Fisher's Exact tests or Kruskal-Wallis tests, as applicable. The prevalence of individual gene alterations (consisting of pathogenic/likely pathogenic SNVs/indels and copy number alterations) were compared similarly with adjustment for false-discovery.

Results:

We compared the immune biomarker and DNA mutational landscapes of 1172 samples collected after a period of treatment with abemaciclib, ribociclib, or palbociclib. Across all pts, the most commonly altered genes were TP53, PIK3CA, ESR1, CDH1, and GATA3. Abemaciclib-treated pts had the highest median TMB and MSI-high frequency (Table). Palbociclib-treated pts were less likely to have a high TMB (≥ 10 mutations/megabase) or RB1 mutations, a known biomarker of resistance to CDK4/6i (Table). We note that the total N for pts positive for TMB high or MSI-high was very low across all groups. We also compared DNA mutational landscapes between pts tested with solid tumor sequencing and liquid biopsy; the lower prevalence of RB1 mutations in palbociclib-treated pts trended towards significance in both groups (Table).

Conclusions:

Results from our real-world dataset suggest that treatment with the different CDK4/6i drugs results in unique immune biomarkers and DNA mutational profiles. Detection of relevant alterations such as RB1 by both tissue testing and liquid biopsy supports a role for either assay in identifying mutations associated with CDK4/6i. Our findings raise the possibility that unique targeted treatment strategies and combination therapies may be warranted after progression on the different CDK4/6i drugs. Additional investigation into the differences in genomic alterations and outcomes among CDK4/6i drugs is necessary to further explore the hypotheses generated by this real-world study.

Prevalence of immune biomarkers and DNA mutations in pts treated with each CDK4/6i drug

Table: Prevalence of immune biomarkers and DNA mutations in pts treated with each CDK4/6i drug

Biomarker	Abemaciclib (N=122)	Palbociclib (N=954)	Ribociclib (N=96)	p-value ¹	q-value ²
TMB, Median (IQR) ³	4.6 (3.4, 7.1)	3.1 (1.9, 5.0)	2.8 (2.0, 4.1)	0.004	N/A

Introduction: Highly proliferative cancers are known to respond better to neoadjuvant chemotherapy (NAC), and pathological complete response (pCR) is a surrogate for survival benefit in breast cancer. Ki67 is the most commonly used cell proliferation marker; however, conventional immunostaining is subjected to variability by the assessor and the institution including the antibody used. To this end, we used the Ki67 gene expression to identify highly proliferative breast cancer and investigated whether it is associated with better response to NAC and survival by intrinsic subtype. Materials and Methods: Total of 6623 breast cancer patients from 11 independent cohorts with full transcriptome and clinical data were analyzed. The top 20% of Ki67 gene expression in each cohort were defined as highly proliferative group based on previous studies using immuno-staining. Results: Highly proliferative breast cancer was associated with high proliferation score, and all five cell proliferation-related gene sets in the Hallmark collection; E2F Targets, G2M Checkpoint, Mitotic Spindle, and Myc Targets v1 and v2 were enriched by gene set enrichment analysis in multiple cohorts regardless of subtype. MKI67 gene expression increased with higher grade in both ER-positive breast cancer and TNBC in multiple cohorts, but no clear association with staging was observed. Highly proliferative ER-positive breast cancer was significantly associated with worse disease-free, disease-specific, and overall survival consistently in METABRIC and GSE96058 cohorts, and showed a trend toward worse overall survival in TCGA; however, this was not the case in TNBC. Further, we found that highly proliferative tumor was significantly associated with better pathologic complete response (pCR) rate in six of the eight neoadjuvant chemotherapy cohorts of ER-positive breast cancer, but only two for TNBC. We also found that highly proliferative ER-positive breast cancer was associated with abundant silent and non-silent mutations, increased intra-tumoral heterogeneity, and homologous recombination defect scores when compared to lower proliferation groups, and this was not seen in TNBC in TCGA cohort. Although DNA

repair gene set was enriched in the highly proliferative ER-positive breast cancer, it was also associated with higher neoantigen activity, higher infiltration of tumor infiltrating lymphocytes including Th1 cells, Th2 cells, regulatory T cells, and M1 macrophages, as well as with enrichment of Interferon-gamma response gene set consistently in 3 large cohorts. In contrast, several stromal cell fractions were decreased in this group. Conclusions: Highly proliferative ER-positive breast cancer is significantly associated with pCR after NAC with increased tumor infiltrating lymphocytes, but is not a surrogate for survival, which are not the case in TNBC.

Background: The DESTINY-Breast04 clinical trial demonstrated the superiority of trastuzumab deruxtecan (T-DXd) versus physician's choice chemotherapy in HER2-low [immunohistochemistry (IHC) staining score 1+ or 2+ with no gene amplification by in-situ hybridization] metastatic breast cancer. The reproducibility of HER2 IHC category 0 versus 1+ scoring is poor in community practice. 89% of the DESTINY-04 participants were hormone receptor positive (HR+). In HR+ breast cancers, the Oncotype DX® (ODX) assay is widely used to estimate risk of recurrence and guide adjuvant chemotherapy selection. It also provides standardized quantification of HER2 mRNA expression by RT-PCR. Prior studies have demonstrated a high degree of overall concordance between central IHC and RT-PCR using ODX in HER2+ and HER2- cases. Here, we (i) compare HER2 mRNA levels quantified by ODX in HER2 IHC 0, 1+ and 2+ invasive breast carcinomas (IBC), (ii) compare the Recurrence Score® (RS) distribution across these three IHC categories and (iii) describe RS distribution and proliferation score in HER2-low IBC.

Methods: 212 patients with HER2 IHC 0, 1+ and 2+ who were negative for HER2 gene amplification by FISH and had RS results were identified in Yale Department of Pathology archives. All US samples submitted for IBC ODX testing between 2005 to 2021 were reviewed in the Exact Sciences database. RS, quantitative HER2 mRNA expression, and proliferation scores were examined. IHC results were not available. Based on quantitative RT-PCR measures of HER2 expression, cases were assigned to: HER2 positive ≥ 11.5 , equivocal ≥ 10.7 to < 11.5 , and negative < 10.7 (1 unit increment is equivalent to approximately 2-fold change). Results: In the Yale cohort, 42%, 33%, and 25% of cases were IHC 0, 1+ and 2+, respectively. There was no difference in age or tumor grade by IHC category. HER2 mRNA levels increased across IHC categories (means 9.05, 9.16, 9.39, respectively), but in group-wise comparisons, only the IHC 0 compared to IHC 2+ reached statistical significance (Mann-Whitney test, $p=0.0014$). The RS scores were also modestly, but significantly higher in IHC 2+ compared to IHC 0 cases (mean 19.5 vs 14.51, Mann-Whitney $p=0.034$). Among IHC 0 and 1+ cases, 14% had RS >25 , and among IHC 2+ cases, 32% had RS >25 . All IHC 0 and 1+ cases were HER2 negative by RT-PCR. Of the HER2 2+ cases, there was one HER2 positive and one HER2 equivocal by RT-PCR. There was substantial variation in HER2 expression by RT-PCR in all IHC groups. In the Exact Sciences cohort, a total of 957,624 samples were analyzed. 0.8% of samples were HER2 positive, 1.2% were equivocal, and 98% were negative by RT-PCR. There was a wide range of RS results. Of the HER2 positive cases, 94.7% had RS >25 . Among the HER2 equivocal cases 39.1% had RS >25 , and among the HER2 negative cases, 15.5% had RS >25 .

Conclusions: HER2 IHC 0 and HER2 low IBC have a broad and overlapping range of HER2 expression by RT-PCR. Whether RT-PCR based HER2 expression predicts benefit from T-DXd is yet to be determined. Most HER2 low cases have RS ≤ 25 , indicating no or limited benefit from adjuvant chemotherapy. Further studies are required to determine if patients with HER2 low IBC and RS ≤ 25 , particularly with high anatomical risk, could benefit from adjuvant T-DXd.

Background: Invasive lobular carcinomas (ILCs) are the most frequent special histologic subtype of breast cancer, accounting for up to 15% of all breast cancer cases. ILCs are characterized by a distinctive discohesive growth pattern, with cells arranged in single cell infiltrative file and dispersed throughout the stroma, which stems from the loss of E-cadherin expression due to bi-allelic inactivation of the CDH1 gene. A subset of breast cancers display a

similar single cell infiltrative growth pattern but, in contrast to classic ILC, display diffuse strong membranous E-cadherin reactivity and membranous p120 expression. We refer to such cases as “lobular-like invasive ductal carcinoma” (LLIDC), but it is unclear if this terminology is appropriate and if such cases show biallelic inactivation of CDH1, similarly to ILCs. Here, we sought to define whether LLIDCs would harbor bi-allelic alterations of CDH1 and to perform an exploratory, hypothesis generating analysis of the repertoire of somatic genetic alterations of LLIDCs and classic ILCs. Materials and methods: Representative H&Es, as well as sections subjected to E-cadherin and p120 immunohistochemistry from seven classic ILCs and seven bona fide “lobular-like invasive ductal carcinomas” were retrieved and independently reviewed by two pathologists with experience and expertise in breast pathology. DNA samples were extracted from representative sections from tumor and normal breast tissue from each patient and subjected to an FDA-approved targeted sequencing assay comprising the coding regions and selected regulatory elements of 515 genes. Somatic single nucleotide variants (SNVs) were detected with MuTect, indels with Strelka, VarScan2, Scalpel and Lancet. All mutations were manually inspected using the Integrative Genomics Viewer (IGV). The cancer cell fraction (CCF) of each mutation was inferred, as well as clonal probability, using ABSOLUTE. Copy number alterations and loss of heterozygosity were determined using FACETS. Mutational signatures were inferred using SigMA based on all synonymous and nonsynonymous somatic mutations. Results: Based on the histopathologic evaluation, of the 14 cases analyzed, seven were classified as ILC, and the other seven were classified as LLIDC. Sequencing analysis revealed that the classic ILCs harbored 16q LOH and CDH1 mutations (7/7), of which five were frameshift indel and two were splice site mutations consistently coupled with loss-of-heterozygosity (LOH) of the wild-type allele. Conversely, five of the seven LLIDCs did not harbor CDH1 mutations or genomic rearrangements. CDH1 mutations were identified in 2 LLIDCs: one harbored a subclonal CDH1 in-frame indel mutation coupled with LOH. This case displayed membranous E-cadherin and p120 expression with areas of aberrant expression. The other CDH1-mutated LLIDC harbored a complex in-frame indel with subclonal LOH. This case displayed membranous E-cadherin and p120 expression. The comparative analysis of the repertoire of somatic genetic alterations and mutational signatures present in LLIDCs and classic ILCs did not reveal any significant differences. Conclusion: Despite the histologic similarities, LLIDCs differ from classic lobular carcinomas based on the lack of CDH1 bi-allelic inactivation and the patterns of expression of E-cadherin and p120 catenin. Further whole-genome sequencing analyses are warranted to define the molecular basis of the discohesive cancer cells of LLIDC display.

INTRODUCTION

Breast cancer (BC) is a highly prevalent and heterogeneous disease, entailing different so-called intrinsic subtypes (IS) according to gene expression, namely Luminal A, Luminal B, HER2-Enriched (HER2E) and Basal-like, as well as a normal breast-like group. The HER2E is still a poorly understood entity, which needs further biologic characterization to improve

therapeutic management.

MATERIAL AND METHODS

Patients (pts) treated at Hospital Clinic (Barcelona, Spain) over 18 years with a diagnosis of metastatic BC, with available matched primary and metastatic tumor samples for gene expression analyses were retrospectively recruited. Using the nCounter® Breast Cancer 360 panel, we studied the expression of 776 genes pertaining to different tumor and immune pathway-related signatures, with a focus on HER2E vs. non-HER2E tumors. Significant changes were considered at a false discovery rate (FDR) < 5%. Main clinicopathological features were also compared. IS changes from primary to metastatic disease were assessed.

RESULTS

Ninety-one pts with paired tumor samples were included. Briefly, primary tumors were 67.0% hormone receptor-positive (HR+)/HER2-negative (HER2-), 14.8% were HER2-positive (HER2+) and 18.2% were triple-negative (TNBC). IS distribution in primary tumors was the following: 25 Luminal A (28%), 22 Luminal B (24%), 24 HER2E (26%), 12 Basal-like (13%), and 8 Normal-like (9%). In contrast, IS distribution in metastatic tumors was the following: 13 Luminal A (14%), 22 Luminal B (24%), 34 HER2-E (37%), 16 Basal-like (18%), and 6 Normal-like (7%). The HER2E disease proved to be a relatively stable subtype, with 16 (66.7%) tumors not changing IS in the transition to metastatic disease ($p=0.078$). Particularly, within HR+/HER2-, HER2+ and TNBC, 8/12 (66.7%), 8/10 (80.0%) and 1/2 (50.0%) tumors remained HER2E. Conversely, an overall significant switch from Luminal to non-Luminal tumors at the metastatic progression was observed ($p=0.031$), with 14/19 (73.7%) new non-Luminal BC being HER2E.

When considering all primary and metastatic tumors, HER2E were observed to be less frequently estrogen receptor (ER) positive than non-HER2E tumors (55.8% vs. 78.7%; $p=0.002$), with lower mean progesterone receptor (PR) levels (15.3% vs. 25.8%; $p=0.027$). Compared to the other subtypes (as a group), the PAM50 risk of recurrence score (ROR-P) was higher for HER2E tumors (59.1 vs. 41.7; $p < 0.001$), which were also more frequently HER2+ (36.5% vs. 5.8%) and less likely HR+/HER2- (50.0% vs. 73.6%) and TNBC (13.5% vs. 20.7%), compared to non-HER2E ($p < 0.001$). No significant differences in grade, TILs, Ki67 and histotype were observed. Overall, 140/776 genes were significantly downregulated in HER2E vs. non-HER2E tumors, including genes related to cell adhesion, migration, DNA damage repair, apoptosis, estrogen signalling pathway, senescence. Conversely, 178/776 genes were significantly upregulated, including the tyrosine-kinase receptor FGFR4, genes involved in nuclear activity, DNA transcription regulation, MAP-kinase signaling pathways, proliferation, cytokine response, epithelial-to-mesenchymal transition (EMT), cell cycle progression, and immune-related genes such as CD274 (PD-L1 gene).

DISCUSSION

A switch towards more aggressive IS from primary to advanced disease was observed, with an increase in HER2E prevalence. HER2E tumors, which tend to maintain their IS at the metastatic disease, showed upregulation of genes related to proliferation, survival and EMT, coherently with their well-known worse prognosis. FGFR4 and CD274 upregulation, along with downregulation of genes involved in DNA damage repair suggest these tumors might benefit from targeted therapeutic approaches. Genomic higher risk was not conveyed by consistent clinicopathological features, except for lower PR levels and HER2 overexpression at IHC. Further characterization according to primary/metastatic and HR status is ongoing.

Intrinsic subtype distribution across primary and metastatic breast tumors

INTRINSIC SUBTYPES	PRIMARY SAMPLES		METASTATIC SAMPLES	
	N	%	N	%
	91	100.00	91	100.00
<i>Luminal A</i>	25	27.47	13	14.29
<i>Luminal B</i>	22	24.18	22	24.18
<i>HER2-Enriched</i>	24	26.37	34	37.36
<i>Basal-like</i>	12	13.19	16	17.58
<i>Normal-like</i>	8	8.79	6	6.59

Introduction: The incidence of triple negative breast cancer (TNBC) in West Africa appears to mirror the higher incidence of the disease among African American women in the United States. However, there remains a paucity of molecular data on TNBC from sub-Saharan Africa, despite the emergence of effective immunotherapies. Methods: Consecutive patients diagnosed with invasive breast cancer between March 2018-Jan 2020 were identified from a prospective clinical database and paired biobank at Obafemi Awolowo University Teaching Hospital (OAUTH). All specimens were processed and fixed in formalin within 60 minutes of excision by a trained pathologist. Tissue sections (4µm thick) representative of tumor were selected for routine evaluation of estrogen, progesterone and human epidermal growth factor receptor-2 expression by immunohistochemistry. This was performed at OAUTH with adequate controls according to the ASCO/CAP guidelines and verified at an outside institution for quality assurance. Additional sections from the FFPE blocks of TNBC specimens were further stained using the Dako PharmDx 22C3 PD-L1 commercial assay according to manufacturer protocols at Dalhousie University. External on-slide controls included tonsil, PD-L1 negative TNBC, and PD-L1 positive TNBC. PD-L1 expression was scored using the combined positive score (CPS), which is the number of 22C3 staining tumour cells, lymphocytes, and macrophages divided by

the number of viable tumour cells, multiplied by 100. The threshold for a positive result was a CPS of ≥ 10 as per manufacturer instructions and institutional protocol. Research ethics board approval as well as data and material transfer agreements between institutions was obtained for this study. Results: From 85 cases, 32 were TNBC (37.6%). The mean age and BMI were $49.6 \pm SD 7.7$ and 26.2 ± 5.7 , respectively. The majority of patients presented with locally advanced disease (64.2% Stage III, 14.2% Stage IV). Seventy-nine percent (78.5%) of patients received an average of five cycles of neoadjuvant chemotherapy (SD 2.3). From 32 TNBC specimens, 27 had available FFPE tissue blocks, and of those, 24 had interpretable PD-L1 IHC for inclusion in the analysis. A total of 37.5% (9/24) of cases demonstrated a CPS ≥ 10 . Conclusions: Over a third of breast cancer specimens in this Nigerian cohort were triple negative, 37.5% of which had PD-L1 CPS scores of ≥ 10 . These results suggest a large proportion of patients in Nigeria may benefit from access to immunotherapy. This is the first reported incidence of PD-L1 expression in breast cancer from sub-Saharan Africa.

Background:

Galectins are sugar binding proteins that play a role in adhesion, apoptosis, immune regulation, and many other cellular processes. There are three different classes of galectins, and they are all found intracellularly and secreted in serum. Galectins have an established relationship with breast cancer, and galectin-3 has been repeatedly associated with cancer cell survival and tumor progression. Most research regarding breast cancer and galectins has used immunohistochemistry (IHC) as a method for identifying galectin expression in breast cancer tissue samples. However, little research has identified a relationship between serum galectin concentrations and breast cancer subtypes. Breast cancer is characterized both by histological and molecular subtype, and this identification often directs treatment decisions. The current method for identifying breast cancer subtypes is through invasive biopsy and the subsequent use of IHC. This project characterized serum galectin concentrations in breast cancer patients to determine if they changed based on different histological and molecular subtypes, cancer stage, and other patient characteristics. Our goal was to evaluate a potential noninvasive means of breast cancer subtype identification and to identify potential therapeutic targets.

Methods:

One-hundred breast cancer patient serum samples were studied using Enzyme-linked Immunosorbent Assays (ELISAs) to determine concentrations of galectins -1, -3, -7, and -9. Results were compared using many patient characteristics, including breast cancer subtype,

stage, and patient history (smoking status and treatment). Statistical Analysis was performed using ANOVA, Student's t-test, and the Wilcoxon Method.

Results:

The concentrations of galectins -1, -3, and -9 in breast cancer patients were all significantly higher than those of healthy controls (Table 1), which is consistent with previous studies. The concentration of galectin-3 was significantly higher in invasive lobular carcinoma samples (N, 6; mean, 13.04 ng/mL) compared to invasive ductal carcinoma samples (N, 80; mean, 9.93 ng/mL; p-value, 0.0428). Galectin-3 concentrations were significantly lower in samples from breast cancer patients who received chemotherapy (N, 9; mean, 9.22 ng/mL) versus those who did not (N, 7; mean, 14.60 ng/mL; p-value, 0.0228). Concentrations of galectin-1 were found to increase by stage (p-value, 0.0031), with significant differences between samples from patients with stage I breast cancer (N, 45; mean, 19.02 ng/mL) and both stage II (N, 40; mean, 24.15 ng/mL; p-value, 0.0127) and stage III (N, 12; mean, 28.37 ng/mL; p-value, 0.0026) disease.

Conclusions:

Our findings suggest a potential use for serum galectin-3 concentrations as a non-invasive means for breast cancer histological subtype differentiation and more refined diagnosis. In addition, our results suggest a possible use of galectin-1 concentrations for more accurate cancer staging. Further research could explore the relationship of serum galectin concentrations and other breast cancer subtypes. Future studies could also analyze how galectin concentrations change with patient treatment status and determine the potential of galectins as specific targets for breast cancer treatment.

Table 1: Galectin Concentrations in Breast Cancer vs Healthy Controls

Table 1: Galectin Concentrations in Breast Cancer vs Healthy Controls						
	Galectin-1		Galectin-3		Galectin-9	
	Cancer	Healthy	Cancer	Healthy	Cancer	Healthy
N	98	16	100	15	33	36
Mean (ng/mL)	22.25	14.14	10.08	1.44	10.14	7.00
p-value	0.0015		<0.0001		0.0032

Tumors are multicellular ecosystems that communicate through the exchange of extracellular signaling molecules. In breast cancer, this multicellular communication can enable tumor cells to cooperate in a range of contexts, including tumor invasion and the outgrowth of distal metastases. Illuminating the mechanisms by which tumor cells communicate may reveal new therapies. To this end, three-dimensional tumor organoid models have emerged as versatile platforms for modeling multicellular behavior *ex vivo*. However, organoid culture typically requires the use of poorly defined, animal-derived extracellular matrices, such as Matrigel. These exogenous matrices contain thousands of proteins that dominate over and conceal cell-secreted factors in conventional proteomics approaches. Revealing low abundance cell-secreted factors from this complex exogenous background presents a formidable challenge. To surmount this challenge, we develop a new method to isolate the pericellular proteome in 3D organotypic culture models. This technology harnesses biorthogonal click chemistry to bypass exogenous factors, infiltrate intercellular spaces, and retrieve the endogenous intercellular proteome. This approach requires no genetic manipulation, requires only 1 million cells, and can be adapted to diverse organotypic models. These capabilities enable isolation of intercellular signaling factors in models that yield precious amounts of material and that can sustain only limited manipulation *ex vivo*, which we demonstrate using organoids established from patient-derived xenografts. To establish the generalizability of our approach, we apply this technology to a panel of breast cancer and small-cell lung cancer organoid models. Furthermore, we demonstrate that this method can be readily adapted to different extracellular matrix environments that are widely employed in organoid research, including basement membrane matrices and collagen gels. Taken together, our results establish this technology as a scalable and generalizable platform that may open opportunities for researchers investigating diverse questions in organoid models of cancer. Moving forward, we are leveraging these capabilities to investigate changes in the intercellular proteome that emerge after the acquisition of therapy resistance. We hope to uncover new mechanisms of collective signaling that may be targeted to overcome therapy resistance.

Microtubule targeting agents (MTAs) are some of the most commonly used and effective chemotherapeutic agents used in the treatment of breast cancer and other solid tumors. Clinically approved MTAs include microtubule destabilizers, such as the vinca alkaloids or eribulin, as well as the taxane class of microtubule stabilizers, including paclitaxel. While MTAs are effective chemotherapeutics, the development of resistance due to drug efflux or changes in β -tubulin isotype expression are major clinical limitations to each the currently approved drugs of this class. One strategy for overcoming drug resistance is the development of drugs that covalently bind to their drug target, which has been validated in the clinic with the success of irreversible EGFR inhibitors in drug resistant non-small cell lung cancer. We have identified the C22,23-epoxytaccalonolides (taccas) as a class of plant-derived microtubule stabilizers that covalently bind to β -tubulin with a high degree of specificity and retain efficacy in drug-resistant models in vitro and in vivo. Although the taccas have potent and persistent antitumor efficacy in vivo, they suffer from a narrow therapeutic index and short serum half-life that provides optimal efficacy when targeted directly to the tumor site. We are undertaking a multipronged approach to generate synthetic tacca analogs (taccalogs) that retain the efficacy of the natural product with improved pharmacokinetic properties, including improved serum binding, to increase half-life and provide better in vivo tolerability. We are also identifying strategies to improve tumor targeting of the taccas, which is being guided by determining their in vivo distribution with radiolabeled analogs. In a complementary approach, we tested the hypothesis that non-covalent microtubule stabilizers that have increased binding affinity to tubulin share properties with the taccas, such as the ability to circumvent drug resistance and provide potent and persistent in vivo efficacy with a more tolerable therapeutic window. Our data suggest that while non-covalent microtubule stabilizers with improved binding compared to paclitaxel provide improved cellular persistence after drug washout and potent antitumor efficacy, they are not able to overcome drug resistance to some degree as covalent inhibitors, demonstrating the advantage of continuing to develop irreversible drugs such as the taccalonolides for the treatment of drug resistant disease.

The immunosuppressive tumor microenvironment governed by tumor-associated macrophages (TAMs) remains a major obstacle to effective cancer immunotherapy. A novel humanized antibody bexmarilimab, targeting the scavenger receptor Clever-1 on TAMs, has shown clinical benefit in ~40% of patients with late-stage ER+ breast cancer (MATINS; NCT03733990). To increase response rates, a comprehensive understanding on how TAM phenotype and the tumor immune landscape affect bexmarilimab-induced immune activation is needed. Single-cell RNA sequencing analysis of breast tumor macrophages shows high phenotypic variation across pathological subtypes and Clever-1 mRNA (STAB1) expression on various immunosuppressive IL4I1+ and TREM2+ monocyte-derived TAMs. STAB1 expressing macrophages were located in both lymphocyte rich and excluded areas in the tumor stroma based on digital spatial profiling with GeoMx. Due to this diversity, we studied bexmarilimab mode-of-action in breast cancer patient-derived tumor explant cultures (PDEC) by RNA sequencing and cytokine profiling. Our results show that bexmarilimab induced TNF α and CXCL10 secretion in 30-40% of the treated explants. In depth analysis of the responsive PDECs revealed a lower baseline expression of interferon responsive genes in their tumor microenvironment. Correspondingly, in vitro assays with primary human macrophages showed that chronic IFN γ priming abolished bexmarilimab-induced immune activation, suggesting potential use of bexmarilimab in patients with immunologically cold breast tumors.

Background: Z-Endoxifen (ENDX), the active metabolite of tamoxifen (TAM) and a selective estrogen receptor modulator (SERM), exhibited high antitumor activity in endocrine-resistant hormone receptor-positive breast and other gynecologic cancer. ENDX has also been shown to be a protein kinase C (PKC) inhibitor. PKCs participate in diverse cellular functions and their activity is often elevated in breast tumors. Guided by mechanistic insights from our recently determined crystal structure of PKC β I, we sought to determine the effects of ENDX on PKC β I in a breast cancer cell line model. Methods: To determine how ENDX regulates PKC activity, we used a Z'LYTE kinase activity assay. This Fluorescence Resonance Energy Transfer (FRET) based biochemical method can detect differential sensitivity of phosphorylated and non-phosphorylated peptides to proteolytic cleavage. We probed changes in activity for conventional and novel PKCs, as well as the purified catalytic domain of conventional PKCs in vitro. Alongside, as kinase activity of PKC relies on its spatial assembly, therefore we studied its intracellular localization using live cell confocal imaging. MCF7 cells expressing YFP-tagged PKC β I were grown in a glass bottom chamber and treated with ENDX and other modulators for relevant time and doses for this study. Images were taken using Zeiss LSM 780 confocal laser scanning microscope and analyzed in Zeiss-ZEN microscope software and GraphPad Prism 9. Results: Our data from an in vitro kinase assay indicates that ENDX inhibits the kinase activity of conventional (PKC β I) and novel (PKC δ) PKC isoforms with a similar IC₅₀, however PKC β I catalytic domain is less sensitive to ENDX. We also identified a multi-domain mechanism of PKC inhibition through an allosteric inhibitory mechanism. Our live cell imaging study demonstrated that ENDX promotes the recruitment of PKC β I to the cell membrane in both a dose and time-dependent manner. Moreover, this translocation can also be mitigated by co-treatment with inhibitors of the PKC-regulator PHLPP phosphatases. Conclusion: Taken together, these results suggest the allosteric effects of ENDX trigger PKC β I recruitment to the cell membrane, yet since ENDX also inhibits kinase activity it suggests that ENDX triggers a non-productive interaction with the enzyme and "breaks" the well-known mechanism of PKC activation upon binding the cell membrane. Furthermore, ENDX is likely to trigger dephosphorylation and ultimately degradation, suggesting that ENDX represents a new mechanistic basis for targeting and downregulating PKC in cancer cells. Hence, the current study provides an integrated pattern of highly specific treatments regimen that can exploit PKC β I as a repurposing clinical target in breast cancer.

The ER antagonist giredestrant induces profound chromatin remodeling including activation of cis-regulatory elements bound by FOXA1 and GATA3 in HR+ breast cancer models

The progression of HR+ breast cancers is governed by ER signaling which makes the development of optimized ER-targeting agents a high priority. Among current therapeutics, selective ER antagonists and degraders (SERDs) have emerged as a particularly attractive class. Fulvestrant is the only SERD that is currently approved, but its clinical potential is hypothesized to be somewhat limited by poor physicochemical properties, dosage and exposure. We identified giredestrant as an orally bioavailable, highly potent non-steroidal ER antagonist, immobilizer and degrader with robust anti-proliferative activity. Giredestrant is currently being evaluated in phase III clinical trials for the treatment of ER+ breast cancer, after showing evidence of clinical activity in phase I and II trials. Here, we set out to investigate the impact of giredestrant on the transcriptome and chromatin landscape of ER+ breast cancer cells in vitro and in vivo. RNA-seq data from MCF-7 cells in vitro and three patient-derived xenograft (PDX) models in vivo showed that giredestrant inversely regulates the RNA levels of E2-regulated genes. Transcriptome wide, the expression of genes affected by giredestrant are strongly correlated ($r^2=0.8$) with those affected by siRNA-mediated silencing of ESR1, consistent with on-target ER antagonism. Performing ATAC-seq in the three PDX models, including one ESR1 mutant model, reveals that giredestrant reduces accessibility in up to 18,173 chromatin regions that are associated with genes induced by E2. These regions are also enriched in the ER binding motif. In addition, we found up to 17,127 chromatin regions with increased accessibility upon giredestrant treatment. These regions are associated with genes suppressed by E2, and are enriched in the FOXA1 binding motif. To probe giredestrant's role in functional modulation of cis-regulatory elements (CREs), we performed ChIP-seq targeting FOXA1 and GATA3, as key pioneer factors for ER, as well as ER itself and H3K27ac as a marker of active enhancers in MCF-7 cells. We identified 3,195 regions with significantly reduced H3K27ac signals that also exhibit significant reduction of both ER and FOXA1 binding

upon giredestrant treatment, indicating that giredestrant deactivates these CREs concomitantly with suppressing ER and FOXA1 binding. ChIP-seq analysis further revealed 2,292 regions with a significant increase in H3K27ac signals upon giredestrant treatment. Interestingly, the GATA3 motif was identified as the most enriched motif in these activated CREs. Further, GATA3 and FOXA1 ChIP-seq signals were stronger in the activated CREs compared to the deactivated ones. Similar profiling of both tamoxifen, an approved selective ER modulator (SERM), as well as GNE-858, a SERM from the same chemical series as giredestrant, showed their epigenetic effects to be highly distinct from those observed for giredestrant, suggesting that the high degree of chromatin remodeling is likely related to giredestrant's mechanism of action. Our studies here show that giredestrant profoundly alters ER binding and remodels the chromatin landscape, thus changing the transcriptional profile of cells in a manner that is associated with an anti-proliferative response. While deactivation of CREs with ER binding is perhaps in line with expectations, giredestrant treatment also leads to the activation of a number of regions associated with pioneer factors, potentially through their redistribution. This raises the question of the functional consequences of CRE activation and if this is relevant for the anti-proliferative effects of giredestrant.

TAVO412 - A Novel Trispecific cMet x EGFR x VEGF Antibody for Triple Negative Breast Cancer

Presenting Author(s) and Co-Author(s):

Mark Chiu, Ph.D., *President - Tavotek Biotherapeutics*

Country: United States

Novel Multispecific Antibody with Superior Activity in TNBC INTRO: TNBC (Triple Negative Breast Cancer) has a diverse etiology and high unmet need. We created a novel multispecific antibody with unique 2:1:1 ratio of EGFR:cMet:VEGF binding arms with excellent activity against TNBC. METHOD: Multiple in vitro EGFR & cMet signaling pathway inhibition, proliferation inhibition, and ADCC, ADCP, and CDC were conducted. Various in vivo studies using the TNBC cell lines (MDA-MB-468, MDA-MB-231, HCC70, BT20) with diverse levels of EGFR and cMet receptor density levels were tested. RESULTS: Strong tumor growth inhibition was found in multiple TNBC animal models (56% tumor growth inhibition (TGI) in BT20, 26% TGI in HCC70, 62% TGI in MDA-MB-231). Tavo412 demonstrated better activity than comparator molecules in several in vivo models using lung, gastric, and pancreatic cancer cell lines (data not shown). A one month GLP toxicity study in cynomolgus monkeys has been completed with well-expected tolerability and pharmacokinetic profiles. Besides shutting down three important cancer pathways, TAVO412 showed high potency because it also has strong EGFR and VEGF binding at pH 6 in the tumor microenvironment. Moreover, Tavo412 has exemplary Fc effector function engaging the innate immune responses that include ADCC, ADCP, and CDC. There is also a synergistic tumor growth inhibition in the presence of a standard of care molecule such as doxorubicin (61% in HCC70 with TAVO412 + doxorubicin, 66% TGI in BT20 with TAVO412 + doxorubicin, 71% TGI in MDA-MB-231 with TAVO412 + doxorubicin). In addition, gastric, pancreatic, and lung cancer in vivo models showed excellent TGI profiles. CONCLUSIONS: Tavo412 has the potential activity to be a superior multispecific antibody to treat patients with triple negative breast cancer. Phase 1 clinical testing in patients is anticipated in early 2023.

Triple Negative Breast Cancer (TNBC) is an aggressive subtype of breast cancer with high metastatic potential and increased morbidity and mortality. Although expression of, and signaling by the epidermal growth factor receptor (EGFR) is commonly seen in TNBC, anti-EGFR antibodies such as Cetuximab have had limited therapeutic efficacy, used alone or in combination with chemotherapy. Primary TNBC tumor growth and metastases require supporting vasculature, which develops through a combination of endothelial angiogenesis and vasculogenic mimicry (VM). VM is more frequently seen in TNBC than other breast cancer subtypes, and is associated with aggressive metastatic behavior. We previously developed α EGFR-E-P125A, an antibody-endostatin fusion protein, linking an anti-EGFR antibody targeting domain to a mutated version of the anti-angiogenic protein endostatin (E-P125A). α EGFR-E-P125A delivers a dimeric E-P125A payload which inhibits TNBC angiogenesis and VM in vitro and in vivo, and markedly decreases metastasis in both the MDA-MB-231-4175 and MDA-MB-468 TNBC xenograft models. To determine the mechanism of α EGFR-E-P125A action on inhibition of VM, we studied the effects of α EGFR-E-P125A on both the transcriptome and proteome. RNA-seq was conducted on MDA-MB-231-4175 TNBC cells plated on matrigel and undergoing VM, and on TNBC cells plated in matrigel and treated with α EGFR-E-P125A.

Gene set enrichment analysis demonstrated that α EGFR-E-P125A treatment downregulated genes on the KRAS, JAK-STAT, and angiogenesis signaling pathways, including EGF, VEGFA, STAT3, PTK2, ITGB1, ITGB3, ITGAV, and ITGA5. Phospho-array analysis was used to interrogate the proteome and demonstrated downregulation of phosphorylation on multiple sites downstream of the EGFR and the α 5 β 1 integrin receptors, such as the EGFR Y1069 site, the FAK Y397 site, implicated in the regulation of endothelial and TNBC motility, and the STAT3 Y705 and S727 sites, known for their role in promoting the transcription of angiogenic genes. Since inhibition of EGFR signaling alone does not inhibit VM, we interrogated the mechanistic relationship between α EGFR-E-P125A and VM inhibition through the α 5 β 1 integrin/FAK signaling pathway. Specific inhibition of FAK at the Y397 site using the small molecule inhibitor, PF-573228 inhibited TNBC VM in vitro. Transient siRNA knockdown of FAK in MDA-MB-231-4175 cells and shRNA-mediated knockdown of FAK in MDA-MB-231 TNBC cells confirmed that downregulation of FAK inhibited VM in vitro. To understand the effect of α EGFR-E-P125A on the EGFR and α 5 β 1 integrin receptors, competition assays were conducted. α EGFR-E-P125A competed with EGF for the EGFR receptor and with the binding of fibronectin to α 5 β 1 integrin. Treatment of TNBC cells with α EGFR-E-P125A reduced total α 5 integrin protein levels and decreased co-localization of EGFR and α 5 β 1 integrin receptors. These results indicate that α EGFR-E-P125A is bound to both EGFR and α 5 β 1 integrin, simultaneously suppressing downstream EGFR and integrin signaling. Simultaneous inhibition of EGFR and α 5 β 1 integrin signaling by α EGFR-E-P125A fusion is a promising approach to inhibition of TNBC growth and metastases.

OP-1250, a complete estrogen receptor antagonist (CERAN) and selective estrogen receptor degrader (SERD), is currently in Phase I/II clinical trials for the treatment of estrogen receptor positive (ER+)/ human epidermal growth factor receptor 2 negative (HER2-) breast cancer. OP-1250 has previously demonstrated efficacy in both estrogen receptor 1 (ESR1) wild-type and Y537S mutant breast cancer xenograft models. Inhibitors of cyclin-dependent kinases 4 and 6 (CDK4/6) are a standard first-line treatment for ER+ advanced or metastatic breast cancer in combination with endocrine therapy. To characterize OP-1250 efficacy in this setting, we explored the combination of OP-1250 with CDK4/6 inhibitors palbociclib and ribociclib in ER+/HER2- breast cancer preclinical models, and profiled the transcriptional changes associated with single agent and combination therapy. OP-1250 and CDK4/6 inhibitors were tested alone and in combination in ESR1 wild-type MCF7 and ESR1 Y537S mutant ST941 xenograft models. Higher doses of OP-1250 and either CDK4/6 inhibitor, when given as a monotherapy, suppress tumor growth and increase animal survival, while lower doses of the compounds display a modest or minimal effect on tumor growth or survival. In combination, lower doses of OP-1250 and either CDK4/6 inhibitor result in significantly greater tumor growth suppression (both xenograft models), tumor regression (MCF7) and animal survival (ST491) than each compound individually. RNA sequencing revealed substantially more gene expression changes with combination treatment than monotherapy. In particular, pathways associated with cell cycle progression displayed greater changes with combination treatment, similar to what was observed with a much higher dose of monotherapy. This study supports the clinical evaluation of OP-1250 in combination with CDK4/6 inhibitors (palbociclib or ribociclib) and provides additional context to mechanisms of combination efficacy. OP-1250 is currently

being evaluated in a Phase Ib clinical trial in combination with palbociclib and a study including evaluation of the combination of OP-1250 with ribociclib is planned to initiate in Q3 2022.

We recently reported the cellular signal-modulating properties of altersolanol B (AB), a minor fungal tetrahydroanthraquinone (THAQ) metabolite, in the estrogen receptor positive (ER+) human breast adenocarcinoma cell lines, MCF-7 and T47D. MCF-7 (IC₅₀ 5.5 μ M) and T47D (IC₅₀ 8.8 μ M) were observed to be 4- and 2.4-fold more sensitive to the antiproliferative effects of AB, respectively, compared to MDA-MB-231 (triple-negative, IC₅₀ 21.3 μ M). AB disrupted both AKT and ERK1/2 signaling leading to intrinsic apoptosis in MCF-7. The clinical limitations of multi-agent combination therapy that targets multiple pathways in cancer may potentially be circumvented by using a single molecule, such as AB, that inhibits both AKT and ERK1/2 signaling. The THAQ pharmacophore, with its disrupted conjugated ring system and relative redox inactivity, may possess greater mechanistic advantage against ER+ breast cancer when compared to the fully conjugated ring systems of the anthracyclines (doxorubicin) and anthraquinone (mitoxantrone) that are associated with nonselective mechanisms. The present phase of our study provides evidence that AB downregulated ER α expression at the post-translational level through the induction of proteasome-dependent degradation similar to a classical selective estrogen receptor degrader (SERD). AB dose-dependently downregulated both wild-type (WT)- and 17 β -estradiol (E2)-stimulated ER α protein expression without altering mRNA expression in ER+ cells. This was corroborated by the marked reduction in the expression of downstream ER α target genes (cathepsin D and pS2). AB also dose-dependently downregulated cyclin D1, the estrogen-independent activator of ER. Antiproliferative effects were enhanced when ER+ cells were exposed to a combination of AB and the ER α -selective antagonist, MPP dihydrochloride. The AKT activator, SC79, showed that the AB-induced ER α protein downregulation was independent of the inhibition of AKT-FOXO1 signaling. The expression of Hsp90 was not affected. Co-treatment with the protein synthesis inhibitor, cycloheximide, revealed that AB downregulated ER α expression at the post-translational level.

The proteasome inhibitor, MG-132, effectively suppressed AB-induced ER α degradation and restored cellular proliferation. In silico approaches were adopted to probe the direct binding of AB to ER α . AB demonstrated significant binding affinity with human ER α (PDB ID - 3ert) compared to the binding of the standard SERD, fulvestrant. Non-covalent bonding interaction analysis further revealed that, much like fulvestrant, AB successfully interacted with 5 major amino acid residues (i.e., Ala350, Asp351, Leu525, Leu536 and Trp383) at the ligand-binding domain of ER α which is stabilized by 7 non-bonding interactions. Principal component analysis indicated that binding with AB improved the compactness of 3ert folding. Molecular dynamics simulation indicated that the 3ert-AB interaction was stable even in the 100 ns simulated physiological environment.

TRPS1 Regulates angiogenesis via JAG1 and TYMP in Triple-Negative Breast Cancer

Background: Triple-negative breast cancer (TNBC), the most difficult subtype to treat, is defined as estrogen receptor (ER), HER2, and progesterone receptor (PR) negative and comprises roughly 15-20% of all breast cancers. Patients with a TNBC diagnosis have worse outcomes and poorer survival rates when compared to women with other breast cancers, despite adjuvant chemotherapy. One of the factors contributing to its metastatic ability is the angiogenic process it undergoes. Clinical trials with anti-angiogenic therapeutics showed to be inadequate, with moderate response rates and insignificant survival gains for patients. TRPS1, a GATA and GATA-like transcription factor, has been proven to play a role in the epithelial to mesenchymal transition (EMT) which ultimately promotes tumor growth and metastasis. It has previously been shown that TRPS1 regulates angiogenesis via the expression of VEGF proteins in breast cancer. Our purpose in this study was to further investigate the functional role of TRPS1-regulated genes involved in TNBC angiogenic pathways. Methods: Sleeping-Beauty (SB) transposons help detect cancer progression genes which participate in tumorigenesis and metastasis, not easily identified with current sequencing technology. Using the SB transposon methodology, several candidate trunk drivers were elucidated using Pten mutant mice. Validation studies further showed TRPS1 as one of the eight TNBC tumor suppressor genes discovered by this technology. Then, ChIP-seq array studies were performed which showed that TRPS1 regulates expression of genes involved in the angiogenesis pathway. To corroborate the functional role of TRPS1 in angiogenesis, tube formation and sprouting assays were performed using overexpression and inactivation of TRPS1 in MDA-MD-231 and HCC70 cells, respectively. Furthermore, we performed a ChIP qPCR human angiogenesis array to determine TRPS1-regulated angiogenic genes. A luciferase reporter assay was performed to determine whether TRPS1 is a direct transcriptional regulator of these genes. Results: Inactivation of TRPS1 expression allowed tube formation and cell branching in the sprouting assays. Tumor xenografts overexpressing TRPS1 were analyzed by immunohistochemistry, showed a significant reduction of angiogenic vasculature when stained with CD31; and a substantial increase in blood vessels when TRPS1 was shRNA inactivated. Furthermore, human ChIP qPCR angiogenesis array identified 10 top candidate genes potentially regulated by TRPS1 transcription factor. Of these candidates, JAG1 and TYMP showed to have a higher fold enrichment compared to other angiogenic related genes. Finally, we validated its direct functional binding by using luciferase reporter assay, such demonstrated that TRPS1 is a direct transcriptional regulator of JAG1 and TYMP. Discussion: It has been previously established that

the NOTCH ligand, JAG1 and the thymidine phosphorylase enzyme, TYMP are powerful genes participating in angiogenesis. Furthermore, elevated expression of JAG1 mRNA and protein has been associated with poor patient outcomes in breast cancer. Similarly, TYMP activity has been shown to be higher in triple-negative breast tumors, leading to poor outcomes as well. Although several anti-angiogenic drugs have been approved, tumor-acquired resistance to therapy limit their effectiveness. An increased understanding of tumor vessel mechanisms involved in tumorigenesis and metastasis is necessary to overcome the obstacles that prevent successful control of the angiogenic response in tumors. This would require as many paths as can be unraveled regarding the angiogenic mechanisms driving TNBC. Understanding the relationship between the function of TRPS1 in regulating the expression of important genes such as JAG1 and TYMP lays a better foundation for new drugs and drug targets that control and inhibit tumor angiogenesis.

Introduction: β -Arrestin1 (ARRB1) belongs to the arrestin family originally identified as a multifunctional adaptor protein that negatively regulates the desensitization and internalization of G-protein-coupled receptors. Recent studies have indicated that ARRB1 can form multiprotein complexes with transcription regulators, thereby indirectly inhibiting the function of some transcription factors, e.g., NF- κ B, and promoting the activity of others, e.g., p53. Further, arrestins function as multifunctional adaptors in many signalling pathways, such as the Hedgehog (Hh), Wnt, Notch, and transforming growth factor- β (TGF- β) pathways. Expression of ARRB1 is downregulated in TNBC patients and ARRB1 expression level is inversely correlated with the histological grade of the breast cancer and positively associated with TNBC patient survival, suggestive of a tumour-suppressive function of ARRB1 in breast cancer. Loss of ARRB1 expression is associated with a poor prognosis for non-small cell lung cancer patients. However, the mechanisms regulating the expression of ARRB1 in human cancers remain unclear. We hypothesized that metabolic endoplasmic reticulum (EnR) stressors including low glucose and hypoxia that activate an unfolded protein response (UPR) in tumour cells might regulate the expression of ARRB1 in human cancers. Methods: Expression of ARRB1 was determined by a combination of real-time RT-PCR, western blotting along with promoter reporter assays. Computational target prediction analysis was done to identify miRNAs targeting ARRB1 as well as transcription factors regulating ARRB1 expression. ARRB1 overexpressing breast cancer clones were generated by lentiviral transduction to investigate its functional role in tumour progression and drug sensitivity. Results: We observed that ARRB1 expression was significantly reduced in several cancers including breast tumours as compared to normal tissue and decreased expression of ARRB1 was associated with poor prognosis in Luminal A subtype. We found significant downregulation of ARRB1 mRNA and protein during conditions of EnR stress in multiple ER-positive breast cancer cell lines. Using PERK, ATF6 and XBP1 knockdown sub-clones of MCF7 we observed that PERK signalling was required for the downregulation of ARRB1. ATF4 and miR-204/211 downstream of PERK were identified as key regulators of ARRB1 expression. Conclusion: Our results show that

ATF4 and miR-204/211 downstream of the PERK signalling pathway repress ARRB1 expression in breast cancer cells. Our results suggest that the downregulation of ARRB1 by EnR stressors in the tumour microenvironment may contribute to breast cancer progression.

Background: Many analyzes on tumor microenvironment has made it clear that tumor infiltrating lymphocytes (TILs) plays an important role in treating cancers with high tumor mutation burden such as triple-negative breast cancer (TNBC). We reported that the relationship between TILs and PD-L1 expression (Oncotarget 2017) and revealed that high-TILs/positive-PD-L1 expression population in TNBC was associated with better prognosis. However, its molecular mechanism is still unclear. Meanwhile, it was well-known that activated T-cells work as antitumor lymphocytes by enhancing the apoptosis by granzyme B (GZMB) and perforin, and then production of cytokines such as INF γ . We focused on GZMB and examined the function of activated T-cells. Patients and Methods: This study included 230 patients with primary TNBC who underwent resection without neoadjuvant chemotherapy at our three hospitals between January 2004 and December 2014. The immunohistochemistry (IHC) scoring for GZMB expression on TILs was defined as 1 or 5%. PD-L1 positivity was defined as ≥ 10 Combined Positive Score (CPS) based on tumor and immune cells staining positive for PD-L1. Results: Of the 230 TNBC, GZMB on TILs was expressed as more than 1% and 5% positive in 181 (79%) and 50 (22%) tumors, respectively, and PD-L1 and CD8 on TILs was expressed as positive in 99 (43%) and 127 (55%) tumors, respectively. GZMB expression (more than 5%) was significantly correlated with PD-L1 expression ($P=0.0048$) and CD8 expression ($P=0.0156$). There was no significant difference in recurrence free survival (RFS) and overall survival (OS) regardless of CD8 or PD-L1 expression level. Meanwhile, the patients with GZMB-positive tumors had a longer OS, compared to the patients with GZMB-negative tumors ($P = 0.0155$ in RFS and $P = 0.0202$ in OS) when PD-L1 expression on TILs was high, but not when it was low. Conclusion: OS was significantly longer among patients with high GZMB expressing TNBC. These results may validate the significance of GZMB as a biomarker for various immunotherapies in TNBC.

Background: Despite advances in breast cancer imaging, research and treatment, higher mortality among racial/ethnic minority and low-income populations persists. Consent and enrollment of diverse and vulnerable patients into breast cancer research is critical. Given this urgent need for diversity in breast cancer research, successful collection and banking of fresh biospecimens from diverse patients is key to ameliorating some of the cancer disparities. Given our access to a unique and vulnerable patient population, we developed and implemented a clinical information and biospecimen repository for patients evaluated in the breast radiology and breast oncology outpatient clinics at Boston Medical Center (BMC). Our goal was to consent patients for donation of percutaneous breast biopsy samples, surgical tissue, and blood to develop a breast cancer biospecimen bank. Our long-term goal is to provide high-yield human samples for translational research studies in breast cancer from a diverse and vulnerable patient population. Methods: We designed a multi-disciplinary team of clinical providers and basic science researchers to envision a breast cancer biospecimen bank for research. Key stakeholders were identified, workflow was arranged, IRB obtained, and research staff trained. Patients presenting with suspicious mass on breast imaging (BI-RADS 4C and 5 categories) were eligible to enroll. Two percutaneous biopsy cores were obtained for research at the time of ultrasound guided biopsy. We leveraged the Hematology Oncology translational research program at Boston Medical Center and pilot finding to launch the project. Results: Since initiation in April 2021, we approached 68 patients and consented 44, for a successful consent rate of 64.7%. Of the 44 patients consented, 22 (50.0%) identified themselves as Black/African American, 11 (25.0%) as White/Caucasian, 10 (22.73%) as Hispanic and 1 (2.27%) as Asian. Of all patients enrolled, 41 (93.2%) had a breast malignancy, of which 27 (70.7%) were hormone-sensitive and 7 (17.1%) were TNBC. Additionally, of the 44 patients on study, only 9 (20.4%) had commercial insurance or managed care plan on the day of the consent. In total, 84 percutaneous biopsy cores were collected from 42 patients. Corresponding surgical tissue, plasma, serum and PBMCs were also obtained. Conclusion: Our program demonstrates that the enrollment of diverse and vulnerable breast cancer patients onto cancer research is achievable. We successfully created a breast biopsy program to provide access to diverse human samples for breast cancer translational research studies. Currently this repository serves to address many ongoing translational projects to understand:

1) the gap in knowledge of inherent differences in tumor biology and tumor environment, 2) metabolic regulation in the breast cancer microenvironment, and 3) heterogeneity of tumors and its effects on clinical outcomes and microenvironment interactions.

Introduction: Breast cancer is the second leading cause of death among women after lung cancer. Despite the increase and improvement in preventive screening, breast cancer still remains a threat, both for pre- and postmenopausal women, due to the rapid development of resistance to drug treatments, which recalls the complicity of multiple factors. Breast cancer prognosis can be correlated with specific histological subtypes and their receptor status. Depending on stage and invasiveness, ER + and PR + breast cancers are treated with surgery and adjuvant chemotherapy, which includes endocrine-based agents, such as SERMS (Tamoxifen), SERDs (Fulvestrant) and aromatase inhibitors (Letrozole and Anastrozole). Resistance to endocrine therapy can be explained by various mechanisms, such as mutations of the estrogen receptor, epigenetic modifications of the same receptor, alterations in hormone synthesis and metabolism, aberrant activation of signaling transduction pathways (up-regulation of PI3K, MAPK, CDKs). To reduce pharmacological resistance, it is possible to use histone deacetylase inhibitors, such as valproic acid, as the epigenetic alterations play an important role in the oncogenesis of breast cancer. Epigenetic modifications of genes are a mechanism used by cancer cells to silence the expression of tumor suppressor genes, driven by epigenetic mutations of regulator factors. The valproic acid, used as an antiepileptic drug and for the treatment of bipolar disorders, is also a selective inhibitor of class I and class II HDAC isoforms, involved in the progression of different types of tumors. In this study, we tested the effects of valproic acid on the signaling involved in apoptosis and in the generation of Reactive Oxygen Species (ROS) in MCF-7 breast cancer cells. Methods: MTT assay was performed to evaluate cell proliferation. Cell cycle, ROS levels and apoptosis were analyzed by flow cytometry, while protein levels were detected by Western Blotting (WB). Results: Cell treatment with valproic acid reduced cell proliferation and induced G0/G1 cell cycle arrest. In addition, the drug enhanced the generation of ROS by the mitochondria and addressed breast cell death by

apoptosis. Indeed, the valproic acid was found to downregulate the anti-apoptotic marker Bcl-2 and to upregulate the expression of pro-apoptotic markers, such as Bax and Bad, leading to release of cytochrome C into the cytosol and PARP cleavage. The drastic reduction in mitochondrial membrane potential and in mitochondrial mass was observed following treatment with valproic acid, indeed the ratio between the two parameters, index of functionality per mitochondrion, resulted to be lowered, thus emphasizing the metabolic perturbation in the cells. Conclusion: In summary, our results have demonstrated that in estrogen receptor positive breast cancer cells the valproic acid is a suitable drug to arrest cell growth, to address apoptosis and mitochondrial perturbations, all factors that are important in determining cell fate and health. This study encourages that valproic acid, as an epigenetic drug, is a promising class of antineoplastic agent to be further explored also in combination with other classical chemotherapeutics in breast tumors.

TRAF3 (TNF Receptor Associated Factor 3) is a regulator of NF- κ B signaling, acting mainly as an inhibitor of the alternative NF- κ B pathway through the interaction with other TRAF molecules and the downregulation of NIK (MAP3K14) kinase. While NF- κ B has a well-established role in breast cancer development and progression, TRAF3 which acts as a ubiquitin-ligase in the NF- κ B cascade has never been studied in mammary carcinomas. Here by employing breast cancer cell lines in invasion and colony formation assays, we show that TRAF3 forced expression inhibits aggressive traits of breast cancer cells. In addition, immunohistochemistry (IHC) for TRAF3 protein in breast cancer FFPE samples and analysis of TRAF3 gene expression from publicly available data sets, indicates that TRAF3 mRNA and protein expression in breast cancer tissue correlates with Recurrence Free Survival (RFS), Overall Survival (OS) and other clinicopathological parameters such as Histological Grade and proliferation index (ki-67). To our knowledge this is the first report on TRAF3 protein in breast cancer providing preliminary evidence for an inhibitory role of this protein in breast cancer development and progression.

Toll like receptor-9 (TLR9) is an innate immunity DNA-receptor, which is widely expressed in various cancers, including breast cancer. Low TLR9 expression in cancer cells was initially associated with poor prognosis among patients with triple negative breast cancer. We have now discovered a similar association also among other breast cancer subtypes. The mechanism for TLR9-associated poor prognosis is not currently known, but our ongoing studies suggest that it may be due to poor chemotherapy responses. Regulation of TLR9 expression in breast cancer is poorly understood. It has been demonstrated that in cervical cancers, TLR9 expression is suppressed by human papillomavirus (HPV) infections. Although breast cancer is not typically considered HPV-associated, there are reports of HPV in breast cancer. The aim here was to test the hypothesis, that HPV-infections suppress TLR9 expression also in breast cancer. To study this, human breast cancer cells were infected with HPV16 E6-oncoprotein, followed by measurement of TLR9 mRNA and protein in vitro. We also aimed to compare the presence of HPV DNA with TLR9 protein expression in clinical breast cancer specimens. We further studied E6-infection effects on breast cancer proliferation, migration, and invasion. E6-infection decreased TLR9 protein expression in TNBC but not in estrogen receptor expressing (ER+) cells. E6-overexpression significantly altered breast cancer proliferation, but the impact was opposite in TNBC and ER+ cells. No effect on migration and invasion was observed. E6-transfected breast cancer cells were significantly less sensitive in vitro to chemotherapies typically used for the treatment of breast cancer in the adjuvant setting. In vivo studies are pending. HPV DNA was not detected in a pilot cohort of clinical breast cancer specimens (n=37) among Northern Finnish breast cancer specimens. These results indicate that HPV may affect breast cancer TLR9 expression and thereby breast cancer prognosis, through treatment

responses. Although HPV was not detected in the small pilot set of our clinical samples, this issue needs to be further studied in larger data sets.

Background: Circulating tumor cells (CTCs) in breast cancer (BC) are commonly defined as epithelial cells (EPCAM and cytokeratin (CK) positive), lacking the universal blood cell marker CD45. Nonetheless, CTCs expressing both CK and CD45 (= dual-positive, DP cells) can be observed in the blood of cancer patients. Early evidence suggests that DP cells might derive from the fusion of tumor cells and macrophages, and we have previously demonstrated that they present aberrant genomes and are associated with worse prognosis in BC [1,2]. Here, to further investigate the mechanisms/pathways underlying their presence, we analyzed the association between DP cells and circulating tumor DNA (ctDNA) alterations. Methods: Blood

samples were collected from patients with advanced BC (aBC), before starting a new line of therapy. All patients were enrolled in a prospective clinical trial. For CTC and DP cells analysis, 7.5 ml of blood collected in CellSave® tubes was processed with the FDA-approved CellSearch® platform (positivity cutoffs were ≥ 1 cell for DPcells and ≥ 5 cells for CTCs). For ctDNA analysis, plasma was collected from Streck stabilizing tubes and analyzed with the Guardant360™ NGS platform for the detection of somatic single nucleotide variants (SNVs), insertions/deletions (indels), gene fusions/rearrangements and copy number variations (CNVs), which were then classified into pathways based on previously defined profiles generated on the Cancer Genome Atlas database (RTK, RAS, RAF, MEK, NRF2, ER, WNT, MYC, P53, cell cycle, notch, PI3K). Associations between ctDNA-detected gene alterations and circulating cell types were analyzed through chi square test, while mutant allele frequency (MAF) and number of detected alterations (NDA) were tested by Mann Whitney test. Results: We analyzed blood samples from 169 patients with luminal-like (n=80), HER2+ (n=34) and triple-negative (n=52) aBC. DPcells were detected in 85 patients (50.3 %, range 0-53), of which 40 (47 %) were CTC-positive and 45 (53%) CTC-negative. Somatic ctDNA alterations were detected in all analyzed samples. In the overall population, the presence of ≥ 1 DPcell was associated with SNVs in the cell cycle pathway ($p = 0.043$), a numerically higher incidence was also observed for CNVs in this pathway. SNVs and CNVs in the cell cycle pathway were associated with CTCs ≥ 5 as well ($p = 0.005$ and $p = 0.003$, respectively). Moreover, associations with CTCs ≥ 5 were observed for RTK SNVs and CNVs ($p = 0.041$ and $p = 0.046$, respectively), PI3K SNVs and CNVs ($p = 0.006$ and $p = 0.007$, respectively), MYC SNVs and CNVs ($p = 0.042$). No associations were observed in terms of MAF and NDA. In the luminal-like subgroup an association was highlighted for CNVs in the cell cycle pathway, $p = 0.038$. CTCs ≥ 5 were associated with PI3K SNVs ($p = 0.031$). In the triple-negative subgroup DPcells were associated with SNVs in the RAF pathway ($p = 0.041$), whereas CTCs ≥ 5 were associated with PI3K SNVs and CNVs ($p = 0.044$ and $p = 0.024$, respectively) and RTK SNVs ($p = 0.008$). In the HER2 positive subgroup, a higher MAF and number of detected SNVs was observed for samples with ≥ 1 DPcell ($p = 0.0286$ and $p = 0.0099$, respectively). Conclusions: The study analyzed ctDNA features associated with canonical and CK+/CD45+ CTCs, showing differential gene alteration profiles. Cell cycle pathway SNVs were common in both CTC populations, while other pathways (RTK, PI3K, MYC and RAF) were significantly altered in a mutually exclusive pattern. These results suggest that DPcells might have a different biological meaning compared to canonical CTCs. More studies need to be conducted to better characterize this understudied CTC subpopulation and understand their specific contribution to cancer progression. Background: Abemaciclib is a selective CDK4 and CDK6 inhibitor with demonstrated efficacy in hormone receptor-positive, human epidermal growth factor receptor 2-negative advanced breast cancer. The most common adverse event across previous trials was early-onset diarrhea, affecting the patients' quality of life and necessitating dose reductions. However, the exact mechanism for the lower rate of diarrhea in the other CDK4 and CDK6 inhibitors

compared with abemaciclib is unknown. Ample evidence indicates that the gut microbiome is a tumor-extrinsic factor associated with the anti-tumor response; however, reported microbial signatures associated with adverse events by anti-cancer agent are inconsistent. To determine the underlying mechanism, we evaluated the correlation between diarrhea with abemaciclib and microbiota signatures in a metastatic breast cancer cohort.

Methods: The KBCRN-A002 study is a multicenter, prospective cohort study, which aims to evaluate the association between gut microbiota signatures and abemaciclib-induced diarrhea in breast cancer patients. Patients with metastatic breast cancer who were receiving abemaciclib were eligible. The primary objective of this study is the correlation between diarrhea and the microbiota signatures and immune profile. Incidence and severity of diarrhea were evaluated by the Bristol stool scale at baseline, from day 1 to day 14, and at day 90 of treatment. Stool samples were collected at baseline and at day 90 after the start of abemaciclib treatment. The gut microbiota signature was evaluated by 16S rRNA analysis. Blood samples were collected at baseline and at days 14 and 90 after starting abemaciclib to evaluate the correlation between the gut microbiota signatures and the systemic immune profile in peripheral blood mononuclear cells (PBMCs). The immune profile was evaluated by mass cytometry, multi-plex cytokines assay, and RNA-sequencing of bulk PBMCs. We characterized the gut microbiota signatures, immune cell composition, immune cell signature, comprehensive cytokines, and severity of diarrhea in all patients.

Results: We analyzed 39 patients, 77 stool samples, and 117 blood samples. In the preplanned interim analysis, among the 39 patients, 90% experienced diarrhea. Depleted gut microbiome α -diversity was positively associated with abemaciclib treatment and the severity of diarrhea. The relative abundances of 10 intestinal bacteria species increased and those of 18 intestinal bacteria decreased significantly after abemaciclib treatment, including bacteria known to be involved in diarrhea severity and anti-tumor immunity, such as *Faecalibacterium* (Table). The immune cell and cytokine profiles in PBMCs were also associated with the gut microbiota signatures.

Conclusions: Gut microbiota signatures are associated with abemaciclib-induced diarrhea and the immune profile in metastatic breast cancer patients. These findings can help to elucidate the mechanism of diarrhea caused by abemaciclib and offer strategies for its management and prevention.

The biologic basis of genetic ancestry-dependent variability in disease incidence and outcome is just beginning to be explored. We recently reported enrichment of a population of ZEB1-expressing cells located adjacent to the ductal epithelial cells in the normal breast of women of African Ancestry (AA) compared to European Ancestry (EA). By establishing and characterizing cell lines corresponding to these cells and validating in vitro findings with tissue microarrays of healthy breast tissue from AA, EA and Latina Ancestry (LA) women, we demonstrate that these cells have the properties of fibroadipogenic/mesenchymal stromal cells that express PROCR and PDGFR α . PROCR+/ZEB1+/PDGFR α + cells, hence renamed as PZP cells, are enriched in the normal breast tissues of AA compared to EA or LA women. In vitro, PZP cells trans-differentiated into adipocytes or osteocytes. In co-culture conditions, PZP:epithelial cell communication resulted in luminal epithelial cells acquiring basal/stem cell characteristics and increased expression of IL-6 suggesting the impact of this communication on the microenvironment and breast epithelial hierarchy. Consistent with this possibility, the level of phospho-STAT3, which is a downstream target of IL-6, was higher in the normal and cancerous breast tissues of AA compared to EA women. PZP cells transformed with HRasG12V \pm SV40-T/t antigens generated metaplastic carcinoma in NSG mice suggesting that these cells could be the cell-of-origin of metaplastic breast cancers. Collectively, these results identify a stromal cell component that could influence the biology of breast cancer in AA women.

Background: The PI3K inhibition has been an appealing approach for anticancer therapy due to its crucial role in cell growth, proliferation, and survival in various cancers. Emerging data suggest the PI3K pathway is also involved in DNA replication and genome stability, making DNA damage response (DDR) inhibitors as an attractive combination treatment for PI3K pathway blockades. Here, to enhance the efficacy of PI3K inhibitors, we investigated the novel approach combining PI3K inhibitors (alpelisib, AZD8835, AZD8186, NVP-BKM120) with DDR blockade using ATR inhibitor (AZD6738) in breast cancer preclinical models. Methods: Hormone receptor-positive breast cancer cells, MCF7 (PIK3CA E545K mutation) and T47D (PIK3CA H1047R mutation) were used. First, cell viability and the synergistic effect of combination drug was carried out by MTT assay. Next, western blot, cell cycle analysis, apoptosis assay, and immunocytochemistry were conducted to validate the hypothesis. Finally, tumor xenograft experiments were conducted using BALB/c nude mice to validate the in vitro data. Results: A synergistic antiproliferative effect was observed over a wide range of combination (PI3K inhibitor + ATR inhibitor) concentrations (even in a lower concentration as 1/10 x IC50) in vitro, suggesting that when alpelisib is combined with an ATR inhibitor, there may be possibility of lowering the effective dosage of alpelisib. After confirmation of the strong synergistic effect in sub-G1/G0-G1 arrest-mediated apoptosis by the combination treatment, we demonstrated that expressions of phospho ATR, ATM, and CHK1 were suppressed but γ -H2AX markedly increased by combination treatment as compared to PI3K inhibitors and ATR inhibitor alone. This suggests that combination treatment activates apoptotic pathway through enhanced DNA double strand breaks. Finally, the in vivo study showed that the combination treatment group tended to show a greater tumor growth inhibition compared with PI3K inhibitor or ATR inhibitor alone. Conclusion: The combined inhibition of PI3K and ATR showed a synergistic anticancer effect in vitro and in vivo. ATR inhibitor in combination with PI3K inhibitor merits further clinical investigation to enhance the activity of PI3K inhibitor for the treatment of PIK3CA mutated breast cancer patients.

Background: Statins were suggested for repurposed drugs, having multifaceted effects which include anti-tumor activities by modulating the immune response. Here, we aimed to demonstrate the effect of statins on programmed death-ligand 1 (PD-L1) expression in triple-negative breast cancer (TNBC) cells. Methods: Thirteen human TNBC cell lines, mouse macrophage cell line (RAW 264.7), cholesterol and 27-hydroxycholesterol, and clinically approved lovastatin and simvastatin were used. Flow cytometry, Annexin V/propidium iodide assay, western blot, qRT-PCR, transwell migration assay, and immunohistochemistry were employed. A co-culture of macrophages with various breast cancer cells was performed. An orthotopic breast tumor mouse model and metastasis model by injection of GFP-tagged MDA-MB-231 cells into mammary gland fat pad and the tail vein injection were produced. In tumor model mice, lovastatin(10mg/kg) was daily injected intraperitoneally. In vivo fluorescent imaging was used to identify primary tumor development and lung metastasis. Results: Among thirteen TNBC cell lines, MDA-MB-231, HCC38, and HCC70 highly expressed endogenous/constitutive PD-L1. Statins reduced PD-L1 expression and exerted anti-proliferative and apoptotic effects in MDA-MB-231, HCC38, HCC70, and Raw264.7 in a dose- and time-dependent manner ($p < 0.05$). Meanwhile, statins increased the expression of PD-L1 in Hs578T and MDA-MB-468. STAT3 phosphorylation was inhibited in MDA-MB-231 and HCC70, but not in Hs578T, while AKT phosphorylation was reduced in MDA-MB-231, HCC70, Hs578T, and MDA-MB-468 when statins were treated. The migration of MDA-MB-231 and Raw264.7 in statin-treated conditioned media was decreased ($p < 0.05$). Cholesterol and 27-hydroxy cholesterol did not restore PD-L1 expression in statin-treated MDA-MB-231. Statins suppressed the expression of M2 markers

(PD-L1, CD206, YM-1, Fizz1, arginase-1) in RAW26437 stimulated by a conditioned medium of MDA-MB-231. Lovastatin suppressed the primary tumor growth and metastasis in xenograft tumor mice. Conclusions: Our findings show that statins have an anti-tumor effect, which kills breast cancer cells and triggers macrophage reprogramming by reducing PD-L1 expression, impairing the AKT, ERK, and STAT3 signal pathways, and decreasing M2 markers. Further study is needed to investigate an in-depth molecular mechanism study by which statins regulate PD-L1 expression in TNBC and to confirm the safe and effective use of statins as adjuvant therapy in TNBC.

Introduction. Protein phosphatase-1 (PP1) belongs to the Serine/threonine-protein phosphatase family and is known to participate in multiple functions in the cells including glycogen metabolism, cellular proliferation and cell receptor regulations. Protein phosphatase-1 has three catalytic units, namely PPP1CA, PPP1CB and PPP1CC. A PP1 protein complex is composed of one of the catalytic units and at least of one the various phosphatase regulatory units (PPP1Rs). The regulatory units of the phosphatase, abundant in numbers, also influence the functions of the protein phosphatase within cells. PP1 has been indicated to have a role in certain clinical conditions such as the Alzheimer's and certain viral infections. The value of the PP1 catalytic units in clinical cancers including breast cancer is not well established, therefore this current study aimed to examine the expression profile of the three PP1 catalytic units in human breast cancer and attempted to establish the clinical relevance of the catalytic units in the disease progression of breast cancer. Methods. Fresh frozen normal mammary tissues and breast cancer tissues were investigated for the levels of gene transcripts of the three PP1 catalytic units were quantified and corrected with an epithelial cell marker. The expression and integrated expression profile of PPP1A, PPP1B and PPP1C in the tissues were assessed against the pathological, clinical and outcome of the patients as well as the hormone receptor status. Results. All three catalytic units of PP1 were positively expressed in normal and tumour breast tissues, with PPP1A at significantly higher levels in normal mammary tissues than tumours ($p=0.01$) and PPP1B and PPP1C showing no significant difference. Expression of PPP1B in breast cancer was significantly lower in high grade breast cancers ($p < 0.05$ vs low grade), in tumours from patients who died of breast cancer ($p=0.047$ vs those who survived) and with breast cancer related incidence ($p=0.048$ vs incidence free). The most significant finding of the present study was a correlation between high levels of all three catalytic units and favourable overall survival of the patients. Those patients with high levels of PPP1A, PPP1B and PPP1C in breast tumours had a mean survival time of 142.6, 141.6 and 140.3 months compared with those with low levels respectively at 111.8, 115.8 and 117.6 months. When the expression profiles of the three units were integrated, the integrated profile formed a highly valuable and independent indicator for both overall survival ($p=0.008$, HR=0.694) and for disease free survival ($p=0.004$, HR=0.702). The predictive value of PPP1A/PPP1B/PPP1C for survival was more significant for ER negative tumours than ER positive tumours ($p=0.003$), but

appeared to be indifferent for Her2 status. Finally, our data indicated that the integrated expression of the three catalytic units had a significant predictive value in bone metastasis of the patients ($p=0.008$, $HR=0.546$). Discussion. Protein phosphatase-1 catalytic units, PPP1CA, PPP1CB and PPP1CC are expressed in human mammary tissues; raised levels of the catalytic units are a favourable clinical indicator for the survival of patients and for a decreased tendency to develop bone metastasis.

1) Background: It is well known that solid tumors have the ability to form metastases. The development of distant metastases is due to the primary tumor shedding cells that travel to distant sites via the blood vessels. Platelets specifically promote tumor cells survival in the bloodstream. To investigate the interplay between platelets and circulating tumor cells, we implemented our approach to label simultaneously circulating epithelial tumor cells and platelets. 2) Methods: 40 breast cancer patients were enrolled into the study. Blood samples were collected in EDTA tubes without fixatives and processed at 3 timepoints (0h, 24h and 48h) using the maintrac® approach. In order to visualize platelets we used anti-CD36 antibody staining. 3) Results: We observed at 0h post-blood draw platelet aggregates strictly attached to single cells that did not stain with anti-EpCAM antibody. After keeping blood samples at room temperature for 24h platelet aggregates could still be detected, but the anti-EpCAM antibody became accessible to the underlying cells. CTCs were detected in 94% of patients on day 1 post-blood draw. At 48h following initial blood drawing, platelets had almost completely disappeared from the cell surface and the number of detected CTCs remains stable between 24h and 48h. Furthermore, the number of CTCs correlates with clinical stage of disease. Patients with stage I/II have significantly less CTCs as compared to patients with stage III/IV (median 5 vs. 19 CTCs/100µl cell suspension, $p < 0.05$). 4) Conclusion: Our results suggest that platelets play a key role in masking circulating tumor cells. Masking may explain the difficulties in detection of these cells and prevention of their elimination by the immune system.

The type I insulin-like Growth Factor Receptor (IGF-IR) plays important roles in breast cancer cell proliferation and metastasis. However, preclinical and clinical research targeting IGF-IR also revealed the potential for insulin receptor (IR) to compensate for IGF-1R inhibition. IR is expressed as two isoforms (IRA and IRB) through alternative splicing. The IRB is expressed in adult tissues and thought responsible for cell metabolism while IRA is expressed in fetal development to enhance cell growth. Since breast cancer cells usually express both IGF-IR and IRA/IRB, differential signaling by IRA and IRB has not been clearly demonstrated. To further define the role for IR, we used CRISPR technology for gene editing in exon 2 of IR in MCF-7L cells to delete IR. Cells were selected for absent IR expression by flow cytometry and Sanger sequencing confirmed that one of the clones (CL35) had the targeted 4 base pair deletions in exon 2. Immunoblotting using an antibody to the α subunit of IR showed no expression in CL35. Unexpectedly, 10 nM insulin exposure resulted in downstream AKT and Erk1,2 phosphorylation. Immunoprecipitation showed that IGF-IR was activated by the insulin in CL35 cells. Insulin signaling in CL35 through IGF-IR was inhibited by huEM164, an anti IGF-IR monoclonal antibody. Compared to MCF-7L parental cells, CL35 was more sensitive to IGF-I and less sensitive to insulin as demonstrated by downstream AKT phosphorylation and MTT monolayer growth assay. Insulin stimulated monolayer growth of CL35 measured by MTT was not affected in testing serum free media (SFM) unless transferrin was deleted from the media. These data suggest IGF-IR can function to activate signaling in response to insulin. To ensure that our clone does not contain alternate splicing products resulting in aberrant IR proteins, we are further sequencing IR mRNA in CL35. In conclusion, we have established an IR null breast cancer cell line with reduced sensitivity to insulin and increased sensitivity to IGF-I. This cell line can be used to express the IRA and IRB isoforms to characterize their function in breast cancer cells.

Despite significant improvement in therapeutic development in the past decades, breast cancer remains a formidable cause of death for women worldwide. The hormone positive subtype (HR(+)) (also known as luminal type) is the most prevalent category of breast cancer, comprising ~70% of patients. The clinical success of the three CDK4/6 inhibitors palbociclib, ribociclib, and abemaciclib has revolutionized the treatment of choice for metastatic HR(+) breast cancer. Accumulating evidence demonstrate that the properties of CDK4/6 inhibitors extend beyond inhibition of the cell cycle, including modulation of immune function, sensitizing PI3K inhibitors, metabolism reprogramming, kinome rewiring, modulation of the proteasome, and many others. The ubiquitin–proteasome pathway (UPP) is a crucial cellular proteolytic system that maintains the homeostasis and turnover of proteins. By transcriptional profiling of the HR(+) breast cancer cell lines MCF7 and T47D treated with Palbociclib, we have uncovered a novel mechanism that demonstrate the CDK4/6 inhibitors suppress the expression of three ubiquitin conjugating enzymes UBE2C, UBE2S, UBE2T. Further validation in the HR(+) cell lines show that Palbociclib and ribociclib decrease UBE2C at both the mRNA and protein level, but this phenomenon was not shared with abemaciclib. These three E2 enzymes modulate several E3 ubiquitin ligases, including the APC/C complex which plays a role in G1/S progression. We further demonstrate the UBE2C/UBE2T expression levels are associated with breast cancer survival, and HR(+) breast cancer cells demonstrate dependence on the UBE2C. Our study suggests a novel link between CDK4/6 inhibitor and UPP pathway, adding to the potential mechanisms of their clinical efficacy in cancer.

Background: Inflammatory breast cancer is an aggressive breast cancer characterized by florid congestion of lymphovascular spaces by tumor emboli. CCR7 is an immune cell receptor that mediates traffic of immune cells into lymphatics that can be expressed on tumor cells. An RNA-seq screen of tumor promoting mammary glands in mice identified CCR7 as an upregulated signal in mammary glands that promoted IBC-like skin invasion. We examined the expression of CCR7 in IBC cell lines and patients to determine the prevalence of this receptor in IBC. Methods: Protein lysates from IBC and non-IBC cell lines were subjected to immunoblotting using anti CCR7 (R&D systems). An IBC tissue microarray from post-chemotherapy mastectomy specimens of 39 patients, each with three replicates was subjected to immunohistochemical staining for CCR7 (Invitrogen, catalog number MA5-31992) performed using a Leica Bond RX autostainer with an incubation time of 60 minutes at 1:15,000 after 20 minutes of heat-induced antigen retrieval at pH 6.0. In 15 cases there were no tumor cells observed in the cores. Staining was scored by an expert breast pathologist for intensity and percent tumor stained. Staining patterns were scored. Descriptive statistics were examined for

representation by receptor subtype. Results: CCR7 staining was strong in all lines examined including MCF7, SUM149, SUM190, MDA-IBC, and SUM159. Among 24 IBC patient cores with tumor in the tissue, 23 (96%) expressed CCR7 in tumor, 15 with complete membranous staining and 9 with incomplete membranous staining. In one case with LVSI the emboli were CCR7 positive. Among the 24 positive cases, 22 were 3+ intensity while two were 2+. Nine CCR7+ cases were estrogen receptor (ER) ER+, 8 ER-, and 6 unknown. HER2 status is pending. Conclusions: CCR7 expression is present across tumor subtypes in IBC cell lines and in both ER+ and ER- patient tumors. Given developing novel pharmacologic targeting of CCR7, this target warrants further investigation in IBC and other breast cancers.

Introduction and objectives Estrogen receptor positive (ER+) tumors are the most common form of breast cancer and are responsible for most of the deaths from the disease. Treatment of ER+ breast cancer comprises interventions that suppress estrogen production and/or target the ER directly. While endocrine therapy has considerably reduced recurrence and mortality from breast cancer, de novo and acquired resistance to this treatment remains a major challenge. In this context, patient-derived organoids (PDOs), 3D structures composed of epithelial cells, are changing our understanding of cancer heterogeneity and its implications for personalized medicine. Our aim was to establish and characterize a PDO platform of ER+ breast cancer as preclinical tool to decipher and target this heterogeneity in order to tailor effective treatments based on the precise molecular makeup of the tumor. **Material and Methods** Surgical resections were collected from patients diagnosed with ER+ breast cancer. Organoid generation from patient material were divided in three main steps: 1) mechanical fragmentation of tissue pieces; 2) digestion of fragments into single-cell suspension; and 3) plating of cell preparations into matrigel domes to mimic the extracellular matrix. Organoids were passaged every 7–21 days based on confluency. Each newly organoid line was cryopreserved for further expansion. **Results** We have successfully achieved an outgrowth efficiency of almost 50% for PDOs from patients diagnosed with breast cancer. Characterization of PDO cultures is essential to validate its predictive potential. To asses that PDOs represent the tumor of the patient, for each organoid line, expression levels of the main histological markers (ER, PR, HER2, Ki67) were evaluated and correlated with the tissue of origin. In parallel, we have performed immunofluorescence on paraffin-embedded organoid samples with routinely used cancer stem

cell markers. Potential contamination with normal cells (present in the resection used to establish the culture) should be considered. To address the tumor purity of the culture we have performed targeted DNA sequencing in both the original tissue and established PDOs. Conclusions PDOs represent a superior preclinical system compared to previous models due to their inherent heterogeneity, long-term stability, applicability for high-throughput screens and enhanced capacity to capture tumor characteristics. Therefore, the implementation of a well-annotated patient-derived organoid biobank will be of great interest for drug discovery and personalized therapy. Understanding the sources and implications of tumor heterogeneity will undoubtedly improve our evolving definition of cancer and aid in the design of effective patient-specific treatment strategies.

Introduction: Breast cancer is the most diagnosed neoplasia and the second leading cause of malignancy death in women. Drug resistance is still the major challenge in the clinical management of breast cancer patients. Indeed, despite the improvements in the early diagnosis and in the therapeutic approaches, many breast cancer patients experience disease relapse due to de novo or acquired drug resistance. Growing evidence recognized a small population of breast cancer cells, named Breast Cancer Stem Cells (BCSCs), as the leading cause of tumor progression, metastasis formation and resistance against conventional therapy. BCSCs have some specific properties such as self-renewal, differentiation into different cell types, migration, tumorsphere formation, antioxidative activity, that make tumors more aggressive. Tumor microenvironment plays a crucial role in the regulation of stem cell proliferation and resistance to apoptosis through the secretion of cytokines and growth factors. Adipocytes represent the most abundant cellular component of mammary microenvironment. The excessive fat accumulation in obesity leads to the development of a dysfunctional adipose tissue, producing an unbalance in adipokines secretion. Among the secreted factors, adiponectin plays a crucial role in breast cancer development and progression. The aim of the present study was to investigate the effects of low adiponectin level (5 µl/ml), hallmark of obese status, on BCSCs activity in hormone-resistant cells. Methods: We tested the ability of MCF-7 wild type (WT) and tamoxifen-resistant (TR) to grow as mammospheres (Mammospheres Forming Efficiency, MFE), measuring the ability to maintain cell viability (self-renewal) upon serial non-adherent passages. mRNA levels of stemness, EMT and cell cycle markers were

evaluated by qRT-PCR. CD44⁺/CD24⁻ cell ratio, ALDH expression, ROS production, cell cycle, were analyzed by flow cytometry. Results: Adiponectin treatment significantly enhanced MFE and self-renewal capacity in TR-MCF-7 cells compared to MCF-7 WT cells. To identify the presence of BCSCs into mammospheres it has been evaluated the CD44⁺/CD24⁻ biomarker signature. Flow cytometry revealed an enrichment of CD44, a trans-membrane glycoprotein which regulates growth signals in stem cells, in TR-MCF-7 mammospheres, whereas expression levels of the differentiation marker CD24 were decreased. The gene expression of these biomarkers was also analyzed by qRT-PCR. The increased BCSCs subpopulation in adiponectin-treated TR-MCF-7 mammospheres was also confirmed by the enhanced ALDH-expressing cells. qRT-PCR revealed that adiponectin increased the mRNA levels of stemness and EMT markers in TR-MCF-7 cells mammospheres. Interestingly, cell cycle analysis showed in adiponectin-treated TR-MCF-7 mammospheres a reduction of apoptosis. Moreover, flow cytometry analysis displayed a reduction of ROS levels, which generally are assumed as cues determining DNA damage-induced cell death, in adiponectin-treated TR-MCF-7 mammospheres. Conclusions: Our results demonstrated that low adiponectin level, as it occurs in obese breast cancer microenvironment, driving EMT, enhances stem-like features in TR-MCF-7 cells to sustain tumor progression.

Zhengxing Zhou^{1,3}, Zhiyuan Ma^{2,3}, Xuemei Liu², Chengmin Zhang¹, Hu Wang¹, Renmin Mu¹, Xiaoming Cheng¹, Biguang Tuo², Taolang Li^{1*} 1 Breast and Thyroid Surgery, Department of General Surgery, Affiliated Hospital of Zunyi Medical University, Dalian Road 149, Zunyi 563000, China 2 Department of Gastroenterology, Digestive Hospital, Affiliated Hospital of Zunyi Medical University, Zunyi, Guizhou Province, China 3 These authors contributed equally: Zhengxing Zhou, Zhiyuan Ma *Corresponding author: Taolang Li, M.D., Ph.D. Goals: Ion transporters play an important regulatory role in the progression and development of breast cancer (BC). Slc26a9 is a member of the Slc26a anion transporter family, which is mainly involved in regulating the secretion of chloride ions and bicarbonate, but the role of Slc26a9 in HER2-positive BC is still unclear. Methods: Tissue microarray and BC cell line were used to detect the expression level of Slc26a9 and its clinical relevance. By changing the expression level of Slc26a9 gene in BC cells, the effect of Slc26a9 gene on the biological behavior of BC cells and its related molecular mechanism were discussed. Results: We found that the expression of Slc26a9 was significantly upregulated in BC compared with adjacent tissues, and the upregulated Slc26a9 was associated with TNM staging and poor prognosis in BC patients. In addition, the expression of Slc26a9 was significantly upregulated in HER2-positive BC compared with HER2-negative BC, and similar results were obtained in BC cell lines, with Slc26a9 was the highest expression in HER2-enriched SKBR3 cells. Functionally, the proliferation, migration, invasion and anti-apoptotic abilities of SKBR3 cells were

significantly inhibited after silencing Slc26a9, and tumorigenesis and metastasis were significantly inhibited in vivo. On the contrary, overexpression of Slc26a9 resulted in the opposite result. Mechanistically, overexpression of Slc26a9 activated the PI3K/AKT/mTOR signaling pathway, the key signaling pathway implicated in HER2-positive breast carcinogenesis, and promoted the expression of downstream proliferation related genes CCND1 (Cyclin D1) and c-Myc, and downregulated the expression of apoptosis related genes Caspase9, apoptosis-inducing factor (AIF) and endonuclease G (Endo G), indicating the simultaneous inhibition of caspase dependent and independent apoptosis pathway. At the same time, accompanied by changes in markers of epithelial-mesenchymal transition (EMT), including downregulation of E-cadherin and ZO-1, and upregulation of N-cadherin and Fibronectin, and SKBR3 cells changed from epithelioid morphology to mesenchymal morphology. In addition, immunofluorescence and protein nucleoplasm separation experiments showed that Slc26a9 upregulated the expression of HER2 and co-localized with HER2 in the nucleus. Co-immunoprecipitation experiments proved that Slc26a9 interacted with HER2. Furthermore, trastuzumab downregulated the expression of Slc26a9 by targeting HER2 in SKBR3 cells. Moreover, when Slc26a9 was overexpressed, the inhibitory effect of trastuzumab on HER2 was partially reversed, and we also verified the PI3K/AKT/mTOR signaling pathway. Not only that, we found that Slc26a9 was significantly upregulated in drug-resistant cell lines relative to parental cells by constructing SKBR3 drug-resistant cell lines, indicating that Slc26a9 expression was significantly correlated with chemotherapy resistance in HER2-positive BC. Conclusion(s): Slc26a9 may interact with HER2 in the form of molecular chaperones to activate PI3K/AKT/mTOR signaling pathway to promote the progression and development of HER2-positive BC and be associated with chemotherapy resistance, but the precise molecular mechanism needs further exploration. Conflict of Interest: No significant relationships.

Marvel D3 and its associated junctional proteins in breast cancer Wenxiao Ji, Wen G. Jiang, Tracey A. Martin CCMRC, Cardiff University School of Medicine, Cardiff, Wales, UK
Introduction. Marvel (Membrane Associated Domain Containing) proteins are a small family of proteins that are concentrated at the tight junction (TJ) region of epithelial and endothelial cells. They are important players in the formation and regulation of TJs. The Marvel protein family has three members, Marvel-D1, Marvel-D2 and Marvel-D3, all known to be TJ components. Marvel-D3 is more prominent in TJ regulation, by interacting widely with other proteins that co-localised at TJs. In the present study, we have examined the expression of Marvel-D3 and its splicing variants, their relationship with other known interactive TJ partners in breast cancer and in disease progression and clinical outcome. Methods. Marvel-D3 and its variants were quantified in a breast cancer cohort that contained both normal and tumour tissues. The expression was analysed together with the known Marvel-D3 interactive molecules available in our database of the same cohort. The profile of the expression of the molecules was also integrated to search for a pattern of the expression that may have clinical significance including the survival of the patients. Results. Marvel-D3 had significantly high levels in breast cancer tissues than normal tissues ($p=0.011$). The difference between normal and tumour tissues for two Marvel-D3 variants were not statistically significant. Of all the known Marvel-D3 interactive proteins that were available for analyses, we identified thirteen with viability in integrated analyses; they include the JAM family members, Marvel-D2, occludin, the zonula occluden family members, small number of the claudin family members and cingulin, all being important TJ components. The integrated expression of these Marvel-D3 partners presented a highly significant predictive power for the overall survival of the patients ($RUC=0.821$, $p < 0.0001$). Stratifying the patients based on the profile has a significant value in evaluating survival (survival rate 95.7% with favourable expression versus 57.1% unfavourable, during the followup period). This predictive power is independent of other clinical and hormonal receptor status ($p < 0.001$, $HR=1.226$ (95% CI 1.094-1.373)). We have also noted that this predictive value is applicable to subtypes of the breast cancer and hormone receptor status with similar predictive power. Conclusion. Expression of Marvel-D3, a TJ component, together with its interactive TJ partners, including both transmembrane and intracellular subcoat proteins, form an important clinical indicator for clinical progression of breast cancer.

Background: Patient-derived xenografts (PDXs) are increasingly used in cancer research as tools for studying cancer biology and personalized immunotherapy response. However, a comprehensive evaluation of patient-derived breast cancer xenograft generation rates in various settings is understudied. Methods: We conducted a prospective study of breast cancer patients treated with surgery to generate PDXs. PDXs were characterized by molecular subtypes, specific diagnostic entities, modified Bloom-Richardson system nuclear and histologic grades, treatment with neoadjuvant chemotherapy (NAC), Miller Payne grade, residual cancer burden class, invasive tumor size, lymphovascular invasion status, number of positive lymph nodes, and the percentage of tumor infiltrating lymphocytes in the implanted tumors. Results: Three hundred and seventy-two (157 post-chemotherapy, 215 chemo-naïve) patient-derived tumors were implanted and 63 PDXs were established (17.0%). PDX engraftment was higher in the patients with higher nuclear and histologic grades using the modified Bloom-Richardson system (27.6% vs. 3.2%, $p = 0.003$) and triple negative breast cancer (TNBC) than in those with hormone receptor-positive cancer (36.4% vs. 3.2%, $p = 0.02$). Tumors from patients who received NAC (30.0% vs. 7.4%, $p = 0.05$) were also close to being statistically significant for successful PDX generation. Conclusions: PDXs can be established from clinically aggressive breast cancers, especially in patients with high nuclear and histologic grade TNBC treated with NAC. The prediction of engraftment success using these factors would establish cost-effective immunotherapy trials employing PDXs.

Glycobiology has proved to be a new frontier in oncology research in recent years. One sector of glycobiology involves examining glycan expression of cancerous cells. Glycans are complex carbohydrates found on cell surfaces, and patterns of aberrant glycan expression, such as increased sialylation and fucosylation, have been proposed as potential novel biomarkers of cancer tumorigenesis and metastasis. However, to our knowledge, there is little literature examining the differences in expression of high mannose glycans, a subtype of N-linked glycans, which is the focus of this study. Thirty-nine samples of malignant and surrounding benign tissue from breast cancer patients were collected from the Prisma Health Cancer Institute Biorepository. Additionally, forty malignant serum samples were collected—ten of these samples were from the same patients included in the tissue samples. Serum samples from ten healthy volunteers were also obtained as controls. The malignant samples included specimens from breast cancer staged I through IV at the time of the patients' diagnosis. Samples were analyzed using MALDI-TOF mass spectroscopy for the presence of glycans by Emory Glycomics and Molecular Interactions Core. The known masses of sixty-one unique glycans were then compared to the spectra of the samples analyzed to determine the type of glycans present, and the relative amount of each glycan present was determined using the area under the curve in the spectral data. Data analysis revealed the means of the area under the curve for high mannose glycans in the malignant and normal tissue samples to be 247.18 and 163.6 respectively; the t-test established the difference in these means to be statistically significant (p-value, 0.0138). This finding was consistent in serum samples; the mean area under the curve for malignant and normal serum was 1650.34 and 376.26 respectively (p-value, >.0001). Furthermore, there were differences in expression of high mannose glycans between stages of breast cancer, with expression in stage III being significantly greater than expression

in stage II in both serum (p-value, .0097) and tissue (p-value, .0003) samples. The results of this analysis suggest a higher expression of high mannose glycans to be a promising biomarker for breast cancer. This could lead to important clinical applications such as being a helpful distinction in obtaining negative margins during tumor resection, as well as providing a non-invasive diagnostic method. Future research could include expanding the sample size and comparing the glycan composition of the samples to a library specific for high-mannose type glycans, with the goal of establishing a signature high-mannose expression pattern in each stage of cancer.

Background Despite adequate neoadjuvant chemotherapy, TNBC remains poor prognosis. Non-responding patient have 25-40% risk of relapse at 5 years. pCR is therefore currently considered as a major goal in TNBC and new tools of early prediction of residual disease should be identified. TransTep is a phase 2 monocentric clinical trial which aims to identify transcriptomic profile of triple-negative cancer cells associated with early tumor chemoresistance, as identified by FDG PET after the first course of neoadjuvant chemotherapy. Twenty patients were included between January 2015 and October 2017, with stage II or III of the UICC classification (except stage T4d). All patients received neoadjuvant chemotherapy with anthracyclines and taxanes sequentially, none of them had a dose-dense chemotherapy. Six patients obtained metabolic response (Delta SUV < -30%) after one cycle of anthracycline. Methods Total RNA was extracted from biopsies (HES > 30%) and used to prepare libraries thanks to TruSeq RNA library Prep kit (Illumina) and sequenced on NextSeq500 device. Results Transcriptomic expression analysis between tumors before chemotherapy and tumors after one course of chemotherapy showed that tumors showing a significant decrease of their Delta SUV (<-30%) had a much higher gene expression variation than tumors with a Delta SUV >-30%. These tumors presented, after one course of chemotherapy, a decrease of cell cycle, DNA replication and Fanconi anemia pathway related genes, while they harbored an increase of genes belonging to immunity related pathways such as natural killer cell mediated toxicity, TH17 cell differentiation, or chemokine signaling pathway. As patients had a surgery after neoadjuvant chemotherapy, we had Chevalier tumor response. As observed with FDG PET data, patients with a good response according to Chevalier (class 1) criteria presented a much higher transcriptomic modification after one course of chemotherapy. Patients with a little gene

expression modification were classified as Chevalier 3. When we focused on pathways impacted by chemotherapy in tumors classified as Chevalier 1, we observed a significant decrease of cell cycle, DNA replication and DNA repair pathways related gene after one course of chemotherapy, whereas a high number of genes belonging to immunity related genes (NK cells, antigen processing and presentation, or chemokine signaling pathway) were increased. Conclusion Our results tend to indicate that transcriptomic tumor response after one course of chemotherapy could forecast final response to treatment. Moreover, it seems that one cycle of anthracycline-based chemotherapy is able to get hot some breast tumors, and that this tumor warming could be a marker of good response to the full treatment. In the following months, we will test whether transcriptomic could predict progression free survival and/or overall survival of patients. We will also look for the best early marker of response between PET FDG and tumor transcriptomic modifications. Based on these results, a new trial will be organized. A therapeutic adaptation depending on the transcriptomic or metabolic data will be proposed to increase pCR rate and prognosis of patients. Moreover, with years and therapeutic innovations, patient management obviously evolves. This was recently the case with a new standard of care in triple negative breast cancer with combination of platinum salt and immunotherapy. Therefore, a new trial, similar to TRANSTEP, will be carried out with this new standard of care.

Currently, the standard of care for luminal metastatic breast cancer is the combination of cyclin inhibitors with hormone therapy. Palbociclib and Ribociclib have been approved for marketing since 2017 and Abemaciclib since 2019 in Spain. In our center we have experience with the three cdk 4/6 inhibitors in different lines of treatment and patient profiles. We gather in the present work the unicentric experience with the three icdk 4/6. We have collected a total of 152 patients treated with the different cyclin inhibitors, achieving median PFS of 32.1 months for Palbociclib, 28.6 months for Ribociclib and 18.4 months for Abemaciclib. Overall survival data is still immature. The context of the patient and the disease has a significant impact on the results, as well as the line of treatment used. The toxicity profile of the three drugs does not differ from what the registry trials describe, with neutropenia being the most common side effect. We also describe dose reductions produced by the three icdk4/6. Conclusions: This is a real-life study with experience in a single center with the three icdk4/6 currently marketed with a cohort of more than 150 patients. We present data that conform to what was reported by the clinical trials PALOMA, MONALEESA and MONARCH. The data will be updated on the date of the congress for its presentation.

Background Triple negative breast cancer (TNBC) is a heterogeneous disease characterized by at least five molecular subtypes, namely basal like (BL), immunomodulatory (IM), luminal androgen receptor (LAR), mesenchymal (M) and mesenchymal stem like (MSL), associated with distinct gene expression, genomic and tumor microenvironment (TME) profiles. Recent technological advances allow to investigate intratumor geographic heterogeneity ignored by

bulk tumor analyses. Here, we deployed spatial transcriptomics (ST) to interrogate tumor and stroma compartments heterogeneity and assess its association with clinical outcome. Methods Spatial transcriptomics (Visium® Spatial Gene Expression, 10X Genomics) was performed on a retrospective series of 94 case-control TNBC samples matched for known clinic-pathological parameters with available long term outcome. Detailed morphological annotations spanning 11 histomorphological categories were performed by a breast dedicated pathologist assisted by the automated QuPath digital pathology software. Bioinformatic analyses were performed using in house pipelines. Results We investigated the distribution of each morphological category across the five TNBC molecular subtypes. We found that LAR, M and MSL, even though they had less tumor cells, had more patches of very small size ($p < 0.0001$). On the other hand, BL and IM had few large and dense patches. Stroma had an opposite distribution compared to tumor, with LAR and MSL being enriched with stroma ($p < 0.0001$). Tumor infiltrating lymphocytes were specific of the IM ($p < 0.0001$) and to a lesser extent the BL subtype. Normal structures, like fat tissue ($p < 0.008$), lactiferous ducts ($p < 0.03$) and vessels ($p < 0.02$), were more present in MSL and LAR. The differences between the molecular subtypes are mirrored at the level of their cell composition and tumor organization, suggesting the possibility to assess TNBC molecular subtypes from imaging data alone. At the gene expression level, spatial deconvolution analyses revealed the co-existence of tumor and stroma compartments from different TNBC subtypes within a tumor sample of a given subtype as defined by bulk tumor analysis. Interestingly, these different tumor-stroma combinations were associated with prognosis. For example, M tumors associated with MSL stroma seem to have a better prognosis than M tumors with an M stroma ($p = 0.001$). Furthermore, spatial resolution of the gene expression identified 418 individual clusters (median 4 clusters per sample) associated with specific molecular and cellular features highlighting a substantial intra-patient heterogeneity. These clusters were further grouped into 11 ecotypes associated with distinct hallmarks and pathways, including EMT, angiogenesis, DNA repair and immune profiles revealing an important inter-patient heterogeneity beyond TNBC classification. Interestingly, 2 ecotypes were identified within the IM subtype associated with distinct clinical outcome, with ecotype 6 characterized by high EMT, mesenchymal stroma and worse prognosis ($p = 0,021$). Conclusion To our knowledge, this is the largest study demonstrating the substantial intra- and inter-patient heterogeneity characterizing TNBC at an unprecedented level, with differences both in tumor and stroma composition as well as spatial organization and clinical outcome. Our results highlight the need to consider TNBC heterogeneity for patient care and future clinical development including immunotherapy.

Background: It is well known that immunological pathways are relevant for response to classical neoadjuvant chemotherapy as well as combined chemo-immunotherapy. In addition, it has been shown that combined chemo-immunotherapy significantly improves survival, even in the context of only moderate effects on pCR. Due to the window therapy with durvalumab-alone and the option to analyze multiple consecutive biopsies, the GeparNuevo trial offers the opportunity to 1) determine gene expression patterns for pCR and DDFS endpoints 2) identify pathways most relevant for pCR and DDFS 3) identify genes specifically regulated by immunotherapy (comparison of samples pre-and post-window) 4) identify genes specifically regulated by chemotherapy (comparison of samples pre-Tx and after 4 cycles of chemotherapy) 5) identify longitudinal patterns of gene expression by comparison of up to four time points and

6) identify changes in the tumor microenvironment by spatial sequencing of tumor cell and stroma areas. Methods: 292 tumor samples were evaluated by gene expression analysis: 162 pretherapeutic core biopsies, 79 post-window biopsies, 32 biopsies during chemotherapy and 19 biopsies of the residual tumor after therapy. These samples were analyzed by HTG OBP panel targeting 2549 genes which are assigned to 25 different biological mechanisms or cellular pathways. In addition, spatial profiling was compared in a subset of pre-and post-window samples using Nanostring GeoMx spatial profiling system. Endpoints were pCR and DDFS. Results: A total of more than 600 genes were significantly associated with either the pCR or the DDFS endpoint in either the complete GeparNuevo cohort or one of the two therapy arms. Interestingly, there was a large number of predictive or prognostic genes (n=247 for pCR and n=179 for DDFS) in the durvalumab arm, while the number of genes in the placebo arm was considerably lower (n=113 for pCR and n=61 for DDFS). We used existing pathway information for HTG OBP panel to analyze the contribution of different cellular processes to pCR and DDFS signatures in different therapy arms. Immune pathways were particularly relevant for durvalumab signatures (pCR and DDFS), while cell cycle related gene expression patterns were particularly involved in signatures predictive of pCR in both therapy arms. To further assign genes to the cellular response to durvalumab-alone or chemotherapy-alone, we compared gene expression patterns in durvalumab arm before and after the window phase (gene expression patterns induced by one dose of durvalumab) with gene expression patterns in placebo arm before and after 4 cycles of chemotherapy. Further longitudinal alterations were analyzed by comparison of longitudinal samples for 4 different time-points (a: before NACT, n=162; b: after window phase, n=79; c: after 4 cycles, n=31 and d: at surgery, n=19). Using the Nanostring GeoMx spatial RNA profiling system guided by cytokeratine immunofluorescence, we compared areas with high tumor cell content with stromal areas with or without TILs. In combination with the HTG gene expression data, we were able to allocate the changes induced by durvalumab vs chemotherapy to the stromal cell and tumor cell compartment, indicating a re-organization of the tumor-microenvironment. Conclusions: In our analysis, we show that immune gene signatures are particularly relevant for neoadjuvant response to durvalumab as well as prognosis after durvalumab treatment, while proliferation signatures are involved in pCR-signatures after durvalumab as well as chemotherapy. The spatial analysis showed that relevant changes occur in the stromal compartment, indicating a re-organization of the tumor microenvironment. The parallel targeting of immune- and proliferation pathways might explain why a combined immunotherapy-chemotherapy approach is more successful than each single therapy strategy alone.

Background The status of the tumor microenvironment (TME) can profoundly affect the response to immune-based therapies for the treatment of cancer. Results previously reported from the AWARE-1 study in early breast cancer patients demonstrated that pelareorep (pela, an oncolytic reovirus), alone or in combination with checkpoint inhibitor (CPI) therapy, modified the inflammatory state of the TME. We also showed that many of pela's effects on the TME were enhanced by the addition of checkpoint blockade. Here, we report the effect of treatment with pela on selected molecular markers associated with enhanced anti-tumor immunity. **Methods** Newly diagnosed HR+/HER2- early BC patients were enrolled into two cohorts: Cohort 1 (C1): pela + letrozole (n=10); and Cohort 2 (C2): pela + letrozole + atezolizumab (n=10). Pela was intravenously administered on days 1, 2 and 8, 9, and atezolizumab was given on day 3. For this analysis, tumor biopsies (FFPE samples) collected pre-treatment (D1) and on days 3 (D3, prior to the atezolizumab administration) were examined by GeoMx digital spatial profiling (DSP, using Nanostring's Cancer Transcriptome Atlas [CTA]). Moreover, the expression of 770 immune-related genes was analyzed using a specific immune panel (n=20). Gene Set

Enrichment Analysis (GSEA) (version 4.1.0) was used to assess pela-induced activation pathways. Results GeoMx DSP showed that pela therapy significantly activated IFN-gamma signaling and associated interferon response genes from D1 to D3 (Normalized Enrichment Score [NES] = 3.3, p-values < 0.02) in the cytokeratin-positive subset of the tumor samples. GSEA of the immune dataset (730 immune genes + 30 housekeeping genes) from the whole tissue also showed a significant upregulation of IFN-gamma signaling pathway genes (FDR < 25%, p-value < 0.001). Increases were also observed in genes reported to be associated with an enhanced tumor inflammatory signal (TIS) including PD-L1, IDO1, HLA-E and STAT1 (p-values < 0.005). Conclusions These results demonstrate that treatment with pela alters the TME to induce and enhance anti-tumor immunity. This enhancement of anti-tumor immunity may potentiate the TME for CPI therapy.

Background: Understanding breast cancer progression and the relationships among biomarkers in the tumor and tumor microenvironment could go beyond established prognostic markers of breast cancer. Poor response and recurrence may indeed be a consequence of the highly heterogeneous spatial distribution of biomarkers within cancers, and/or the synergistic and antagonistic relationship between co-localized biomarkers. Recently, mechanical and physical microenvironmental signatures have emerged as relevant in determining cancer aggressiveness and invasiveness. This suggests that physical structures in the tumor tissue may drive favorable immune-tumor-stroma cell patterns. However, current assessment of tumor biopsies is limited in the ability to quantify and spatially resolve several different subtypes of cells and biomarkers within tumors. Methods: We developed a 60-marker imaging mass cytometry panel to resolve high-plex spatial patterns of cells, signaling, and microenvironmental biomarkers within tumor tissues. Our panel includes 16 tumor markers, 20 immune markers and 24 microenvironmental markers. We built an innovative computational tool to identify recurring spatial patterns of these markers within the tumor microenvironment, and define the spatial scale of heterogeneity of such patterns. We correlated the results from this spatial analysis to prospectively collected long term clinical outcome variables (e.g. 10 year survival, local and distant recurrence) in primary breast cancers sampled at baseline. Our patient cohort comprised 287 samples of patients treated with surgery and a radiation, chemotherapy, endocrine therapy, or combinations of these post-surgery. Of these, 174 were from patients alive 5 years post diagnosis, and 113 from patients lost to breast cancer deaths. Living patients were evaluated for recurrence, and of these 94% were disease free at the end of the study, while 4% had local recurrence and 2% distant metastasis. Of the dead patients, 59% had local recurrence while 27% had distant metastasis. Results: We investigated first all patients independent of tumor subtype; in this analysis the presence of both endothelial (CD31+) or HLADR+ cells were consistently associated with long term survival. We further investigated the distribution of all 60 markers in Lum A, Lum B, Lum like, Her2+ and triple negative subtypes. Among the results we confirmed the prognostic role of known biomarkers such as p53+ as a biomarker for poor survival in Luminal B. We also identified complex microenvironmental patterns associated with outcome. For example, the presence of PD1+ cells in collagen rich environments were generally associated with long terms survival in Luminal B patients. With our spatial analysis tool we further investigated intra-patient and inter-patient spatial distribution and classified clusters predictive of outcome beyond heterogeneity. We found that beyond the mere positivity of each marker, the spatial distribution and co-localization of different immune, tumor and mechanical markers determines long term outcome in different subtypes. Specifically, we investigated the role of vimentin within different microenvironments and tumor subtypes. We identified the co-localization of hCa9 and vimentin as strongly associated with poor 5 year outcome, independent of tumor subtype. Moreover, in Luminal A patients while the presence of clusters exclusively positive for vimentin was associated with poor survival, vimentin co-expression with β actin and co-localization of XBP1+ cancer cells and immune cells in a collagen matrix was associated with longer survival. Conclusion: These results suggest the importance of mechanics and physics in determining spatial distribution of tumor-promoting and tumor-inhibiting immune cells, offering new avenues of physics-based therapeutic targets.

Background: Immune checkpoint inhibitors (ICIs) targeting the PD-1/PD-L1 axis have emerged as constituting a new pillar for breast cancer; however, they benefit only a subset of patients, and predictive biomarkers are urgently needed. While dendritic cells (DCs) are essential for the orchestration of antitumor immune response, the clinical value of DCs in breast cancer immunotherapy remains unclear. An improved understanding of the functional diversity of DC subsets, as well as their relationship with ICI response, would eventually improve the efficacy of ICIs in breast cancer patients. Objective: We sought to comprehensively characterize DC heterogeneity within the tumor microenvironment, identify distinct DC subsets associated with the response to ICIs, and define clinically applicable predictive biomarkers for ICI therapy. Methods: We performed a comprehensive single-cell RNA sequencing (scRNA-seq) analysis of 53 breast tumors receiving ICIs or chemotherapy in two retrospective studies (NCT03197389 and GSE169246) to identify specific DC populations associated with ICI responsiveness. Next, we harnessed multiplex immunohistochemistry (n = 186), multiparametric flow cytometry of fresh tissues (n = 87), large consecutive transcriptomic datasets (The Cancer Genome Atlas [TCGA] and Fudan University Shanghai Cancer Center [FUSCC]), and in vivo experiments to illustrate the molecular portraits and clinical relevance of the identified DC subsets. Additionally, except for the two scRNA-seq datasets, we leveraged another four independent cohorts (NCT03805399, NCT04613674, NCT04129996, GSE124821) and assessed the clinical utility of the established clinically applicable biomarkers derived from prior analyses to predict response following treatment with ICIs or chemotherapy. Results: By obtaining single-cell transcriptome data of 1,955 high-quality DCs, we identified five distinct DC subpopulations (CLEC9A+, CD1A+, CLEC10A+, CCL19+, and LILRA4+). We then illustrated that a specific CCL19+ DC population, but not whole DCs or other subsets, was associated with ICI responsiveness, particularly in triple-negative breast cancer (TNBC). Mechanistically, a potent CD8+ T-cell response was unleashed, rendering tumors susceptible to PD-1 blockade in vivo and confirming their putative immunomodulatory capacity. This phenomenon was only

observed in CCL19+ DCs but not in CCL19- DCs, indicating CCL19 as a specific marker and could reflect the infiltration and functional phenotype of CCL19+ DCs in breast tumors. Finally, by integrating six independent ICI therapy cohorts, we demonstrated that baseline CCL19 in both tumor and blood could predict better response and survival in TNBC patients receiving ICIs, but not so for chemotherapy. Conclusions: Our results provide important insights into the relationship between the clinical outcome of ICIs and DC heterogeneity at single-cell resolution, support the development of therapies modulating CCL19+ DCs to trigger antitumor CD8+ T-cell immunity, and suggest baseline CCL19 levels as a noninvasive predictive biomarker for patients receiving ICIs, that are potentially applicable in the clinic. In light of these results, we suggest CCL19+ DC modulation as a possible precision immunotherapy approach for cancer patients.

Background: Breast cancer (BC) is one of the cancer types recognized as an obesity-associated disease. Current understandings of molecular mechanisms underlying the BC-obesity connection however largely came from experimental models while systematic investigation of the impact of obesity on BC biology in large patient series is still lacking. The purpose of this study is to discover changes in the transcriptomic profile of primary BC according to patients' body mass index (BMI). Data and Methods: Bulk and single-cell gene expression data from treatment-naïve primary breast tumors from non-underweight patients were retrieved from the MINDACT trial (NCT00433589; N = 1481) and the pre-treatment cohort of the BioKey trial (NCT03197389, N = 36), respectively. Three categories were considered for BMI: lean, overweight and obese. The main analyses focused on the invasive carcinoma of no special type (NST) estrogen receptor-positive/HER2-negative (ER+/HER2-, N_bulk = 735, N_single-cell(sc) = 10) and NST ER-/HER2- (N_bulk = 118, N_sc = 15) subgroups. The bulk expression data was subjected to differential gene expression analyses according to BMI which was adjusted for menopausal status and tumor grade, then followed by gene set enrichment analyses. Clustering and cluster annotation were performed on the single-cell profiling data before differentially expressed genes according to BMI were identified for each of the present cell types. Results: Obesity-associated differences in the transcriptomic profile of breast tumors, which were subtle but potentially indicative of a biological relationship, were revealed by the bulk data. In both investigated subgroups, tumors from obese patients were shown to be enriched in cell cycle hallmarks. In ER-/HER2- tumors, adiposity further increased MYC signaling. We also observed different obesity-associated changes according to the ER status. Among ER+/HER2- tumors, those from obese patients were enriched in hallmarks related to inflammatory response compared to those from lean patients. In contrast, these hallmarks appeared to be enriched in the ER-/HER2- tumors from lean patients. Our investigation of the single-cell data further revealed shifts in the cell composition of tumor tissue and cell type-specific transcriptomic differences according to BMI which were more pronounced than those detected from the bulk data. ER+/HER2- tumors from obese patients have a higher frequency of immunosuppressive and pro-tumoral cell subpopulations such as dendritic cells (DC) enriched in immunoregulatory molecules ($p = .03$), LYVE1+ macrophages ($p = .02$) and myofibroblasts ($p = .03$) than those from lean patients. Overexpression of Cyclin D1 and CD24 was found in cancer cells in ER+/HER2- tumors from obese patients. A reduction in anti-tumor immune responses was evident with downregulation of multiple interferons in CD8+ and CD4+ T cells as well as B cells. We observed in the ER-/HER2- subgroup increased infiltration of plasmacytoid DC ($p = .01$), CCL2+ macrophages ($p = .01$) in tumors from obese versus lean patients, while fibroblasts showed an opposite tendency. Additionally, significant obesity-associated downregulation of major histocompatibility complex (MHC) molecules class I in cancer cells and MHC class II molecules in B cells could be suggestive of deficient antigen presentation and activation of cytotoxic and helper T cells. Conclusion: We highlighted the impact of obesity on the remodeling of tumor and tumor microenvironment which might generally lead to a suppression of anti-tumor immune responses, albeit potentially via diverse

axes according to the ER status. Although investigation on a larger cohort is warranted, our current results suggest that obesity-associated transcriptomic changes in BC could be highly cell type-specific, hence we recommend single-cell approaches in addition to spatial multi-omics analysis to further elucidate the interplay between obesity and BC.

Background Mixed invasive ductal and lobular carcinoma (mDLC) is a rare special subtype (3-6%, ~10,000 cases/annually in US) of invasive breast cancer with elusive pathophysiology. This entity exhibits a mix of ductal-like and lobular-like tumor sub-components within the same tumor. With few seminal studies, mDLC remains poorly understood with little molecular

understanding of its sub-components including their origin and implications on disease evolution, prognosis, and treatment response. With increasing recognition of no special type (NST) and invasive lobular carcinoma (ILC) as distinct diseases with unique biology, it is important to understand whether this mixed entity, and its sub-components are like NST and ILC subtypes or a distinct disease. **Methods** We identified mDLC cases from the UPMC cancer registry. These underwent comprehensive evaluation by a panel of expert pathologists. Three cases (each with a ductal and lobular sub-component on the same FFPE block) were shortlisted. These cases underwent digital spatial profiling (DSP) using Nanostring GeoMX Human Whole Transcriptome Atlas. Briefly, 5um slides were stained using RNAscope morphology marker probes (E-cadherin and PanCK) and GeoMX DSP oligo-conjugated RNA detection probes. Between 3-6 ductal and lobular regions of interest (ROI) per tumor were selected by pathologists. DSP barcodes were cleaved off using UV light and collected into 96-well plate. These underwent library preparation and sequencing. Raw reads were aligned to reference probes to quantify RNA counts. Q3 normalized counts were used in downstream analyses using R version 4.1. Linear modeling was used to assess differentially expressed genes (DEGs). Hypergeometric enrichment tests were used for geneset enrichment. T-tests was used to compare gene expression between two groups. **Results** In total 26 ROIs (14 ductal and 15 lobular) were profiled across the three mDLC FFPE slides. Overall data quality was excellent with > 90% sequencing saturation across profiled ROIs. Principle component analysis and consensus clustering showed that lobular and ductal ROIs clustered separately indicating distinct molecular profiles. Similarly, PAM50 analysis showed that ductal and lobular ROIs within each patient tumor had distinct PAM50 subtypes. To further investigate the molecular differences between ductal vs lobular ROIs, we performed differential gene expression analysis. We identified 38 up-regulated and 78 down-regulated genes in lobular compared to ductal ROIs. To assess whether mDLC sub-components share any molecular similarities to pure counterparts i.e., ILC and NST, we compared mDLC lobular vs ductal DEGs with those from TCGA ILC vs NST comparison. SHROOM1, KLK10 and KLK11 were up-regulated while CDH1, DCD, and CPB1 were down-regulated in both mDLC lobular ROIs and ILC vs mDLC ductal ROIs and NST, respectively. Pathway analysis revealed estrogen response, adhesion, and metabolism related differences between mDLC lobular vs ductal ROIs. Furthermore, key transcription factor signatures enriched in the up-regulated genes in lobular vs ductal ROIs included ESR1, FOXA2, GATA1/2 and AR signatures while those enriched in the down-regulated genes in lobular vs ductal ROIs included RCOR1, MYC, ZBTB7A, NELFE, and SPI1 signatures. **Conclusion and Future Work** Using DSP, we uncovered the molecular heterogeneity of mDLC. We revealed that lobular and ductal sub-components have distinct biology with differences in transcriptional signatures and hormone signaling, adhesion and metabolism related pathways. Our pilot study is the first to shed light on this elusive mixed entity using spatial profiling. Our future work will focus on DNA sequencing of mDLC sub-components to identify sub-component specific driver mutations. Our findings will need further investigation in larger mDLC cohorts to better understand their clinical implications in terms of evolution of this disease and its prognosis.

A Novel Single Cell Model of Tamoxifen Response in Primary Human Breast Tumors Austin Whitman, Hyunsoo Kim, Kamila Wisniewska, Rasha Kakati, Susana Garcia Recio, Hector Franco, Charles Perou, Philip Spanheimer Background: Resistance to endocrine therapy is a primary cause of treatment failure and death in patients with estrogen receptor (ER)-positive breast cancer. Intratumor heterogeneity is associated with resistance to therapy across tumors, and specifically in ER+/HER2- breast cancer, heterogeneity in ER and PR expression is associated with a worse response to endocrine therapy. We hypothesize that subpopulations within and across ER+/HER2- human breast tumors have distinct responses to tamoxifen and that discerning heterogeneity in response will improve understanding of inherent and emerging resistance to endocrine therapy. Methods: We developed an operating room-to-laboratory pipeline immediately after surgical resection for studies using alive tissue. Tissue samples were obtained and single cell suspensions created using physical and enzymatic dissociation. Cells were treated with tamoxifen (10 μ M) or control media for 12 hours in suspension and single cell RNA libraries generated using the 10X Genomics droplet-based kit and sequenced using the

Illumina NextSeq2000. Results: We obtained normal breast tissue from 2 women undergoing reduction mammoplasty and tumor tissue from 10 women with ER+/HER2- invasive breast carcinoma. In tamoxifen treated and control matched pairs, a total of 22,195 cells from normal breast and 94,558 cells from tumor samples were sequenced. Computational analysis using consensus clustering was performed and cell types assigned using canonical correlation. Both tumor and normal samples identified clustering by cell type and not by patient revealing significant variability in cell type abundance between samples. In the normal breast samples, we performed differentially expressed genes (DEG) analysis comparing tamoxifen treatment to control for each cell type (Immune cells, fibroblasts, basal epithelial cells, luminal progenitor cells, and mature luminal cells) and enrichment analysis of up- and down-regulated genes performed. Strong depletion of estrogen induced genes was observed in tamoxifen-treated normal luminal progenitor and mature luminal cells, but not in basal epithelial cells or fibroblasts, demonstrating distinct, subpopulation-specific response to tamoxifen. In the 10 tumor matched pairs, 4 had a high epithelial proportion and tumor cells identified using inferred copy number variation. Tumor cells in 3 of these 4 samples showed significant down regulation of estrogen response genes with tamoxifen treatment. Using scBCSubtype to assign PAM50 subtype to individual tumor cells, the 3 responsive tumors were comprised primarily of LumA cells while the unresponsive tumor was predominantly LumB. Finally, we developed a novel score to quantify responsiveness at the single cell level based on downregulation of estrogen response genes with tamoxifen treatment relative to matched cluster-specific untreated expression. This analysis demonstrated heterogeneity in response to tamoxifen in tumor cells and identified distinct subpopulations of responsive and unresponsive tumor cells to tamoxifen treatment. Conclusion: We developed a novel ex vivo model to determine heterogeneity in therapeutic response to tamoxifen in normal human breast tissue and primary human breast tumors. We demonstrate differences in tamoxifen response by cell type and identify distinctly responsive and resistant subpopulations within human tumors. This provides a foundation to define features of responsive and resistant populations on the individual cell and specimen basis, and should allow us to develop precise, single cell-based predictors of response to endocrine therapy, and to identify genes and pathways driving resistance to therapy.

Introduction: Triple Negative Breast Cancer (TNBC) is an aggressive disease with a poor prognosis that accounts for 10-20% of breast cancer cases worldwide. Intra-tumoral heterogeneity and tumor cell plasticity are thought to contribute to drug resistance in TNBCs. Our work aims to: 1) precisely identify the intra-tumoral heterogeneity in cellular states present within TNBC, and 2) test whether drugs can block or initiate plasticity between subpopulations to improve drug sensitivity. We hypothesize that treatment(s) induce cellular plasticity, thus causing cells to shift into resistant states that persist until treatment is removed. We further hypothesize that these resistant subpopulations give rise to new tumor outgrowths once the treatment stops. Methods: To test this, we are treating TP53^{-/-} Genetically Engineered Mouse Model (GEMM) syngeneic transplant tumors of the basal-like TNBC phenotype with the chemotherapeutic doublet of carboplatin/paclitaxel, and targeted agents implicated in plasticity including the MEK inhibitor trametinib, a chromatin remodeling inhibitor I-BET151, and the

dihydroorotate dehydrogenase inhibitor brequinar. To identify cellular subpopulations and examine their response to treatment, we performed both in vivo and in vitro drug sensitivity testing, as well as gene expression profiling using single cell RNA-sequencing (scRNAseq). Results: We have identified clear intra-tumoral heterogeneity with at least 6 distinct cell states present, including basal, mesenchymal/claudin-low, and proliferative subpopulations in vivo in most TNBC GEMM models. We performed 18 individual scRNAseq experiments on the TP53-/- 2225L GEMM transplant line with the aforementioned treatments and untreated controls in triplicate and compared subpopulation frequencies in treated versus untreated tumors. Notably, treatment with trametinib and brequinar caused the rise of two rare subpopulations (i.e. 1% to 3-4% of total tumor cells) that express genes consistent with previously described drug-tolerant persisters (DTP), which we have called "Epithelial-DTP" (Tacstd2, Krt6a, and Cryab enriched) and "Mesenchymal-DTP" (Snai2 and Sca-1 enriched). A gene signature generated from the Epithelial-DTP subpopulation predicted poor patient outcomes in neoadjuvant chemotherapy treated TNBC patients. Further, in TNBC patient-derived xenografts (PDX), these two DTP subpopulations are also present and induced by treatment to an even greater frequency. Ongoing experiments include the use of fluorescence-activated cell sorting to isolate and functionally test the tumor-initiating capabilities of these two rare cell subpopulations. In addition, many experiments are underway to identify means to therapeutically target these DTP cells, with these results to be presented. Ultimately, identifying these rare drug resistant subpopulations, and identifying means to eradicate them, could vastly improve therapeutic regimens and outcomes for patients with TNBCs.

Background. Homologous recombination deficiency (HRD), induced by germline and somatic BRCA1 or BRCA2 gene mutations (BRCAmut) and by BRCA1 promoter methylation (BRCA1meth), has been associated with better response to platinum agents in both triple negative breast cancer (TNBC) and ovarian carcinoma (OvCa). A major conundrum arising from recent studies is why patients with BRCA1meth cancers do more poorly compared to those with BRCAmut cancers given the biologically equivalent HRD in both states. Here, we address this question by performing detailed genomic analyses of primary TNBC and OvCa cohorts and through patient-derived xenografts (PDXs) and their derivative cell lines. **Methods.** Both new and publicly available cohorts of primary TNBC and OvCa encompassing 499 individuals treated with a combination of platinum and taxane chemotherapy were analyzed by whole genome and transcriptome sequencing as well as limited epigenetic analyses. A cohort of 43 PDX models of TNBC was genomically characterized and responses to both single agent platinum and docetaxel were evaluated in vivo. PDX longitudinal studies were performed to assess the dynamics of BRCA1 methylation following treatment. **Results.** Genomic analyses revealed that BRCA1mut and BRCA1meth cancers share the same pattern of BRCA1-linked genomic rearrangements. Nonetheless, in all four primary cancer cohorts examined we found that patients with BRCAmut cancers, but not those with BRCA1meth cancers, had significantly better response outcomes compared to those with BRCA proficient cancers. A separate analysis of PDX TNBCs with BRCA1 promoter methylation showed that PDXs derived from treatment naïve cancers had complete methylation of the BRCA1 promoter, whereas those derived from post-treatment cancers invariably had only partial methylation. Compared to PDXs with complete methylation, those with partial methylation had a lower response rate to in vivo platinum-based therapy, but not to docetaxel. Using single cell clonal expansions from BRCA1meth PDX models, we confirmed that partial methylation was the result of demethylation of one of the BRCA1 promoter alleles and not of the outgrowth of a non-methylated clone. Exposure of TNBC PDXs with complete methylation to a single course of platinum therapy resulted in the emergence of an unmethylated BRCA1 promoter allele, which associated with an increase in BRCA1 expression. We confirmed that platinum treatment results in progressive loss of BRCA1 methylation and restoration of BRCA1 expression in the clinical setting, by studying the BRCA1 status of a longitudinal series of four TNBC PDX models established from the same patient at different stages of her clinical history. Differential gene expression analysis revealed an increased immune transcriptional signal, especially an elevated M1 macrophage signature, associated with enhanced response to platinum therapy only in patients with BRCA proficient cancers, in both TNBC and OvCa. Integrating both the strength of this cancer immune signature and the presence of BRCA mutations resulted in more accurate predictions of response when compared to either HRD or BRCA status alone. **Conclusions.** These results suggest that unlike BRCAmut cancers, where BRCA deficiency is more genetically stable, BRCA1meth cancers are highly adaptive to genotoxin exposure resulting in demethylation of one allele, recovery of BRCA1 expression and acquired insensitivity to platinum. On the other end, a high immune transcriptional signature identifies patients with BRCA proficient cancers that are more likely to benefit from platinum therapy. Taken together, our study underscores the importance of characterizing molecular heterogeneity to optimize predictive precision in assigning response probabilities in TNBC and OvCa.

Background: While new treatments and improved subtyping schemas are anticipated to improve treatment response in triple-negative breast cancer (TNBC) patients, therapeutic resistance remains a significant challenge. Moreover, there is an urgent need for additional research model systems to study resistance and residual disease in breast cancer, including aggressive subtypes of breast cancer. Organoid culture is a promising technology used for growing breast cancer cells with high efficiency; however, the extent to which treatment resistance can be modeled using this system is unknown. This research used patient-derived organoid cultures in the context of computational analyses of large molecular and clinical datasets to study resistance mechanisms, biomarkers, and alternative treatment strategies to overcome drug resistance in early-stage TNBC. Methods: Organoid cultures were derived from breast tumor samples (taken from lumpectomy, mastectomy, or core biopsy samples), digested to the organoid level using collagenase, and grown in three dimensional cultures using a basement membrane extract and a fully-defined organoid medium (Dekkers et al. Nat Protoc 2021). An evaluation of all available I-SPY2 biomarker data (Wolf et al. Cancer Cell 2022) was performed focusing on genes, proteins, and pathways associated with resistance. These were then used to study whether resistance biomarkers identified in patient tumors are also present in organoids propagated from breast cancer post-treatment residual disease. To this end, bulk RNA sequencing data of organoids were normalized and merged with the TCGA dataset (Hoadley et al. Cell 2018) to enable analysis in a larger context, and immunofluorescence staining of organoids was performed. A high-throughput 386 anti-cancer drug compound screen and subsequent synergy testing with the most promising compounds were performed to identify and predict alternative treatment strategies. Additional assays to explore kinome activity in this organoid model are in progress. Results: A TNBC organoid biobank was established (n=31), which was enriched for inflammatory breast cancer (IBC; n=15), an aggressive form of breast cancer. Most organoids were derived from residual disease after neoadjuvant therapy. Bulk RNA sequencing analysis performed on 10 TNBC organoids revealed 3 subsets that were characterized predominantly by either normal-like/luminal androgen receptor or basal-like features or expressed distinct gene expression profiles, with IBC cases present in all 3 subsets. Intriguingly, the IBC organoids were characterized by higher expression of a number of immune-related signatures, despite an absence of clear immune cells in culture. A residual disease IBC/TNBC organoid resistant to chemotherapy was used to perform the 386-drug compound screen. The organoid model showed resistance to veliparib-cisplatin, consistent with

the expression of gene/protein biomarkers predictive of drug resistance found in I-SPY2 (low PARPi7 levels and high pFOXO1 and pMEK1/2 expression). In addition, the screen identified multiple classes of inhibitors as promising synergistic/additive candidates for overcoming resistance to cisplatin. Conclusion: In this proof-of-principle study, we demonstrated the utility of matching I-SPY2 resistance biomarkers and signatures to residual disease tumor organoid cultures. We show that tumor organoid cultures modeling drug resistance states are a useful complement to existing research models of breast cancer and can be used for compound testing. We have developed a pipeline to propagate residual tumors from patients enrolled in I-SPY2 into organoid cultures to create a broader platform for preclinical drug testing informed by tumor biology with the ultimate goal of enabling faster, more successful translational studies and increased treatment options for resistant disease.

Background: Detection of circulating tumour DNA (ctDNA) in patients (pts) who have completed treatment for early-stage breast cancer is associated with a high risk of future relapse. Identifying those at high risk of subsequent relapse may allow tailoring of further therapy to delay or prevent recurrence. Previous analysis of this cohort showed that tools capable of detecting ctDNA at lower concentrations are needed to increase sensitivity and lengthen the lead time between ctDNA detection and relapse. We compared ctDNA detection via a personalised sequencing assay to dPCR in patients from the cTRAK TN clinical trial. Methods: The cTRAK-TN trial recruited 161 pts into prospective ctDNA surveillance with dPCR, with ctDNA positive pts randomised to 1) CT staging plus pembrolizumab therapy for patients

without relapse or 2) observation. Pts had serial post-treatment surveillance plasma samples collected every 3 months for up to 2 years. Whole exome sequencing (WES) was performed on tumor DNA from FFPE samples to design personalised Residual Disease and Recurrence (RaDaR®) multiplex PCR based NGS assays. Retrospectively, plasma DNA extracted from a minimum of 2mls banked plasma, was sequenced with personalised RaDaR assays, and ctDNA detection identified with a proprietary algorithm. dPCR assays tracked 1-2 mutations, as previously described. Primary endpoint was rate of positive ctDNA detection by 12 months from start of surveillance in both assays. Secondary endpoints were agreement in ctDNA detection between RaDaR and dPCR assays and lead-time between ctDNA detection and disease recurrence. Results: Overall, 147 pts and 241 tissue samples were subject to WES, and RaDaR assays were developed for 142 pts with sufficient plasma for testing. RaDaR assays tracked a median of 47 variants (range 33-56) per patient, and a total of 907 timepoints were analysed (median 6 timepoints per pt, range 1-11). With RaDaR, 39.4% (56/142) patients tested ctDNA positive during follow-up, with a median ctDNA detected level of 0.081% estimated variant allele fraction (eVAF). With dPCR, 35.2% (50/142) pts tested ctDNA positive. The ctDNA detection rate by 12 months from the start of ctDNA surveillance was 36.2% (95% CI; 27.6% – 43.7%) with RaDaR and 29.9% (95%CI; 21.6% – 37.3%) with dPCR. The overall test agreement between RaDaR and dPCR assays was 92.7% (95%CI; 90.7% – 94.4%). From a patient perspective, 58.7% pts were ctDNA negative for both assays, 32.9% ctDNA were positive for both assays and 8.6% presented discrepancies. ctDNA was detected by RaDaR but not by dPCR in 9 pts and it was detected by dPCR but not by RaDaR in 3 pts. Among ctDNA positive pts, 55.2% were first detected positive by RaDaR, 5.2% by dPCR, and 39.6% were detected at the same time-point (test of proportions, $p < 0.001$). The median lead time from ctDNA detection to relapse was 7.1 months (95% CI 5.9 – 15.9%) with RaDaR and 5.7 months (95% CI 3.2% – 7.4%) with dPCR. Conclusion: The RaDaR personalised multi-mutation sequencing assay detected MRD with a longer median lead time prior to relapse, and with higher sensitivity, than dPCR mutation tracking assays. These findings have implications for the choice of ctDNA assay in clinical trials designed to treat patients at the point of MRD detection.

Background: In previous work we leveraged the I-SPY2 trial to create treatment response predictive subtypes (RPS) incorporating tumor biology beyond clinical HR/HER2, to better predict drug responses in an expanded treatment landscape that includes platinum agents, dual HER2-targeting regimens and immunotherapy [1]. We showed that best performing schemas incorporate Immune, DRD and HER2/Luminal phenotypes, and that treatment allocation based on these would increase the overall pCR rate to 63% from 51% using HR/HER2-based treatment selection. The RPS schema has been selected for prospective evaluation in I-SPY2. Using the RPS, one would prioritize platinum-based therapy for HER2-/Immune-/DRD+, immunotherapy for HER2-/Immune+, and dual-anti-HER2 for HER2+ that are not luminal. HER2+/Luminal patients have low response rates to dual-anti-HER2 therapy but may respond better to anti-AKT. However, there is still a considerable 'biomarker-negative' group of resistant cancers (HER2-/Immune-/DRD-) with very low pCR rates to all tested agents, that require a new therapeutic approach. Here we characterize the protein signaling architecture of these tumors to identify new target candidates. Methods: 987 I-SPY 2 patients from 10 arms of the trial were considered for this analysis. All have gene expression, pCR and RPS; 944 have distant recurrence free survival (DRFS) data; and 736 have reverse phase protein array (RPPA) data from laser capture microdissected tumor epithelium. These data – known collectively as the I-SPY2-990 mRNA/RPPA Data Resource - were recently made public on NCBI's Gene Expression Omnibus [GEO: GSE196096]. We focus on HER2-/Immune-/DRD- tumors, applying Wilcoxon and t-tests to identify phosphoproteins that differ between HR+HER2-/Immune-/DRD- and other HR+HER2- tumors; and between TN/Immune-/DRD- and other TNs. The Benjamini-Hochberg (BH) method is used to adjust p-values for multiple hypothesis testing. In addition, the Kaplan-Meier method is used to estimate DRFS. Results: 201/736 I-SPY 2 patients with RPPA data are classified HER2-/Immune-/DRD- (HR+HER2-:

n=138; TN: n=63). Of these, 8.5% (17/201) achieved pCR. Non-responding HER2-/Immune-DRD- had worse outcomes than responders (~75% vs. ~95% DRFS at 5 years). 60/139 phospho-proteins differ significantly between HR+HER2-/Immune-/DRD- and other HR+HER2-tumors (n=122). These tumors are relatively 'cold', in that 90% (54/60) of the phosphoprotein activities characterizing this group are at lower levels than in the overall HR+HER2- population; including immune (e.g. pPDL1, pJAK/STAT) and proliferation (e.g., Ki67, CyclinB1, pAURK) endpoints. Phosphoproteins showing higher levels in this subset include ERBB2 (BH p=1.7E-06), Cyclin D1 (BH p=1.4E-05), pAR (BH p=1.4E-05), and ER (BH p=3E-04). Within the TN subset, only 3/139 phospho-proteins differed significantly between TN/Immune-/DRD- and other TN tumors (n=189). These were all immune-related (pPDL1, pSTAT1, and HLA DR), with lower expression in the TN/Immune-/DRD- group. Conclusion: HR+HER2- and TN patients who are Immune-Low and DRD-Low have very low pCR rates to all tested therapeutics in I-SPY2 including standard chemotherapy, platinum, and immunotherapy. Senolytics (possibly targeting Cyclin D1), HER2low agents, and AR modulators may overcome resistance in HR+HER2-/Immune-/DRD-, whereas an immune activator beyond checkpoint inhibition is suggested for TN/Immune-/DRD- patients. Triple negative breast cancer (TNBC) is associated with poorer prognosis compared to other subtypes of breast cancer due to aggressive metastatic behavior and lack of targeted therapies. Human kinases are a large family of proteins that play critical roles in multiple biological pathways, and aberrant expression or mutations of kinases drive cancer progression and metastasis. Therefore, we applied Mass Spectrometry (MS)-based Kinase-inhibitor pulldown (KiP) technology to profile unique kinase signatures associated with TNBC and prioritize novel regulators for this subtype. Human kinases were captured by a mixture of nine FDA-approved kinase inhibitors, each conjugated separately to sepharose beads to profile all the major branches of the kinome tree. We performed KiP assay in 16 patient-derived xenografts (PDXs) [PMC5379071] consisting of different molecular subtypes of breast cancers. Differential expression analysis identified Death Associated Protein Kinase 3 (DAPK3) as a significantly upregulated kinase in TNBC PDXs which somehow remains understudied. Furthermore, RNA-seq and proteomics data with the same set of PDXs revealed that the upregulation of DAPK3 expression in TNBC was exclusively at protein levels, not RNA levels. Consistently, DAPK3 protein levels were significantly elevated in TNBC cell lines in DepMap dataset. Genomic knockout of DAPK3 in SUM159 and MDA-MB-231 cells dramatically inhibited migration and invasion measured by the transwell assay. We also observed that DAPK3 knockout reduced

the phosphorylation of Myosin Light Chain 2 (MLC2) at T18/S19 site, which was shown to regulate cancer cell invasion [PMC4195943]. DAPK3 belong to DAPK family protein, and has an N-terminus kinase domain with high homology to its family proteins, and a C-terminus leucine-zipper domain. While re-expression of wild-type (WT) DAPK3 cDNA can rescue the migration and invasion phenotype caused by DAPK3 knockout, kinase-dead mutant (D161N) and leucine-zipper-domain-deleted mutant (Δ LZ) cannot rescue the phenotype. Moreover, not only D161N, but also Δ LZ mutant cannot restore the phosphorylation level of MLC2 as DAPK3 WT does. Therefore, both kinase activity and leucin-zipper domain of DAPK3 are critical for the phosphorylation of its substrate MLC2 and thus migration and invasion phenotype. By unbiased Immunoprecipitation-Mass Spectrometry (IP-MS) method, we identified Leucine-Zipper Protein 1 (LUZP1) as one of the strongest interactors of DAPK3. Interestingly, LUZP1 also has a leucine-zipper domain on its N-terminus. Further study showed that DAPK3 binds to LUZP1 via its leucine-zipper domain as expected. Moreover, we observed a tight correlation between DAPK3 and LUZP1 protein expressions in the proteomics data of PDXs and DepMap cell lines (Pearson correlation coefficient is 0.90 and 0.81, respectively). However, the correlation at RNA levels is not significant. Besides, we found that DAPK3 protein stability, but not RNA, is dependent on LUZP1 presence in TNBC cells, strongly implying the roles of LUZP1 on the post-transcriptional regulation of DAPK3. To summarize, we demonstrated that DAPK3, as a novel TNBC-enriched protein, modulates migration and invasion possibly via MLC2 phosphorylation. Both kinase activity and leucine-zipper domain of DAPK3 is necessary for its functionality. We also found LUZP1 is a strong interactor and a potential regulator of DAPK3 in TNBC biology.

Background: Metaplastic breast carcinomas (mBrCAs) are a rare and highly aggressive subtype of triple negative breast cancer, with histological evidence of non-glandular differentiation and frequent activation of the canonical (β -catenin-dependent) Wnt pathway. Our laboratory has reported that CCN6 is expressed in normal mammary epithelium, but CCN6 expression is lost in 68% of spindle mBrCAs. We found mice with mammary epithelial cell-specific conditional deletion of *Ccn6* (MMTV-Cre; *Ccn6*^{fl/fl} mice) develop mammary tumors that recapitulate human spindle mBrCAs, including upregulation of Wnt pathway genes. We investigated if and how secreted CCN6 protein functions in tumor suppression in spindle mBrCA via effects on the canonical Wnt pathway. Methods: To investigate CCN6 binding to the Wnt co-receptors LRP6 and FZD8 proteins, we performed Flag-IPs on MDA-MB231 mesenchymal-like breast cancer cells expressing Flag-CCN6 or vector. Effects of CCN6 on β -catenin subcellular localization and gene and protein expression were studied by IHC, IF, qRT-PCR and immunoblot in human cell lines and MMTV-Cre;*Ccn6*^{fl/fl} tumors. To test effects of recombinant CCN6 on canonical Wnt signaling, we used the Leading-Light Wnt Reporter Assay and also tested CCN6 effects in WNT3A- and WNT10B-mediated Wnt signaling activation and on MDA-MB231 cell invasion. To study β -catenin/TCF function in invasive growth of CCN6-deficient cancer cells, we employed two independent approaches: i) expression of a dominant-negative Tcf4 (dnTcf4) versus control vector in MMTV-Cre; *Ccn6*^{fl/fl} tumor-derived cells; and ii) expression of a constitutively active mutant (S33Y) β -catenin in concert with treatment with recombinant human CCN6 (rhCCN6; 500 ug/ml) versus BSA control. Syngeneic orthotopic mammary tumor transplants of MMTV-Cre;*Ccn6*^{fl/fl} were used in vivo for rescue experiments with i.p. injections of rhCCN6 or BSA. We monitored tumor growth and morphology, and performed IHC to determine β -catenin localization and expression. Results: We found in co-IPs that CCN6 interacts with LRP6 and FZD8 to form a complex that antagonizes canonical Wnt signaling. CCN6 ectopic expression in MDA-MB231 cells led to reduced nuclear and increased membrane localization of β -catenin and decreased invasive growth in vitro. In vivo, CCN6 protein administration to MMTV-Cre; *Ccn6*^{fl/fl} mice reduced tumor growth and was linked to decreased nuclear β -catenin in the tumors. Conclusion: CCN6 antagonizes canonical Wnt/ β -catenin in part by binding Wnt ligands, leading to reduced active β -catenin in the cytoplasm and nucleus. Our data indicate a critical role for β -catenin activation for CCN6-deficient mBrCA tumor phenotypes. In vivo, rhCCN6 protein reduces tumorigenesis in MMTV-Cre; *Ccn6*^{fl/fl} mBrCA tumors, highlighting how CCN6 restoration or β -catenin inhibition could be new therapeutic approaches for mBrCAs.

The importance of the antitumor immune response in triple negative breast cancer (TNBC) is well established. We showed previously that the extent of tumor-infiltrating lymphocytes (TILs) in the residual disease after neoadjuvant chemotherapy is associated with a better prognosis. By analyzing 99 pretreatment samples we discovered that the expression of the transcription factor Hepatic Leukemia Factor (HLF) in tumor cells is associated with lower infiltration of immune cells, leading to bad prognosis. Thereby, the aim of our project is to investigate the cellular and molecular mechanism regulated by HLF to better understand the tumor immune microenvironment, so we can develop better treatment options for patients with TNBC. Analysis of publicly available datasets of TNBC (METABRIC and TCGA) showed that tumors with low levels of HLF correlate with the upregulation of genes involved in biological processes associated with the regulation of immune response and in particular with neutrophils activation. Analysis of HLF expression patterns in these patients indicate that tumors presenting a mesenchymal profile exhibited higher HLF levels than the other TNBC subtypes. To elucidate the mechanism of this phenomenon regulated by HLF and his implication in anti-tumoral immune response, we developed several human TNBC cell lines knock-out or knock-down for our target gene using CRISPR/Cas9 editing technology. Comparison of the transcriptomes showed that the silencing of HLF in some mesenchymal TNBC cell lines lead to the upregulation of components involved in the attraction and activation of neutrophils, including CXCL8 (Neutrophil-activating peptide 1), a major cytokine directly responsible for the attraction of neutrophils in the tumor site. In vitro migration experiments supported these observations since purified blood circulating neutrophils have defective migration capacity that depends on the presence or absence of HLF. Finally, the co-culture of neutrophils with tumor cells silenced for HLF showed us, using a large panel of antibodies by spectral flow cytometry, an activated state of mature neutrophils. In conclusion, our study suggest that HLF plays a fundamental role in the regulation of genes involved in the control of tumoral immune microenvironment through the attraction and the activation of mature neutrophils. These findings have the potential for important implications since they suggest that HLF can be a potential target in treating TNBC.

Title: Drug target activation mapping of matched triple negative primary and axillary LN metastases identifies and links the ER-AR-GR steroid hormone receptor axis with downstream AKT activation Background: Triple negative breast cancer (TNBC) is comprised of heterogeneous subtypes that arise from various molecular alterations that result in TNBC having the poorest overall prognosis. There is growing interest in more sensitive ways to measure estrogen receptor (ER) and HER2 levels in the ER “negative” and HER2 “low/negative” settings, as there are patients with TNBC whose tumors are actually ER and/or HER2 “expressing/active”, and who may benefit from ER- and/or HER2-targeted therapies. Given the limitations of IHC in reliably quantitating ER and HER2 in low (0-1+) expressing tumors, we utilized highly sensitive reverse phase protein array (RPPA) to quantitate expression of these therapeutic targets along with downstream signaling activation mapping in

a unique pilot set of patient-matched primary (P) and axillary lymph node (LN) metastases obtained synchronously. The quantitative expression of steroid hormone receptor expression/activation (ER, glucocorticoid receptor (GR), androgen receptor (AR)) along with their signaling architecture and dynamics were analyzed. Methods: A 12 P-LN paired tumor set was chosen for analysis (N=24). Manual macrodissection was used to enrich for tumor epithelium prior to RPPA analysis that quantitatively measured 155 proteins/phosphoprotein drug targets in key signaling pathways known to be involved in steroid hormone receptor biology and tumorigenesis. Statistical analysis using paired sample t-testing or Wilcoxon rank testing was performed ($p < 0.05$ uncorrected). Results: Protein pathway activation mapping and unsupervised clustering analysis revealed a subset of TNBCs from 3 of the 12 (25%) patients (N=4: 1 LN and 1 P, and one patient-matched LN and P) that was characterized by high relative levels of total ER. Interestingly, these same tumors also had amongst the highest relative levels of both total AR and activated (phosphorylated) GR compared to the rest of the 20 tumor samples. Downstream signaling analysis found significant ($p < 0.05$) activation/phosphorylation of AKT (S473 and/or T308) associated with the ER-AR-GR/steroid hormone activated/"high" TNBC signature compared to the 20 tumors that were steroid hormone "low". Conclusions: Functional protein pathway activation mapping of a unique study set of synchronously obtained TNBC primary and LN metastasis revealed a steroid hormone receptor expression/activation signature of co-incidentally activated/expressed ER, GR and AR, that was also characterized by increased AKT activation ($p < 0.05$). This steroid hormone receptor "activated" signature was not observed to be significantly differentially expressed in LN compared to P tissues in cohort or matched pair analysis, suggesting that this signature may be present as an intrinsic event in the P, and not acquired in LN metastases. Recent data from stage I-III TNBC patients treated in the neoadjuvant setting with an AKT inhibitor¹ revealed that responding TNBC patients had pre-treatment tumor biopsies that were enriched for both high AR expression and high phosphoAKT (S473 and/or T308) levels. If these observations that a subset of TNBCs are steroid hormone receptor "activated" despite being ER "negative" are confirmed in larger study sets, we hypothesize that this subgroup, identified by RPPA analysis of both P and LN metastases, could be potentially sensitive to AKT inhibition in combination with agents that target steroid hormone receptors. 1Shi Z, et al. Functional Mapping of AKT Signaling and Biomarkers of Response from the FAIRLANE Trial of Neoadjuvant Ipatasertib plus Paclitaxel for Triple-Negative Breast Cancer. Background: The interest in cancer stem cells in TNBC is encouraged by the finding that CD44+ /CD24- and ALDH1+ breast cancer stem cells (CSC) are enriched in TNBC and contribute to chemotherapy resistance and aggressive tumor progression (O'Connor et al., 2018; Ma et al. 2014). CD44+ CD24- phenotype can be utilized to determine TNBC patients' prognosis (Shadbad et al., 2021; Wang et al., 2017). CD44 has also been known for its tumor-intrinsic function in TNBC (Kong et al., Cancer Res. 2020). We have reported a functional correlation between CD44+/CD24- cancer stem cells and 3D clonogenic growth in testing rational combinations of PI3K pathway inhibitors and Wnt-beta-catenin pathway inhibitors in TNBC (Aske et al., 2016; 2017). We also reported that doubling down on the PI3K pathway enhances the anti-tumor efficacy of PARP inhibitor in TNBC (De et al., 2014). Hypothesis: We hypothesized that the anti-tumor effect of PI3K pathway targeted drugs in combination with PARP inhibitor will regulate the expression of CSC in TNBC. Methods: To test our hypothesis, we examined the expression of stem cell markers CD44, CD44v6, and CD24 in MDA-MB-231, SUM149, and MDA-MB-468 TNBC cells in vitro and in vivo. IHC for CD44 and CD44v6 was standardized using tumor controls and identified in (1) BC TMAs, (2) TNBC cell lines, and (3) patients from our Avera cohort. FFPE sections of tumors from athymic mice (bearing xenograft tumors) treated with a combination of Apatolisib with Veliparib plus carboplatin were used to test stem cell markers by IHC. Staining was evaluated independently by a pathologist who was unaware of the study design. Mechanism-based in vitro studies were conducted to understand the mode of action of the drugs using flow cytometry and qRT-PCR. Results: CD44 was identified primarily in the membrane and to a lesser extent in the cytosol of tumor cells of BC patients (TMA and Avera cohort), TNBC cell lines, and xenograft-tumors. Apatolisib, in combination with Veliparib plus carboplatin, blocked the growth of established xenograft tumors by 80-90%, with a concomitant decrease in Ki67 levels. Membrane expression of CD44 inversely correlated to tumor sizes which significantly reduced in response to drug combinations. The relationship between the expression of CD44 and CD44v6 is being worked out, which will be presented at the meeting. Significance: Our findings showed that the anti-tumor effect of Veliparib plus carboplatin and Apatolisib effectively blocked the specific CD44v6 CSC population in TNBC xenograft tumors. Our results demonstrate the integral role of the

PI3K-mTOR and the DDR pathways in the control of stem-ness orchestrating anti-tumor actions of PARP inhibitor and mTOR-PI3K dual inhibitors in TNBC.

Triple negative breast cancer (TNBC) is the most aggressive subtype of all breast cancers. However, unlike other breast cancer subtypes, current treatments for TNBC are restricted and this scarcity of viable options is the key contributor to the poorer prognosis. Despite early response, almost all the targeted drugs tested in TNBC eventually fail due to the development of resistance. Patients' data have shown that the expression level of Mediator kinases CDK8 and CDK19 are elevated in TNBC, and that

higher expression of CDK8/19 is correlated with more advanced diseases and worse prognosis. Selective CDK8/19 inhibitor SNX631, when used as a single agent, inhibited the growth of several TNBC cell lines in vitro, cell-derived xenografts (CDXs) as well as patient derived xenografts (PDXs) in vivo, suggesting the potential of targeting CDK8/19 in treating TNBC. We also analyzed the effect of CDK8/19 inhibition on the outcome of treatment with mTORC1 inhibitor everolimus (RAD001), an approved drug for several cancers with mutations of PTEN or PI3KCA. SNX631 exhibited a synergistic effect in combination with everolimus on suppressing TNBC cell growth in vitro. In vivo treatment with everolimus alone achieved a strong tumor growth inhibition in TNBC xenograft models but all the tumors eventually resumed growth, indicated the development of resistance. Significantly, the addition of a CDK8/19 inhibitor prevented the emergence of in vivo everolimus resistance both in CDX and PDX tumors upon treatment for up to 150 days, suggesting a potential for extending remission or even achieving cures in TNBC. Transcriptomic analysis demonstrated that this effect was due to the prevention of transcriptional reprogramming associated with everolimus resistance in tumor cells.

Association between the CARG-BC score and clinical decline after adjuvant chemotherapy in fit older adults with breast cancer: Results from the Hurria Older PatiEnts (HOPE) Prospective Study

Background: We previously developed and validated a risk prediction model for grade 3-5 chemotherapy toxicity in patients age ≥ 65 with early breast cancer, known as the Cancer and Aging Research Group-Breast Cancer (CARG-BC) score. The CARG-BC score is calculated by combining eight clinical variables that classify patients as low, intermediate, and high risk for grade 3-5 chemotherapy toxicity. However, whether this score can also identify individuals most likely to experience a clinical decline after chemotherapy remains unknown. Here, we evaluated the association between the CARG-BC score and decline in health status.

Methods: This is a pre-specified secondary analysis of the Hurria Older PatiEnts (HOPE) with Breast Cancer Study (NCT01472094). This multicenter, prospective cohort study gathered biological and clinical data from women ≥ 65 with stage I-III breast cancer scheduled to receive neo/adjuvant chemotherapy. Health status was measured pre- (≤ 14 days) and post-chemotherapy (≤ 30 days) using a Deficit Accumulation Index (DAI), derived from geriatric assessment data (Cohen et al Cancer 2017). The DAI categorized patients as robust ($0.0 < 0.2$), prefrail ($0.2 < 0.35$), or frail (≥ 0.35). Baseline clinical characteristics, blood biomarkers of inflammation (interleukin-6 [IL-6] and C-reactive protein [CRP]), and CARG-BC scores (classified as low [0-5], intermediate [6-11] or high [≥ 12]) were collected pre-chemotherapy. The population of interest was older women who were clinically fit (defined as robust per the DAI) pre-chemotherapy. The primary outcome was chemotherapy-induced decline in health status, a dichotomized (yes/no) variable defined as a decline in DAI from robust pre-chemotherapy to pre-frail or frail post-chemotherapy. Multivariable logistic regression was used to examine the association between baseline CARG-BC score and chemotherapy-induced decline in health status.

Results: Of 392 women included in this analysis, 316 (80.6%) were clinically fit based on DAI assessment pre-chemotherapy. The median age was 70 (range 65-86), 61.7% had stage II or

III disease, 31% had HR+/HER2+ disease, 22% had HR-/HER2- disease, 36% received an anthracycline, and 74% received prophylactic WBC growth factors. At baseline, 38.7% had low, 53.4% had intermediate, and 7.9% had high CARG-BC scores. Among the 316 clinically fit patients, 80 (25.3%) experienced a decline in health status at the end of chemotherapy. In univariate analysis, we observed that patients with high IL-6 (odds ratio [OR]=2.24, 95% CI: 1.32-3.79, p=0.003), high CRP (OR=1.84, 95% CI 1.10-3.09, p=0.02), and intermediate (OR=3.29, 95% CI 1.72-6.29, p< 0.001) or high (OR=6.29, 95% CI 2.36-16.71, p< 0.001) CARG-BC scores were more likely to experience chemotherapy-induced decline in health status. After adjusting for IL-6 and CRP, patients with both intermediate (OR=3.25, 95% CI 1.68-6.27, p< 0.001) and high (OR=5.17, 95% CI 1.90-14.02, p=0.001) CARG-BC scores had significantly higher odds of experiencing chemotherapy-induced clinical decline as compared to patients with low CARG-BC scores.

Conclusions: In this cohort of older women with early breast cancer who were clinically fit pre-chemotherapy, 25% experienced a decline in health status after neo/adjuvant chemotherapy. Women with an intermediate/high CARG-BC score prior to chemotherapy had 3-5-fold increased odds of experiencing chemotherapy-induced decline in health status independent of baseline clinical characteristics and biomarkers of inflammation. These findings may be useful to clinicians for predicting individual probability of chemotherapy-induced clinical decline and informing treatment decisions in older adults with early breast cancer.

Table 1. Univariate and multivariable association of the CARG-BC score with chemotherapy-induced decline in health status.

	Chemotherapy-Induced Clinical Decline		Univariate		Multivariable	
	Yes (N=80)	No (N=236)	OR (95% CI)	p-value	OR (95% CI)	p-value
CARG-BC score*						
Low (0-5)	14 (19%)	104 (45%)	1.00		1.00	
Intermediate (6-11)	50 (67%)	113 (49%)	3.29 (1.72-6.29)	<0.001	3.25 (1.68-6.27)	<0.001
High (≥12)	11 (14%)	13 (6%)	6.29 (2.36-16.71)	<0.001	5.17 (1.90-14.02)	0.001

Multivariable analysis adjusted for baseline demographic, clinical, and inflammatory levels (IL-6 and CRP); *CARG-BC score is calculated using 8 independent predictors (each assigned weighted points): anthracycline use (1 point), stage II or III (3 points), planned treatment duration > 3 months (4 points), abnormal liver function (3 points), low hemoglobin (3 points), falls (4 points), limited walking (3 points), and lack of social support (3 points). The total CARG-BC risk score is the sum of each point derived from these 8 predictors. Each patient's total CARG-BC score can then be classified into three risk groups: low (0-5 points), intermediate (6-11 points), or high (≥ 12 points).

Health-related quality of life (HRQOL) is an important issue for breast cancer patients and clinicians in the treatment decision process. In addition, older women are more vulnerable due to pre-existing comorbidities and socioeconomic status. This study explored 10-year trajectories of HRQoL in older breast cancer survivors and their predictors using patient-reported outcomes data queried from the Surveillance, Epidemiology and End Results - Medicare Health Outcomes Survey (SEER-MHOS) data resources among Medicare beneficiaries. Older women diagnosed with breast cancer in 1998-2012 and who participated in the surveys before and at least once after diagnosis were included in the analysis. HRQOL was measured using SF-36/VR-12 questionnaire and summarized as Physical Component Summary (PCS) Score and Mental Component Summary (MCS) Score. Latent Class Growth Mixture Modeling was conducted to identify distinct groups of women with a similar trajectory of HRQOL. A total of 1089 women with breast cancer completed surveys an average of 2.6 times (range 2 - 19). The results showed that there were three latent classes of PCS trajectory: high-declining (46% of the sample), mid-declining (37%), and low-improving (17%). Two latent classes of MCS trajectory were identified: high-stable (76%) and low-declining (24%). The univariate analysis showed that age at diagnosis, body mass index, level of education, geographic region, tumor grade, tumor size, and the number of comorbidities were related to PCS and MCS scores. Multivariable multinomial logistic regression analysis identified the number of comorbidities as the most significant predictor for PCS score and level of education as the most significant predictor for MCS score. Future research needs to identify the most common comorbidities that influence HRQOL deterioration in older breast cancer survivors to develop interventions that better the physical HRQOL in patients. Also, interventions that target less educated, underserved patients to improve mental HRQOL.

Introduction: Frailty commonly occurs in older persons, including those with breast cancer diagnoses. Methylmalonic acid (MMA), a metabolite and by-product of propionate metabolism, is known to increase significantly with aging. The relation between MMA concentrations and frailty is currently unknown. Objectives: A cross-sectional study was performed to study the association between baseline serum MMA concentrations and clinical frailty (estimated by G8 screening) in older patients with newly diagnosed breast cancer. Methods: 163 patients ≥ 70 years old with early-stage breast cancer were included (median age 76y). G8 screening and serum sample collection were performed at breast cancer diagnosis before any therapy was administered. MMA concentrations were measured via liquid chromatography with tandem

mass spectrometry (LC-MS-MS). Results: MMA concentrations significantly increased with age ($r_s=0.3$, $p<.0001$) and serum creatinine levels ($r_s=0.5$, $p<.0001$) in this older population. The group with an abnormal G8 ($\leq 14/17$ = 'frail', 48% of patients) had significantly higher MMA levels than the group with normal G8 ($>14/17$ = 'fit', 52%): 250nM vs. 189 nM, respectively ($p=.0002$). Higher MMA concentrations were independently associated with abnormal G8 (Odds ratio, 1.003, 95%CI 1.0 to 1.006, $p=.04$) after adjusting for age and serum creatinine levels. Among the different components of G8, MMA concentrations correlated most with weight loss ($r_s= -0.18$, $p=.02$), mobility ($r_s= -0.23$, $p=.002$), and polypharmacy ($r_s= -0.22$, $p=.005$). Conclusion: Elevated serum MMA concentrations at breast cancer diagnosis are significantly associated, not only with age but also independently with clinical frailty in older patients with early-stage breast cancer. MMA may be further evaluated as a biomarker of frailty in older persons with breast cancer.

Background Reducing acute care use is an important strategy for improving value in cancer care. Patients with cancer are at risk for unplanned Emergency Room (ER) visits and hospitalizations during treatment which can increase the cost of care. Patients enrolled in clinical trials have equal access to supportive care and are treated uniformly according to protocol. While demographic factors such as age, race and number of comorbidities have been associated with increased healthcare utilization, less is known about insurance status, which may be a proxy for structural barriers to outpatient quality care, especially since many unplanned ER visits and hospitalizations are preventable. **Methods** We conducted a retrospective analysis among breast cancer patients over the age of 65 treated on SWOG clinical trials from 2001 to 2019 with trial data linked to Medicare claims. Patients were included if they were enrolled in Medicare for at least 12 continuous months after trial registration. Type of insurance at trial enrollment was classified as Medicare alone, Medicare + Commercial or Medicare + Medicaid. The outcomes – derived from Medicare claims – were healthcare utilization ER visits, hospital stays, and healthcare costs in the first year. Demographic, clinical, and prognostic factors were captured from clinical trial records. Logistic regression was used to examine utilization outcomes and linear regression was used to examine healthcare costs. Regression models were adjusted for age, race, and a study-specific prognostic risk score, and stratified by study and treatment. Costs were analyzed in 2021 US dollars. **Results** In total, N = 1,067 patients were analyzed. Median age was 70 years, 32% of patients had Medicare alone, 64% had Medicare + Commercial, and 4% had Medicare + Medicaid. Overall 29% had one or more ER visits and 22% had one or more hospital stays. There were no differences in outcomes between patients with Medicare alone vs. Medicare + Commercial; these groups were combined. In adjusted analyses, patients on Medicare + Medicaid were statistically significantly more likely to have a hospital stay or ER visit (combined outcome) within 12 months of trial registration (58% vs 34%; OR [95% CI], 2.13 [1.05-4.31], p=.04). Separately, patients on Medicare + Medicaid were statistically significantly more likely to have ER visits (51% vs 27.7%, OR [95% CI], 2.09 [1.05-4.19], p=.04), but not hospitalizations (34.9% vs

20.7%, OR [95% CI], 1.55 [0.74-3.24], $p=.25$) compared to the others combined. Mean costs were higher for patients who had Medicare + Medicaid compared to the others combined, but the differences were not statistically significant (\$43,150 vs. \$37,259, $p = 0.55$), possibly due to the small Medicare + Medicaid sample size. Conclusion Despite participation in a BC clinical trial, patients with Medicare + Medicaid had a two-fold increased risk of unplanned ER visits despite controlling for clinical, demographic and prognostic factors. These findings suggest that access and structural factors may adversely influence utilization outcomes for socioeconomically vulnerable older patients with breast cancer. In conjunction with reducing insurance related barriers to clinical trials, efforts are needed to ensure adequate clinical resources to prevent unplanned use of acute care.

Purpose: Vulnerable Elder Survey (VES-13) is a screening tool used in assessing older vulnerable patients at risk of functional decline. We sought to evaluate how VES-13 tool would impact oncologist referral pattern to geriatricians as our primary outcome. We also sought to better understand how VES-13 scores impacted referral to additional services (allied healthcare), and modification to oncological treatment. **Methods:** A retrospective review of VES-13 questionnaires completed by older women (age 70 or older) with breast cancer referred to the Senior Women's Breast Cancer Clinic (SWBCC) was undertaken. Patients with a VES-13 score of three or greater, who were at significantly higher risk of functional decline, had further retrospective chart review for risk factors that would contribute to functional decline such as Eastern Cooperative Oncology Group (ECOG) score, social supports, and current living situation. The primary and secondary endpoints described above were analyzed through bivariate comparisons and multivariable logistical regression to determine if there was any statistical significance ($p < 0.05$). **Results:** 701 patients completed VES-13 form, of which 235 (33.5%) had a VES-13 score of three or greater. Less than 5% of oncologists documented VES-13 scores in their notes, with less than 5% of patients being referred for geriatric services. Neither VES-13 ($p= 0.900$) nor ECOG ($p= 0.424$) were associated with referral for geriatrics assessment. Referral to allied healthcare services was significantly associated with (ECOG) score (OR 2.24 [1.49-3.37], $p < 0.0001$), while not significantly associated with VES-13 score (OR 0.89 [0.78-1.02], $p= 0.102$). VES-13 (OR 1.23 [1.04-1.45], $p=0.014$) and ECOG (OR 2.37 [1.29-4.37], $p=0.005$) were both associated with modification in oncology treatment (chemotherapy or radiation). **Conclusion:** Approximately one third of our population was at risk of functional decline. VES-13 scores were infrequently mentioned in oncologists notes from their clinical assessments, with very few patients being referred for geriatric assessment. By not collecting and analyzing VES-13 scores, and relying on performance status alone, there is a missed opportunity in assessing for functional decline and reducing potential complications from treatment for our patients. **Keywords:** Allied healthcare professionals; Breast cancer; Frailty; Geriatric oncology; Geriatrics; Multidisciplinary; VES-13.

Background: Due to therapeutic advancements, people diagnosed with metastatic breast cancer (MBC) are living longer. This is particularly true for elderly patients who are often diagnosed with more indolent disease. However, elderly patients have higher rates of comorbidity and are vulnerable to other adverse health outcomes, but the primary care management of patients with advanced cancer may be sub-optimal. Every year influenza results in hundreds of thousands of hospitalizations and tens of thousands of deaths. Guidelines recommend the influenza vaccine annually for those over the age of 65 as well as those with cancer based on studies showing a 40-60% reduction in hospitalizations and death. Patterns of use in patients with MBC is unknown. Methods: A retrospective analysis was conducted using the Surveillance, Epidemiology, and End Results (SEER)–Medicare linked data. Patients were included if they were diagnosed with stage IV MBC from 1/1/2008 – 12/31/2017, were ≥ 65 years of age, and had continuous Medicare enrollment for 12 months prior to diagnosis and at least three months after. Our primary outcome of interest was influenza vaccine use identified via CPT codes and defined as any use, use among patients surviving > 3-years, use among patients surviving >5-years, and repeated vaccine use. We then conducted bivariate analyses using demographic variables, including race, ethnicity, SES, age, and marital status, and clinical factors, including chemotherapy use, ER/PR positivity, and HER2 positivity. A multivariable logistic model was used to identify factors associated with influenza vaccine use in each cohort. Results: We identified 5182 patients with stage IV MBC during the study period that met our inclusion criteria. Overall, the median survival was 21 months and only 44% received at least one vaccination at any time after diagnosis. Within the cohort with the > 3-year survival (n=1864), only 1222 (66%) received an influenza vaccination at least one time and only 54% received the vaccine at least two times during 3 years of follow-up. Among patients with at least five-years of survival (n=763), 73% received at least one vaccination and only 65% received the vaccine at least two times during 5 years of follow-up. In a bivariate analysis in the 3-year survival cohort, we found that black race (47% vs 67%, $p <$

0.001) and Hispanic ethnicity (53% vs 66%, $p=0.026$), compared to white race and non-Hispanic ethnicity, respectively, were significantly associated with decreased vaccine use. The only factor associated with increased use was chemotherapy exposure. A multivariable model found lower odds of influenza vaccine receipt for black patients (OR=0.44, 95% CI 0.30-0.65, $p<0.001$) and Hispanic patients (OR=0.58, 95% CI 0.36-.94, $p=0.026$). Similar findings were found in the 5-year survival cohort. Ongoing landmark analyses will be presented evaluating the impact of vaccination on survival. Conclusions: Over 50% of survivors with MBC do not receive the influenza vaccine after diagnosis. Importantly black and Hispanic patients with MBC are about half as likely to receive the influenza vaccine as white patients. Given the known impact of influenza vaccination in the elderly, improving access to vaccination could be an important strategy to reduce disparities in health outcomes. Our findings demonstrate primary care access disparities amongst the MBC population and indicate a need for educational and policy-based interventions.

Background: In women with hormone receptor-positive (HR+) breast cancer, the risk of distant recurrence and death persists for at least 20 years (y) from diagnosis. The risk of late mortality

in men with HR+ breast cancer has not been reported. The aims of this study were to evaluate long-term risks of breast cancer-specific mortality (BCSM) and non-BCSM in men with stage I-III HR+ breast cancer. In addition, we aimed to identify factors associated with late deaths from breast cancer in men.

Methods: Using data from the Surveillance, Epidemiology, and End Results (SEER) program, we identified men diagnosed with stage I-III HR+ breast cancer between 1990-2008. We used cumulative incidence function to estimate the effect of baseline clinical and pathologic variables including age at diagnosis, stage, tumor size (T), nodal status (N), and tumor grade, on cumulative risks of BCSM and non-BCSM over time. We estimated annual rate of events per 100 person-years. We plotted smoothed hazard estimates over time for BCSM by stage and nodal status. Fine and Gray multivariable regression was used to evaluate the association of pre-selected variables with BCSM, conditional on having survived 5 y.

Results: We included 2,836 patients (pts) with a median follow-up of 15.41 y. Median age at diagnosis was 67 y (IQR 57-76 y). Stage distribution was: 34.5% stage I, 46% stage II, and 19.5% stage III. The table shows risks of BCSM and non-BCSM and annual event rates by stage, N status, and grade. The cumulative risk of BCSM in y 0-20 was 12.4% for stage I, 26.2% for stage II and 46.0% for stage III. In contrast, the cumulative risk of non-BCSM over the same period ranged from 42.8% in stage III to 52.4% in stage I. Of all BCSM events, the proportion that occurred 0-< 5y, 5-< 10y and ≥10y was: For stage I 22.55%, 50% and 27.45%; For stage II 37.58%, 38.93% and 23.49%, For stage III 49.15%, 31.62% and 19.23%; respectively ($p < 0.001$). Among pts with stage II breast cancer, we observed a peak in the risk of BCSM at 6 y with a hazard rate of 3%, followed by a minimal decline in risk thereafter. However, among pts with stage III ($n=554$), and those with N3 ($n=160$), we observed a risk of BCSM that peaked first at 4-5 y (hazard rates: 6.3% and 9.9% for stage III and N3, respectively) followed by a small decline and then peaked again at 11-12 y (hazard rates: 7.5% and 12.7% for stage III and N3, respectively). In adjusted Fine and Gray regression conditional on having survived 5 y, risks of BCSM were higher for pts aged < 50 y vs >64 y (Hazard ratio [HzR] 1.59; 95% CI, [1.17 – 2.16]), grade III/IV vs grade I (HzR 1.85; 95% CI, [1.22 – 2.79]), and stage III vs stage I (HzR 3.93; 95% CI, [2.93 – 5.26]).

Conclusions: In HR+ male breast cancer, risks of BCSM persist for at least 20 y after diagnosis and depend on traditional clinicopathologic factors such as age, tumor stage and tumor grade. Among the relatively small group of men with higher stages of disease, we observed a prolonged risk of BCSM with an early and late peak, which is different from the risk that is reported in women (Leone JP, BCRT 2021). Whether the observed trends in hazards over time reflect biologic differences in tumor characteristics, tumor dormancy, and/or host factors between male and female breast cancer cannot be elucidated from these data. Better adjuvant therapies are warranted to reduce early and late BCSM risks.

Risks of BCSM, non-BCSM and annual event rates in men with stage I-III hormone receptor-positive breast cancer

	N	BCSM							non-BCSM	
		% Event-Free		Annual rate (%)				Cumulative risk (%)	Cumulative risk (%)

PD6-10

PD6-10 The impact of post mastectomy radiation therapy on clinical outcomes of male breast cancer: A meta-analysis of comparative studies

Presenting Author(s) and Co-Author(s):

Philip A. Haddad, MD, MPH, MHA, *Professor of Medicine - Louisiana State University Health Science Center/Overton Brooks VAMC*

Country: United States

Usman Zaheer, MD, *Dr. - Louisiana State University Health Science Center/Overton Brooks VAMC*

Country: United States

Background/Rationale: Male breast cancer accounts for less than 1 percent of all cancer diagnoses in men. Because it is rare, it does not lend itself to large, randomized trials. In general, the approach to the treatment of early, non-metastatic male breast cancer has largely been extrapolated from female breast cancer trials. Specifically, the data on early-stage post mastectomy radiation therapy (PMRT) is limited, and its benefits remain unclear. Objectives: We conducted this meta-analysis to determine the impact of PMRT on clinical outcomes of men with breast cancer. Methods: A review of the medical literature was conducted using online databases. Inclusion criteria consisted of English language, diagnosis of invasive non-metastatic male breast cancer (MBC), comparative studies of PMRT versus none, and studies that reported the incidence of local and distant recurrences as well as survival data in the compared arms. A meta-analysis using the Mantel-Haenszel method for calculating the weighted pooled relative risk (RR) under the fixed effects model. Subsequently, the heterogeneity statistic gets incorporated to calculate the summary RR under the random effects model. Results: Ten retrospective comparative studies with 3912 patients were included and analyzed. Eight studies reported survival data. Six and three studies reported local and distant recurrence incidence, respectively. PMRT did not have an impact on overall survival or distant recurrences. However, PMRT significantly lowered the RR of locoregional recurrences (RR=0.53, 95%CI 0.31-0.92). In addition, when survival was analyzed by TNM stage and N status, PMRT was found to have a significant reduction in RR of death in stage III (RR=0.85, 95%CI 0.75-0.97), N1 (RR=0.77, 95%CI 0.61-0.98), and N2 (RR=0.61, 95%CI 0.49-0.78) disease. Conclusions: This is the first meta-analysis to show that PMRT is associated with a lower relative risk of death in stage III MBC as well as N1 and N2 disease. It also demonstrates a significant reduction in RR of locoregional recurrences. In the absence of randomized clinical trials, it represents the most compelling data supporting the use of PMRT in this MBC patient population.

Introduction Breast cancer is uncommon in men. Almost all male breast cancers are hormone receptor-positive, HER2-negative, although the pathogenesis is not always attributable to an endocrine condition. A few studies have compared biological characteristics or molecular signatures with breast cancers in women. We sought to evaluate whether hormone receptor-related gene expression is different in cancers from men compared to equivalent cancers from women. SET2,3 index measures non-proliferative hormone receptor-related transcriptional activity in the cancer (SET-ER/PR index) and adjusts this for a Baseline Prognosis Index (BPI) that combines the measurements of tumor and nodal stage with a 4-gene molecular subtype (ESR1, PGR, ERBB2, and AURKA). Methods We received aliquots of total RNA from male patients with breast cancer included in the retrospective cohort study of the EORTC 10085/BCG/TBCRC/BIG/NCTN International Male Breast Cancer Program (NCT01101425). SET2,3 assay was performed using the QuantiGene assay (Thermo Fisher) using bead-based hybridization and laser spectroscopy (Luminex). The statistical analyses were performed by the EORTC statistician. The primary objective of the study was the assessment of the prognostic value of the SET2,3 index score in patients with early-stage hormone receptor-positive, HER2-negative male breast cancer, treated with endocrine therapy. Clinical outcomes (recurrence-

free survival – RFS; overall survival – OS) were estimated by Kaplan-Meier curves and secondarily compared using multivariable Cox models adjusted for continuous SET2,3 index, tumor size, nodal status, age, and chemotherapy and radiotherapy use. An exploratory analysis to compare the SET2,3 index scores distribution in female and male breast cancer patients was also performed using results from the same assay performed on cancers from women selected on the same inclusion criteria. Due to the low numbers of male patients treated with neoadjuvant treatment (N=6), this analysis was restricted to patients treated with adjuvant treatment (n=315 male and 660 female). Results Of the 321 male patients with breast cancer analyzed, treated between 1990 and 2010, 211 (65.7%) were categorized as high SET2,3 index score, reflecting a high endocrine activity in the cancer and low risk of recurrence, and 110 patients (34.3%) categorized as being low score, reflecting low endocrine activity and high risk of recurrence. At 5 years, the RFS was 75.0% (95% CI, 67.4-81.1) in the high SET2,3 group versus 60.7% (95% CI, 49.1-70.5) in the low SET2,3 group (HR univariate, 0.49; 95% CI, 0.34-0.70; P< 0.0001). The 5-year OS rate among patients with a high SET2,3 index was 84.3% (95% CI, 45.5-73.8), in contrast of 67.8% (95% CI, 56.6-76.7) in the low SET2,3 group (HR univariate, 0.44; 95% CI, 0.30-0.65; P< 0.0001). SET2,3 was independently prognostic for OS, but not RFS in multivariable Cox models. In patients classified as low SET2,3, the addition of neo/adjuvant chemotherapy to adjuvant endocrine therapy was associated with 5-year OS of 76.0% (95% CI, 59.5-86.4) and in patients who received endocrine therapy alone the 5-year OS was 61.3% (95% CI, 45.5-73.8), an absolute difference of 14.7 percentage points. Overall, we did not observe a difference in the distributions (median, interquartile range) of SET2,3 index between men (2.4, 1.9–2.6) and women (2.3, 2.0–2.7). Conclusion SET2,3 index measurements of endocrine-related transcriptional activity in male patients with breast cancer were not different from measurements in female patients with breast cancer. SET2,3 was prognostic in male breast cancer and our exploratory analysis suggests that chemotherapy might improve the poor prognosis for men with breast cancer that has low SET2,3 index. This study was funded by the Breast Cancer Research Foundation (BCRF).

Leveraging Preclinical Models for Translational Breast Cancer Research

Jeffrey M Rosen, Department of Molecular & Cellular Biology, Dan L Duncan Comprehensive Cancer Center, Baylor College of Medicine, 1 Baylor Plaza, Houston, TX 77030

My laboratory originally begin utilizing mouse models several decades ago to better understand normal mammary gland development. Subsequently we developed genetically engineered mouse models for both prostate and breast cancer. As one of the inaugural members of the NCI Mouse Models of Human Cancer Consortium we were fortunate to collaborate with Daniel Medina at BCM and later with Chuck Perou at the University of North Carolina Chapel Hill on the characterization of spontaneous tumors derived from transplantation of Tp53 null mammary epithelial cells isolated from Balb/c mice into the cleared fat pad of wildtype hosts. This led to the development of a large bank of spontaneous tumors which are representative of several of the subtypes of triple negative breast cancer including the claudin-low subtype. These transplantable syngeneic models have been characterized genomically and with respect to their immune microenvironments. These models first were used in my laboratory to study cancer stem cells, intratumoral heterogeneity and the response to radiation and hyperthermia using gold nanoparticles. Subsequently, in collaboration with Shawn Zhang's laboratory we integrated the immunological characterization of murine syngeneic mammary tumor models with analyses of human breast cancer datasets, and demonstrated a relationship between EMT and myeloid cells, specifically tumor-associated macrophages. We also have leveraged our syngeneic GEM models to define the response to immune checkpoint blockade therapy with emphasis on the myeloid cell environment. In collaboration with colleagues at BCM and MD Anderson these models more recently have been employed to study the effects of diverse classes of therapeutics targeting the spliceosome, the unfolded protein response, and mRNA translation, and to elucidate the importance of replication stress for immune checkpoint blockade therapy. Some of these therapeutics are now in clinical trials. Finally, examples of how these models have been employed for combination treatment with chemotherapy and immunotherapy in both the primary and metastatic setting will be discussed, and how durable treatment responses require targeting both tumors and the tumor-immune microenvironment.

In DESTINY-Breast01 (NCT03248492) and DESTINY-Breast03 (NCT03529110), trastuzumab deruxtecan (T-DXd) demonstrated unprecedented activity in patients (pts) with HER2+ (immunohistochemistry 3+; immunohistochemistry 2+/in situ hybridization+) advanced metastatic breast cancer (mBC), leading to regulatory approvals in several countries for HER2+ unresectable/mBC after a prior anti-HER2-based regimen. DESTINY-Breast02 (NCT03523585) is a phase 3 trial of T-DXd vs treatment of physician's choice (TPC) in patients with centrally confirmed HER2+ mBC previously treated with trastuzumab emtansine (T-DM1). It acts as a confirmatory study for the pivotal phase 2 DESTINY-Breast01 trial. Here we report the primary results of DESTINY-Breast02.

Methods

Pts with HER2+ mBC were randomized 2:1 to receive T-DXd or TPC (trastuzumab + capecitabine or lapatinib + capecitabine) and stratified by hormone receptor (HR) status (HR+/HR-), prior pertuzumab treatment, and history of visceral disease. The primary endpoint of this time-driven primary analysis was progression-free survival (PFS) as determined by blinded independent central review (BICR). The powered secondary endpoint was overall survival (OS). Other secondary endpoints included confirmed objective response rate (ORR) by BICR, duration of response (DoR) by BICR, PFS by investigator assessment, safety, and others.

Results

608 pts were randomized to receive T-DXd (n = 406) or TPC (n = 202). Pts receiving T-DXd and TPC had a median age of 54.2 years (range, 22.4-88.5 years) and 54.7 years (range, 24.7-86.5 years), respectively, with a median of 2 (range, 0-10 and range, 1-8) prior lines of systemic therapy (excluding hormone therapy) in the metastatic setting. Median treatment duration was 11.3 mo in the T-DXd arm and ~4.5 mo in the TPC arm. Efficacy and safety results are shown in the table below. T-DXd significantly improved PFS (HR, 0.36; 95% CI, 0.28-0.45; P <0.000001) and OS (HR, 0.66; 95% CI, 0.50-0.86; P = 0.0021) compared with TPC. Confirmed ORR was 69.7% (14% complete response) with T-DXd and 29.2% (5.0% complete response) with TPC. Grade ≥3 treatment-emergent adverse events (TEAEs) occurred in 52.7% and 44.1% of pts receiving T-DXd and TPC, respectively. Adjudicated drug-related interstitial lung disease (ILD) occurred in 10.4% of pts with T-DXd vs 0.5% of pts with TPC. In pts receiving T-DXd, most ILD cases (88.1%) were grade 1/2 and grade 5 ILD was reported in 2 (0.5%) pts.

Conclusions

Results from DESTINY-Breast02 confirmed the clinical benefit and superiority of T-DXd over

conventional chemotherapy-based regimens in pts with HER2+ mBC previously treated with T-DM1, as evidenced by significant and clinically meaningful improvements in PFS and OS. These data, together with earlier reported results from the DESTINY-Breast03 study of T-DXd vs T-DM1 solidify T-DXd as an optimal treatment option in pts with progressive HER2+ mBC across broad settings.

Editorial Acknowledgment

Under guidance of the authors, assistance in medical writing and editorial support was provided by Caylin Bosch, PhD, of ApotheCom, and was funded by Daiichi Sankyo.

Funding

This study was funded by Daiichi Sankyo and AstraZeneca.

Table. Summary of Efficacy and Safety Results for T-DXd and TPC in Patients With HER2+ mBC Previously Treated With T-DM1

Table. Summary of Efficacy and Safety Results for T-DXd and TPC in Patients With HER2+ mBC Previously Treated With T-DM1 (Data cutoff: June 30, 2022)

	T-DXd	TPC
Efficacy	N = 406	N = 202
mPFS by BICR, months (95% CI)	17.8 (14.3-20.8)	6.9 (5.5-8.4)
HR (95% CI)	0.36 (0.28-0.45); <i>P</i> < 0.000001 ^a	
mPFS by investigator, months (95% CI)	16.7 (14.3-19.6)	5.5 (4.4-7.0)
HR (95% CI); <i>P</i> -value	0.28 (0.23-0.35); <i>P</i> < 0.000001 ^a	
mOS, months (95% CI)	39.2 (32.7-NE)	26.5 (21.0-NE)
HR (95% CI); <i>P</i> -value	0.66 (0.50-0.86); <i>P</i> = 0.0021 ^a	
Confirmed ORR, % (95% CI) ^b	69.7 (65.0-74.1)	29.2 (23.0-36.0)
	<i>P</i> < 0.0001 ^a	
mDoR, months (95% CI) ^b	19.6 (15.9-NE)	8.3 (5.8-9.5)
Median follow up, ^c months (range)	21.5 (0.1-45.6)	18.6 (0-45.7)
Safety, n (%)	N = 404^d	N = 195^d
Any grade TEAEs	403 (99.8)	185 (94.9)
Grade ≥3	213 (52.7)	86 (44.1)
Serious TEAEs	103 (25.5)	46 (23.6)
TEAEs associated with:		
Drug interruption	183 (45.3)	90 (46.2)
Dose reduction	102 (25.2)	89 (45.6)
Drug discontinuation	80 (19.8)	19 (9.7)
Death	11 (2.7)	7 (3.6)

^aTwo-sided.

^bBased on blinded independent central review.

^cMedian follow up for a patient is defined as the date last known alive minus date of randomization plus 1.

^dOf 608 randomized patients, 404 and 195 received ≥1 dose of T-DXd and TPC, respectively.

Background

Trastuzumab deruxtecan (T-DXd) is approved in the United States and European Union for use in patients (pts) with HER2+ unresectable/metastatic breast cancer (mBC) after ≥ 1 prior anti-HER2 regimen(s). Approval was based on the randomized, multicenter, open-label, phase 3 DESTINY-Breast03 study (NCT03529110), in which T-DXd demonstrated statistically significant and clinically meaningful improvement in progression-free survival (PFS) compared with trastuzumab emtansine (T-DM1). At the primary interim analysis (data cutoff May 21, 2021), the risk of disease progression or death was reduced by 72% with T-DXd ($P < 0.001$; Cortes et al. *N Engl J Med* 2022). Overall survival (OS) data were immature for both treatment groups; although the prespecified cutoff for significance was not reached (NR), a trend toward benefit with T-DXd was observed. With further follow-up, we report results from the prespecified OS analysis of DESTINY-Breast03 (data cutoff July 25, 2022), including updated efficacy and safety.

Methods

Pts with HER2+ mBC previously treated with trastuzumab and a taxane in either the metastatic setting or (neo)adjuvant setting with progression within 6 mo of therapy, who could have

received pertuzumab, were randomly assigned 1:1 to receive T-DXd 5.4 mg/kg every 3 weeks (Q3W) or T-DM1 3.6 mg/kg Q3W until disease progression. The primary endpoint was PFS by blinded independent central review (BICR). The key secondary endpoint was OS (80% powered at 2-sided significance level of 5%); other secondary endpoints included objective response rate (ORR), duration of response (DoR), PFS based on investigator assessment, and safety.

Results

524 pts received either T-DXd (n = 261) or T-DM1 (n = 263). As of the updated data cutoff, median duration of study follow-up was 28.4 mo (range, 0.0-46.9 mo) for T-DXd and 26.5 mo (range, 0.0-45.0 mo) for T-DM1. Median treatment duration was 18.2 mo (range, 0.7-44.0 mo) for T-DXd and 6.9 mo (range, 0.7-39.3 mo) for T-DM1. The risk of death was reduced by 36% (HR, 0.64; P = 0.0037) with T-DXd; median OS (mOS) was NR (95% CI, 40.5 mo-not evaluable [NE]), with 72 (27.6%) OS events, for T-DXd vs NR (95% CI, 34.0 mo-NE), with 97 (36.9%) OS events, for T-DM1. Landmark 12-mo OS rate was 94.1% (95% CI, 90.4-96.4) for T-DXd vs 86.0% (95% CI, 81.1-89.8) for T-DM1; 24-mo OS rate was 77.4% (95% CI, 71.7-82.1) for T-DXd vs 69.9% (95% CI, 63.7-75.2) for T-DM1. The P value for OS crossed the prespecified boundary (P = 0.013) and was statistically significant. mPFS by BICR was 28.8 mo (95% CI, 22.4-37.9 mo) with T-DXd, compared with 6.8 mo (95% CI, 5.6-8.2 mo) with T-DM1; HR, 0.33; nominal P < 0.000001. Key efficacy and safety results are shown in the table. Grade ≥ 3 treatment-emergent adverse events were experienced by 56.4% of T-DXd-treated pts and 51.7% of T-DM1-treated pts. Drug-related interstitial lung disease/pneumonitis, as evaluated by an independent adjudication committee, was experienced by 39 pts (15.2%) in the T-DXd arm and 8 pts (3.1%) in the T-DM1 arm; no adjudicated drug-related grade 4 or 5 events were observed in pts who received T-DXd.

Conclusions

Updated results confirm the superiority of T-DXd compared with T-DM1 for pts with HER2+ mBC previously treated with an anti-HER2 therapy, with highly clinically meaningful and statistically significant benefit in OS and PFS and a manageable safety profile with longer treatment duration.

Editorial Acknowledgment

Under the guidance of authors, assistance in medical writing and editorial support was provided by Laura Halvorson, PhD, and Rachel Hood, PhD, of ApotheCom, and was funded by Daiichi Sankyo.

Funding

This study was funded by Daiichi Sankyo and AstraZeneca.

Table. Summary of Efficacy Results for T-DXd and T-DM1

Table. Summary of efficacy and safety results for T-DXd and T-DM1

	T-DXd N = 261	T-DM1 N = 263
Efficacy		
OS HR (95% CI); <i>P</i> value	0.64 (0.47-0.87); 0.0037 ^a

Background

Although patients (pts) with hormone receptor-positive (HR+)/HER2-negative breast cancer (BC) frequently experience disease response to neoadjuvant therapy, fewer than 10% achieve a pathologic complete response (pCR) with standard chemotherapy or endocrine therapy, even in combination with CDK4/6 inhibitors. Thus, finding more effective therapies for this disease remains an unmet need. HER2 is expressed at a low level (IHC 1+ or 2+) in approximately 60-70% of HR+ BC. Trastuzumab deruxtecan (DS-8201a, T-DXd) is a novel HER2-targeting antibody drug conjugate (ADC) that is FDA approved in the US for HER2-positive and HER2-low metastatic BC (with boxed warnings for interstitial lung disease). However, the efficacy of T-DXd in the neoadjuvant setting is not known. The primary objective of TALENT (TRIO-US B-12, NCT04553770) is to evaluate the clinical activity and safety of neoadjuvant T-DXd alone or in combination with endocrine therapy in pts with HR+/HER2-low early BC.

Methods

Men and women with previously untreated, operable invasive early stage, non-recurrent, HR+, HER2-low (IHC 1+ or 2+/ISH- by local or central review) BC measuring > 2 cm were eligible. In stage 1 of clinical trial, participants were randomized 1:1 to receive T-DXd (5.4 mg/kg IV q21 days) alone, Arm A, or in combination with anastrozole AI (1 mg PO QD), Arm B. Originally 6 cycles (cy) were given but in 02/2022, an amendment increased the number of treatment cy

from 6 to 8 for newly enrolled pts, or those who had not yet had surgery. Men and pre/perimenopausal women randomized to Arm B also received a GnRH agonist. Stratification factors were HER2 expression (1+ vs. 2+) and menopausal status (men as postmenopausal). Tumor tissue collected at baseline, cy 1 day 17-21, and at surgery. Breast imaging performed at baseline, cy 2 and pre-surgery/EOT. Primary endpoint is pCR rate (ypT0/is ypN0) at surgery. In stage 1, intent was to randomize 58 pts (if at least 2 pCR occurred in an arm, arm progresses to Stage 2 and an additional 15 pts to be enrolled). Other endpoints include safety, objective response rate (ORR), changes in Ki67 expression, Residual Cancer Burden index, exploratory biomarker analysis, and health-related quality of life. Here we present results from stage 1 of the trial.

Results:

From 09/21/2020 to 10/13/2022, 58 pts were enrolled and treated (29 Arm A, 29 Arm B) in stage 1 of trial. Five pts came off study before completing study therapy (2 after cy 1, 2 after cy 2, 1 after cy 3). As of data cut-off (10/05/2022), 33 pts completed study treatment and have had surgery (17 Arm A, 16 Arm B), 13 are on treatment and 7 are pending surgery; 27 pts completed 6 cy and 13 completed 8 cy. Baseline characteristics were balanced between arms. 19/58 pts were Stage IIA, 26/58 Stage IIB, 12/58 Stage IIIA, and 1/58 Stage IIIB at baseline. 46/58 pts had baseline HER2 expression (from central review) of 1+, 4/58 were 0, 6/58 were 2+, 1/58 had multicentric lesion 1+ and 2+, and 1/58 had a single lesion with 1+ and 2+. In Arm A, 1/17 pt had pCR after 8 cy, 2/17 pts had RCB-I after 6 cy (17.6% RCB 0/1). In Arm B, 1/16 pt had RCB-I after 8 cy (6.3%). The ORR for response-evaluable pts in Arm A was 75% (12/16, 1 CR, 11 PR) and in Arm B was 63.2% (12/19, 2 CR, 10 PR); 1 patient (Arm B) had PD. ILD occurred in 1 pt (1.7%), Gr 2 and resolved 11 days after stopping therapy. Most common treatment-related Grade \geq 3 AEs in Arms A and B, respectively, include hypokalemia (1.7%, 5.2%), diarrhea (3.4%, 3.4%), neutropenia (3.4%, 1.7%), fatigue (1.7%, 3.4%), headache (3.4%, 1.7%), vomiting (3.4%, 1.7%), dehydration (1.7%, 1.7%) and nausea (3.4%, 0%).

Conclusions:

This is the first report of a trial evaluating neoadjuvant T-DXd in HER2 low breast cancer. T-DXd +/- endocrine therapy demonstrates promising clinical activity for pts with HR+ BC. Updated study results will be provided at the time of presentation.

Background: In the metastatic setting, low HER2 expression is associated with clinical benefit from trastuzumab deruxtecan, a HER2-targeting antibody drug conjugates. However, little is known about the biological significance of low HER2 expression in patients with early stage triple-negative breast cancer (TNBC) receiving neoadjuvant therapy (NAT). Methods: Out of 595 patients with stage I-III TNBC enrolled on the prospective ARTEMIS trial (NCT02276443) from 2015-2021, we identified 367 patients with available HER2 immunohistochemistry (IHC) results on pre-NAT tumor tissue (HER2-zero: n=218; HER2-low [IHC 1+, 2+]: n=149). All patients were treated with anthracycline-based NAT. In cases where sufficient pre-NAT tumor tissue were available, additional IHC and/or RNAseq were performed. Differential gene expression (DGE) and pathway analysis were performed using DEseq2. Gene set enrichment analysis (GSEA) was performed using the Hallmark gene sets. Deconvolution analyses were performed using CIBERSORT. We controlled for multiple hypothesis using a false discovery rate (FDR) threshold with the Benjamini-Hochberg method, accepting as significant genes with at least a 2-fold change and < 5% FDR. Results: Table 1 summarizes baseline clinicopathological features of the 367 patients. Compared to HER2-zero tumors, HER2-low

tumors were less likely of metaplastic histology ($p=0.001$), associated with lower Ki67 ($p=0.017$) and were more likely to be androgen receptor (AR)-positive ($p=0.01$). There were no significant differences in tumor-infiltrating lymphocytes (TILs) infiltration and PD-L1 expression between HER2-zero and HER2-low tumors. Among the 226 patients with sufficient pre-NAT tissue for RNAseq, DGE analyses demonstrated upregulation of genes involved in fatty acid metabolism (ACSM1) and steroid hormone metabolism (DHRS2, UGT2B28) in HER2-low tumors compared with HER2-zero tumors. Deconvolution analyses revealed no significant differences between predicted proportions of immune cell subpopulations between HER2-low and HER2-zero tumors. Although rates of pCR were not significantly different between patients with HER2-zero (46%) and HER2-low tumors (40%) ($p=0.34$), non-pCR in patients with HER2-low tumors was associated with increased expression of EREG, which encodes an EGFR ligand, while non-pCR in patients with HER2-zero tumors was associated with downregulation in genes involved in immune response pathways. GSEA further identified the Hallmark allograft rejection (FDR $q=0.001$), interferon gamma response (FDR $q=0.002$), and interferon alpha response pathways (FDR $q=0.007$) as the 3 most significantly downregulated pathways in HER2-zero tumors from patients experiencing a non-pCR relative to HER2-zero tumors from patients experiencing a pCR. Conclusion: In early stage TNBC, low HER2 expression is associated with increased AR expression and upregulation of genes associated with fatty acid and steroid hormone metabolism. Gene expression analyses suggest that drivers of resistance to NAT differ between HER2-low and HER2-zero tumors. Biological differences between HER2-zero and HER2-low tumors exist and may influence future personalized treatment for patients with early stage TNBC.

Introduction: Cyclin-dependent kinase 4/6 inhibitors (CDK4/6i) in combination with endocrine therapy (ET) are the standard first-line treatment for patients with hormone receptor-positive, human epidermal growth factor receptor 2 (HER2)-negative advanced breast cancer (HR+/HER2- aBC). HER2-low BC, which is defined by an IHC score for HER2 of 1+ or 2+ with negative ISH assay, accounts for more than half of all HR+/HER2- aBC cases, and it is associated with remarkable clinical benefit from the novel anti-HER2 antibody drug conjugate (ADC) trastuzumab-deruxtecan. Evidence on the prognostic impact of HER2-low status is controversial in both limited-stage and advanced BC. Here, we sought to investigate the possible prognostic relevance of HER2-low status in a population of aBC patients treated with CDK4/6i plus ET. Methods: We conducted a retrospective-prospective study in six Italian Cancer Centers to investigate the impact of HER2 status (low vs. 0) on the progression-free survival (PFS) and overall survival (OS) of consecutive HR+/HER2- aBC patients treated with

CDK4/6i plus ET (aromatase inhibitors or fulvestrant) as a first-line therapy. In the main study analysis, we considered HER2 status in the last tumor assessment (i.e., primary tumor, or, when available, a metastatic lesion). We also performed a subgroup analysis including only patients with HER2 status evaluation in a metastatic lesion collected before CDK4/6i plus ET therapy initiation. The association between HER2 status (low vs. 0) and PFS or OS was evaluated using log-rank test and Cox regression modeling. Results: We evaluated 767 consecutive HR+/HER2- aBC patients treated with CDK4/6i plus ET between January 2017 and January 2022. Of these, 436 patients (56.8%) received CDK4/6i plus ET as a first-line therapy, and they were included in this analysis. Median age was 63 years (range 27-87), and 362 patients (83.0%) were postmenopausal. The majority of patients were treated with palbociclib (68.3%), while 91 (20.9%) and 47 (10.8%) patients received ribociclib and abemaciclib, respectively. Regarding HER2 status, 269 (62.9%) patients had HER2-low tumors, while 159 (37.1%) patients had HER2-0 neoplasms. HER2-low status was associated with significantly lower PFS when compared to HER2-0 status [median PFS (mPFS) 23.6 vs. 32.3 months, respectively; $p=0.014$]. HER2-low status was also associated with significantly worse OS (mOS 48.7 vs 58.3 months, respectively; $p=0.025$). These results were confirmed in multivariable models adjusting the impact of HER2 status for clinically-relevant covariates, namely estrogen receptor status, Ki-67, age, number of metastatic sites, presence of liver metastases, disease free interval, ECOG Performance Status. In this analysis, HER2-low status, compared with HER2-0 status, was independently associated with worse PFS [adjusted Hazard Ratio (aHR): 1.62; 95% confidence interval (CI): 1.17-2.24; $p < 0.01$] and OS (aHR: 1.74; 95% CI: 1.09-2.76; $p=0.019$). Subgroup analysis conducted in the subset of 256 patients with available metastatic tumor samples collected before CDK4/6i plus ET initiation confirmed that HER2-low status ($n=157$), when compared to HER2-0 status ($n=99$), was independently associated with worse PFS (mPFS 24.5 vs 35.2 months, $p=0.01$; aHR 2.07; 95% CI: 1.28-3.34, $p < 0.01$) and worse OS (mPFS 48.7 vs 72.3 months, $p=0.027$; aHR 3.12; 95% CI 1.44-6.77, $p < 0.01$). Conclusions: This multicenter Italian study revealed that HER2-low status has independent, negative prognostic value in patients with HR+/HER2- aBC treated with CDK4/6i plus ET in the first-line setting. Our results suggest that HER2-low status might be associated with different clinical benefit from standard anticancer therapies in specific clinical settings. The definition of treatment algorithms also taking into account HER2 status is a clinical priority in patients with HR+/HER2- aBC.

Prevalence of HER2-low among Metastatic Breast Cancer Patients and Their Outcomes Compared to HER2 IHC 0 Background: Amplification and/or overexpression of the HER2 gene is detected in approximately 15% to 20% of breast cancer (BC) patients. HER2-targeted therapies improve survival in HER2+ BC. Current HER2 diagnostic tests and thresholds were designed and optimized to predict benefit from HER2-directed therapies. The DESTINY-Breast04 trial demonstrated notable efficacy of HER2 antibody-drug conjugate trastuzumab deruxtecan, in patients whose tumors are not conventionally HER2+, but defined as HER2-low (IHC 1 or 2+ without HER2 amplification). A better understanding of the HER2-low phenotype is therefore of critical importance. Methods: Eligible pts were adults with metastatic HER2 IHC (0,1+,2+/FISH negative) BC seen at MD Anderson between 2006 and 2019. Primary biopsy of the breast was used to test biomarkers. HER2 low was defined as IHC 1+ or 2+ and FISH-negative. HER2-negative was defined as HER2 IHC 0. Multi-covariate logistic regression models were used to evaluate effect of clinical factors on HER2 low status and pCR. Overall survival (OS) was defined as time from diagnosis date until death. Disease free survival (DFS) was defined as time from definitive surgery date until the first local/distant recurrence or death from any cause. Patients alive without events (death for OS, recurrence/death for DFS) were censored at last follow-up date. OS and DFS times were estimated by Kaplan-Meier method. Multivariate Cox proportional hazards regression models were applied to assess effect of covariates of interest on OS and DFS. Results: A total of 3053 early stage and 1203 de novo female BC patients were included in the analysis. The prevalence of HER2 low for early stage patients was 59.3% (1811/3053) and for de novo metastatic disease 59.3% (713/1203). In early stage patients, white race, higher nuclear grade and positive ER status were significantly associated with HER2 low status in multivariate logistic regression. Univariately, pCR rate was significantly associated with negative ER (10.2% in negative vs 2.7% in positive), negative PR (8.6% vs 2%) and negative lymphatic vascular invasion (9.2% vs 2%). Multivariate logistic regression showed ER (p=0.0124), PR (p=0.0439) status and lymphatic vascular invasion (p< 0.0001) were significantly associated with pCR status. With median follow-up of

8.5 years, median OS time was 5.3 years (95% CI: [4.9, 5.4]), 5.4 years and 4.8 years in HER2 low and HER2 0 groups, respectively. In multivariate Cox regression, HER2 low was significantly associated with longer OS (HR=0.87, p=0.008), adjusted for age, race, stage, nuclear grade, lymphatic-vascular invasion and ER/PR status. In patients who received neoadjuvant chemotherapy, adjusted for stage, nuclear grade, ER and PR status and pCR, HER2 low was significantly associated with a longer OS time (HR=0.87, p=0.04). Median DFS time was 1.9 years (95% CI: (1.8, 2.0)). Age, stage, histology, nuclear grade, and ER and PR status were significantly associated with DFS by multivariate Cox regression. Among de novo cases, higher nuclear grade (HR [II vs I]=1.838, p =0.008; HR [III vs I]=1.856, p=0.007) and positive ER status (OR=1.933, p <.0001) were associated with high percentage of HER2 low by multivariate logistic regression. Median OS time was 3.2 years (95% CI: (3.0, 3.5)). By multivariate Cox regression, race, histology, nuclear grade, ER and PR status, and HER2 low status (HR=0.834, p=0.0260) were significantly associated with OS time. Conclusions: In metastatic BC pts, HER2 low status was significantly associated with a longer OS and DFS when compared to HER2 0. Nuclear grade and ER positivity was significantly associated with HER2 low status. Biomarkers on recurrence tumor will be presented. This real world data helps to establish the prevalence of HER2 low and their outcomes for this selective cohort.

Background: About half of all breast cancers exhibit low HER2 expression. Despite lack of ERBB2 amplification, HER2-low tumors respond to trastuzumab deruxtecan (T-DXd), leading to the NCCN recommendation of T-DXd both for patients with HER2+ and HER2-low metastatic breast cancer (MBC). It remains however unclear if HER2-low represents a distinct molecular entity, as compared to HER2-0 MBC. Here, we compare the genomic landscape of HER2-low versus HER2-0 breast cancers in a large, single institution cohort. Methods: We identified consecutive patients with MBC seen at Dana-Farber Cancer Institute between 07/2013 and 12/2020. Patients were included if they had HER2-negative MBC per ASCO/CAP Guidelines and had undergone next generation sequencing (NGS) testing with a targeted, tumor-only platform (OncoPanel). Based on the HER2 status of the specimen tested by NGS, patients were divided into 2 groups: (i) HER2-low if immunohistochemistry (IHC) 1+ or 2+ non-amplified, or (ii) HER2-0 if IHC 0. Mutations of interest detected on NGS were classified as oncogenic using the OncoKB tool and additional annotation. Genomic profiles of HER2-low and HER2-0 tumors were compared using Chi-Square and Kruskal-Wallis tests. To determine genomic event enrichment between the two HER2 groups, logistic regression models were used, accounting for background rate and estrogen receptor (ER) expression. ERBB2 copy counts were calculated for tumors with recorded histology-estimated purities and copy-number segmentation using a simple model of allelic gain/loss. Results: Among 1847 patients with HER2-negative MBC, 1043 underwent NGS testing on a HER2-low (n=489, 47%) or HER2-0 sample (n=554, 53%). Most samples were metastatic (71%, n=743) while 29% (n=300) were from primary tumors. 73% had ductal histology, 13% were lobular and 14% had mixed or other histology. ER expression was enriched among HER2-low vs. HER2-0 tumors (76% vs. 60%; $p < 0.001$). Focusing on the most commonly occurring genetic mutations, no major differences were observed in HER2-low vs. HER2-0 tumors, after correcting for ER status (Table 1). Among all mutational events, any mutation in MPL, CYLD, and MAP3K and oncogenic mutations in TP53 and NF1 were more common in HER2-0, while any mutation in MTOR, RAD21, DNMT3A, and PDGFRA were enriched in HER2-low patients, when controlling for ER status and background mutational rate ($p < 0.05$). However, no mutation reached significance after accounting for multiple hypothesis testing. Similarly, no deep deletion or high amplification CNV events reached significance for either group. Analysis of tumor mutational burden in HER2-low vs. HER2-0 tumors revealed no significant differences (median: 7.26 muts/Mb vs. 7.60 muts/Mb, $p=1.00$), including when accounting for ER status. Finally, among tumors with sufficient tumor purity for ERBB2 copy count analysis (n=374 and 419 for HER2-low and HER2-0, respectively), HER2-low tumors had a significantly higher number of ERBB2 alleles as compared to HER2-0 (< 2 copies, 15.0% vs. 30.9%, 2 copies 67.4% vs. 60.5%, and >2 copies, 17.6% vs. 8.6%; $p < 0.001$ by Kruskal-Wallis). Conclusions: To our knowledge, this is the largest comprehensive genomic analysis of HER2-low MBC to date. In our cohort of patients with HER2-negative MBC, the genomic landscape of HER2-low and HER2-0 tumors did not differ significantly, apart from a higher number of ERBB2 alleles. These data further support the notion that HER2-low, as currently defined, is not a distinct molecular subtype of breast cancer.

Background: Breast cancer with low HER2 expression (HER2-low) is of high clinical relevance because of new therapeutic options with antibody-drug conjugates. We have recently shown in a large cohort from neoadjuvant clinical trials that HER2-low breast cancer has different molecular characteristics as well as different clinical outcomes compared to HER2-zero. Considering the positive correlation between HER2-low expression and hormone receptor positivity observed consistently in many investigations, we have extended our analysis to HR+ tumors from the post-neoadjuvant PenelopeB trial. In PenelopeB, patients with HR+ breast cancer and residual disease after neoadjuvant chemotherapy (NACT) were randomized to post-neoadjuvant palbociclib versus placebo in addition to endocrine therapy. We evaluated the molecular phenotype and clinical outcomes of HER2-low compared to HER2-zero patients. Methods: A total of 1250 patients were randomized, HER2 status was available for 1151 tumors from pretherapeutic core biopsy, determined mainly by local pathology, and from 1213 tumors from the post-NACT sample, determined as part of central pathology. For 1119 patients a paired HER2-status was both available. HER2-zero was defined as IHC0 and HER2-low-positive was defined as IHC1+ or IHC2+/ISH-. Gene expression analysis of 2549 genes using the HTG oncology biomarker panel was performed in 620 pretherapeutic biopsies and 780 post-NACT residual tumor samples, with 539 paired gene expression samples. Breast cancer subtypes were determined using the AIMS approach. Results: In pretherapeutic biopsies, 695 tumors (60%) were HER2-low and 457 (40%) were HER2-zero. A HER2-low status in the biopsy was significantly linked to improved iDFS (HR 0.76 (0.60-0.96; p=0.02). In residual tumors, 632 tumors (60%) were HER2-low and 581 (40%) were HER2-zero, without any prognostic impact of HER2 low status. In addition, a shift of HER2-low-status comparing core biopsy and residual tumor was observed in 415 (37%) of 1119 tumors. 161 (14%) had a shift from HER2-zero to HER2-low and 254 (23%) shifted from HER2-low to HER2-zero. A shift from HER2-zero to HER2-low in the post-NACT samples was significantly linked to reduced iDFS

(HR 1.43 [95%CI 1.01-2.01]), $p=0.04$), compared to HER2-low group, while a shift from HER2-low to HER2-zero was associated with better iDFS compared to HER2-zero group, although not statistically significant ($p=0.17$). We did not observe a significant correlation of HER2-low status and AIMS molecular subtypes. In particular, the HER2-enriched (HER2E) subtype was assigned to only 4.3% of HER2-zero and 3.1% of HER2-low tumors. Significant iDFS differences were observed for HER2-low-status in combination with AIMS subtypes (lumB/basal/HER2E vs. lumA/normL; overall p -value < 0.0001) for both pretherapeutic biopsies and residual tumor. Patients with post-NACT HER2-low tumors had an improved survival in the subgroups of aggressive AIMS subtypes (lumB/basal/HER2E), but not in the less aggressive AIMS subtypes (lumA/normL), with a positive test for interaction ($p=0.02$). For the pre-NACT samples a similar, but non-significant trend was observed. We evaluated a total of 620 core biopsies for differences in gene expression comparing HER2-low and HER2-zero tumors. A total of 417 genes were statistically significantly different, but in a hierarchical clustering there was no clear separation of HER2-low and HER2-zero tumors. Conclusions: In the PenelopeB cohort of HR+ tumors, a HER2-low status in pretherapeutic core biopsies is related to improved disease-free survival, especially for those tumors that have a more aggressive intrinsic subtype. A shift of HER2-low status was observed before and after chemotherapy, indicating an adaptation of the pathway activity to therapy-induced stress, which might become relevant for future diagnostic and therapeutic approaches.

Background: Varying levels of HER2 expression without ERBB2 gene amplification can be detected by immunohistochemistry (IHC) in approximately 60% of all invasive breast cancers (BCs). HER2-low-expressing BCs have recently been shown to respond to novel anti-HER2 antibody drug conjugates. Several studies have demonstrated that HER2-low BCs do not seem

to constitute a distinct clinical and transcriptomic subtype as compared to HER2-0 BCs. Here we sought to define the clinicopathologic features and repertoire of somatic genetic alterations in HER2-low BCs. Methods: We retrieved clinical, pathological, and genomic data of BCs that were subjected to targeted sequencing using the FDA-cleared MSK-IMPACT assay from April 2014 to December 2021. After removing cases where any available biopsy had HER2 3+ and/or positive ERBB2 fluorescence in situ hybridization (FISH), 3608 samples (primary=1347; post-treatment/metastatic=2261) were included. Tumors were classified as HER2-low if they had an HER2 IHC score of 1+ or 2+ with a non-amplified FISH assay and HER2-0 if they had an HER2 IHC score of 0. Somatic mutations and DNA copy number alterations from MSK-IMPACT were analyzed. Multiple testing correction using the Benjamini-Hochberg method was applied to control for the false discovery rate (q). Q values < 0.1 were considered significant. Results: Among 3608 HER2- BCs, 1460 (40%) and 2148 (60%) were HER2-0 and HER2-low, respectively. Hormone receptor (HR) expression was significantly higher in HER2-low than HER2-0 tumors in both primary (781 [68.3%] vs 362 [31.7%]; $p < 0.001$) and metastatic (1031 [60.5%] vs 673 [39.5%]; $p < 0.001$) samples. A higher proportion of HER2-low tumors was found in metastatic than primary samples (59% vs 41%; $p < 0.001$) in this cohort. No difference in histology subtype, tumor grade, disease stage (among primary tumors), mutational signatures, and tumor mutational burden was found overall and when cases were stratified by HR expression. In HR-positive BCs, HER2-0 BCs harbored higher frequency of TP53 (33% vs 25%; odds ratio [OR] 1.49, 95% confidence interval [CI] 1.25-1.78, $q < 0.001$) and CDKN1A (1% vs 0%; OR 17.47, 95% CI 2.48-756.37, $q = 0.02$) alterations than HER2-low BCs. Similar findings were observed in metastatic but not in primary HR-positive BCs. No differences were detected in HR-negative BCs stratified into HER2-low and HER2-0. Given the potential misclassification that exists between IHC HER2-0 and HER2-1+, we then conducted an exploratory analysis splitting the HER2-low group into HER2 1+ and 2+. TP53 alterations remained significantly enriched in HER2-0 compared to HER2-1+ HR-positive tumors (33% vs 24%; OR 1.55, 95% CI 1.28-1.87, $q < 0.001$). In HR-positive BCs, HER2-2+ displayed a higher frequency of genetic alterations in genes encoding for transcription factors, such as MYC (14.2% vs 7.3%; OR 2.09, 95% CI 1.44-3.04, $q = 0.02$) and YAP1 (2% vs 0.3%; OR 6.86, 95% CI 1.7-39.57, $q = 0.1$), and DNA damage response, such as FAM175A (1.6% vs 0%; OR 18.23, 95% CI 2.43-807.73, $q = 0.03$) and BRCA2 (4% vs 1%; OR 3.09, 95% CI 1.49-6.55, $q = 0.1$), than HER2-0 tumors. In HR-negative HER2-2+ tumors, a higher frequency of PIK3CA mutations was observed in comparison to HER2-0 (36.9% vs 19.5%; OR 2.41, 1.4-4.1, $q = 0.1$), overall and in the metastatic setting. Conclusions: HER2-low BCs seem not to represent a distinct pathologic subtype. At the genomic level, however, some differences were identified and these became more conspicuous upon subclassification of HER2 IHC expression into 1+ and 2+. Further investigation into methods that more accurately detect and quantify low levels of HER2 expression in BC samples as well as better characterize the biology behind the HER2-low/ultralow expression is warranted.

Background: Recent groundbreaking work has shown that patients with lower levels of HER2-expression (HER2-low) may benefit from treatment with trastuzumab deruxtecan—an HER2 antibody-drug conjugate FDA-approved for treatment for HER2-positive (HER2+) patients and thus can represent a new molecular subtype. In fact, this HER2-low patient population is enriched with luminal disease but is clinically heterogeneous and outcomes have therefore not been extensively characterized due to the lack of annotated multimodal real-world data (RWD). We used Tempus RWD to identify unique HER2-low subtypes using RNA sequencing and compare outcomes across subtypes. Methods: We retrospectively analyzed 1,545 breast cancer samples from the Tempus database tested with the Tempus xT assay that includes whole-exome capture RNA-seq. Only tumors with known HER2 status determined via immunohistochemistry [IHC] and/or FISH were included. A HER2 RNA gene signature was developed by comparing HER2- (n=464, IHC 0+) and HER2+ (n=161, IHC 3+ or IHC 2+ and FISH+) patients—controlling for HR status—to identify genes associated with HER2 over-expression. This HER2 signature was used to stratify independent HER2-low samples (n=920, determined by IHC 1+ or IHC2+ and FISH-) via hierarchical clustering. Treatment use in this cohort was not assessed. Clusters were subsequently assessed according to clinical, demographic, and molecular factors including PAM50 molecular subtype classification of the RNA signatures. Real-world progression-free survival (rwPFS) was evaluated based on

progression and death captured through manual expert abstraction for a subset of stage 4 patients (n=336) and estimated via Kaplan-Meier analysis. Results: HER2-low patients were clustered according to our HER2 expression signature identifying three distinct molecular clusters (Table 1). Stage and demographic distributions (race, ethnicity, age) were similar across clusters. Of note, cluster 3 (n=186, 20% of the HER2-low population) was significantly enriched in hormone receptor negative (HR-) patients ($p < 1e-5$) and had lower ERBB2 RNA expression ($p < 1e-5$). Interestingly, molecular characterization using PAM50 demonstrated that cluster 3 was predominantly a basal-like subtype, whereas luminal-like samples dominated cluster 1 and 2, and cluster 2 had the largest composition of HER2-like samples (Table 1). Strikingly, cluster 3 stage 4 patients (n=57) had a median rwPFS that was significantly shorter (>12 months) than cluster 1 and 2 stage 4 patients (n=279, HR>1.66, $p < 2e-2$, Table 1). Conclusions: Tempus multimodal RWD reveals that HER2-low breast cancers are comprised of distinct molecular subtypes. In a preliminary analysis, a cluster of HER2-low, predominantly basal-like patients demonstrated dramatically worse outcomes than other clusters. These data further emphasize the importance of using RNA expression to fully characterize clinically relevant subpopulations. Further prospective studies are urgently needed to assess treatment response in this heterogenous emerging HER2-low distinct population.

Background: The emergence of anti-HER2 antibody–drug conjugates (ADCs) gave rise to the concept of HER2-low breast cancer (BC). HER2-low BC, which refers to a subgroup of HER2-negative BC with relatively higher HER2 expression (defined as 1+ or 2+ by immunohistochemistry (IHC) staining, without ERBB2 amplification), represents a rather large part of all BCs. However, the molecular nature and internal heterogeneity of HER2-low breast cancer remain obscure, and little is known about the ethnic differences of HER2-low BC. These limitations prevent us from a more precise patient selection and better drug combination strategies in the era of ADCs. To provide a comprehensive and intensive landscape of HER2-low BCs, we characterized HER2-low BCs both clinically and molecularly, which may help clinicians to achieve a more precise clinical management of these patients. Patients and methods: We established a HER2-low BC cohort (N=441) in early-stage Chinese patients and included HER2-0 (N=114) and HER2-positive (N=181) tumors as auxiliary cohorts to characterize HER2-low breast cancers both clinically and molecularly. Whole-exome sequencing, copy number variation assays, RNA sequencing and isobaric quantitative proteomics were conducted to obtain multiomics data. We compared the clinicopathological and molecular features between HER2-low tumors and other HER2 status subgroups stratified

and not stratified hormone receptor (HR) status to clarify the distinctness of HER2-low BCs. And we analyzed the internal heterogeneity and ethnic difference of HER2-low BCs by characterizing a distinct subgroup of patients with unique driving mechanisms. Results: HER2-low BCs showed different molecular manifestations from HER2-0 BCs in different HR subgroups. In the HR-negative subgroup, HER2-low BCs consisted of more non-basal-like subtypes than HER2-0 tumors (40.0% vs. 9.1%, $P = 0.002$), which was an East Asian-specific phenomenon absent in Western cohorts. Also, HR-negative HER2-low BCs showed significant internal molecular heterogeneity, of which basal-like tumors closely mimicked HER2-0 BCs, whereas non-basal-like tumors were similar to HER2-positive BCs. These non-basal-like tumors were mostly categorized as HER2-enriched and luminal androgen receptor (LAR) subtypes. These molecularly distinct tumors might be driven by frequent mutation in PIK3CA and overexpression of FGFR4 and PTK6, which may also serve as therapeutic targets. These results have also been proved in a triple negative breast cancer cohort we reported previously. In contrast, in the HR-positive subgroup, HER2-low BCs showed no large-scale molecular difference from HER2-0 BCs or internal heterogeneity. However, HER2-low patients showed significantly better distant metastasis-free survival than HER2-0 patients ($P = 0.029$), which might be attributed to the lower loss/deletion levels of 17q11.12 and 17q21.31 in HER2-low breast cancers, in which genes including NF1 and BRCA1 are located. Conclusions: We reported the largest single-center multiomics HER2-low BC cohort in East Asian hitherto, and revealed its molecular nature, internal heterogeneity and ethnic difference. Compared with HR-positive diseases, HER2-low BCs in the HR-negative subgroup were more likely to be a molecularly distinct entity from HER2-0 tumors. Furthermore, HR-negative HER2-low BC also accommodates higher internal heterogeneity, which was ethnicity-specific in our East Asian cohort and may infer a different treatment response. Our work emphasized the need of a more precise stratification within HER2-low BCs and across ethnic groups, which has also been inferred by the results in the subgroup analysis of DESTINY-Breast04 trial.

Background: With the development of novel antibody drug conjugates (ADC), it is increasingly important to understand the changes that occur in cell-surface targets over time from early-stage to metastatic breast cancer. Discordance in HER2 expression per immunohistochemistry (IHC) has been reported between primary and metastatic tumors in patients (pts) with HER2-negative breast cancer defined per ASCO/CAP guidelines, with both gain and loss of expression described. Representation of HR-negative (TNBC) tumors has been limited in these studies, and HER2 status at multiple time points in TNBC has not been described. Here we report changes in HER2 IHC in patients diagnosed with TNBC, using a collection of matched tumor samples over time. Methods: Pts were identified from two sources: 1) an institutional database including all consecutive pts who underwent surgery for stage I-III breast cancer at Dana-Farber/Brigham Cancer Center between 2015-2018, and 2) a prospective research biopsy protocol for pts with known or suspected metastatic breast cancer. Pts were included in the present analysis if they received neoadjuvant chemotherapy (NAC) for stage I-III TNBC (eTNBC), or if they were diagnosed with any stage TNBC and ultimately developed metastatic TNBC (mTNBC). Clinical pathology records were reviewed for HER2 IHC results of samples collected at: initial diagnosis (DX); residual disease (RD) post-NAC, if applicable; and at recurrence (M). HER2 IHC was classified as HER2-0 if HER2 IHC 0, and HER2-low if 1+ or 2+ (and ISH non-amplified). For matched comparisons, if IHC was performed in more than one DX sample (e.g., breast, node), only the breast was considered; if more than one M sample, only the first M biopsy with available IHC was considered. Results: Among 110 pts in this cohort, 101 were initially diagnosed with eTNBC (79 received NAC; 22 underwent surgery as first intervention) and 9 with de novo mTNBC. Median age was 48.7 years (range 19.8-71.6). Among all pts, a total of 292 samples (136 DX, 53 RD, 103 M) had available HER2 IHC scores. When restricting to one sample per time point, HER2-low prevalence was 49/102 (48.0%) in DX breast tumors, 21/53 (39.6%) in RD, and 13/58 (22.4%) in first M samples (with all remaining samples HER2-0, except one HER2 3+ sample). In eTNBC pts, HER2 IHC scores were available for 50 paired DX and RD, and 48 paired DX and M samples. Among 50 pts with paired DX and RD, HER2 IHC was discordant in 56% (28/50) (Table 1). Of the 21 HER2-0 DX tumors, 23.8% (5/21) became HER2-low at RD. Of the 29 HER2-low DX tumors, 51.7% (15/29) became HER2-0 at RD. Among 48 eTNBC pts who recurred and had paired DX and M samples, HER2 IHC was discordant in 50% (24/48) (Table 1). Change from HER2-0 to low was 12.5% (3/24), and from HER2-low to HER2-0 was 66.7% (16/24). Among 9 de novo mTNBC pts, 5 had HER2 IHC available in paired DX breast and M prior to starting therapy; 3 were concordant (IHC 0, n=2; IHC 1+, n=1), one had IHC 0 in DX breast and IHC 2+ in M (liver), one had IHC 1+ in DX breast and IHC 0 in M (node). Conclusions: HER2 IHC classification was discordant in about half of the TNBC cases we examined, with more frequent rates of conversion from HER2-low to HER2-0 in both paired DX/RD post-NAC, and paired DX/M samples. Additional analyses will be presented exploring HER2 IHC changes among multiple metastases per patient. Genomic and molecular analysis, including whole exome sequencing,

RNA sequencing, and methylation profiling, are underway in these samples to further elucidate HER2 evolutionary dynamics.

Title: Epidemiology and Prognosis of HER2-Low Breast Cancer (BC) in the National Cancer Data Base (NCDB) Background: Characterization of HER2 status has focused on HER2 overexpressing BC, which are uniquely sensitive to HER2-directed therapy. However,

approximately 60% of BC traditionally characterized as HER2-negative express low levels of HER2 on immunohistochemistry (IHC). Although these 'HER2-low' cancers are insensitive to traditional HER2 blockade, a recent randomized clinical trial showed that antibody drug conjugates such as trastuzumab deruxtecan (T-DXd) are effective in this population. Given the heterogeneity of low level HER2 expression and the impact of T-DXd on outcomes in this population, further data on the epidemiology and prognosis of HER2-low BC is needed.

Methods: We conducted a retrospective cohort study of patients (pts) in the NCDB diagnosed from 2010 to 2019 with invasive BC classified as HER2-negative, and with HER2 IHC results available. We compared demographics and other clinical characteristics of HER2 0 vs HER2-low (defined as IHC score of 1+ or 2+) cases in this cohort. A logistic regression was used to quantify the independent association of demographic and clinical factors with HER2-low status, and odds ratios (OR) and 95% confidence intervals (CI) were reported. Overall survival (OS) was compared for HER2 0 vs HER2-low by receptor subtype and stage, and a multivariable Cox model was fit to also control for age, race / ethnicity, comorbidity score, treatment facility type, grade, and histologic type. In pts who received neoadjuvant chemotherapy (NAC), a logistic regression was used to determine if pathological complete response (pCR) rate was different between HER2-low and HER2 0 pts. Results: We identified 1,191,389 pts, including 394,937 HER2 0 and 796,452 HER2-low; median follow-up was 54 months with 84.1% of pts surviving. Hispanic and Black pts and pts with higher grade, non-ductal, triple-negative breast cancer (TNBC) and affect minority Hispanic and Black women (table 1). On multivariable analysis, TNBC (odds ratio [OR] 0.48, 95% confidence interval [CI] 0.47 – 0.49), lobular (OR 0.74, 95% CI 0.73 – 0.75) and other non-ductal histology (OR 0.66, 95% CI 0.64 – 0.67) had lower likelihood of HER2-low status. Hispanic ethnicity remained associated with lower likelihood of HER2-low (OR 0.89, 95% CI 0.87 – 0.91), whereas Black race was associated with a slight increased likelihood of HER2-low status (OR 1.06, 95% CI 1.04 – 1.08). In multivariable survival analysis of TNBC patients, HER2-low BC was associated with improved OS for stage 2 (hazard ratio [HR] 0.93, 95% CI 0.90 – 0.96), stage 3 (HR 0.92, 95% CI 0.88 – 0.96) and stage 4 (HR 0.92, 95% CI 0.87 – 0.97) cancer. By contrast, survival analysis of hormone receptor positive cancer showed that HER2-low BC was associated with improved OS only for stage 4 disease (HR 0.96, 95% CI 0.92 – 0.99). In 62,667 pts receiving NAC, HER2-low status was associated with a lower likelihood of pCR (OR 0.88, 95% CI 0.84 – 0.92). Conclusions: HER2-low BC is most frequently HR+ with a ductal histology, and is associated with a lower likelihood of response to chemotherapy but an improved OS, especially for metastatic cases. This lower pCR in the HER2-low population could be explained by a higher proportion of these tumors being HR+. There are racial / ethnic differences in the incidence of HER2-low BC, largely mediated by differences in rates of TNBC, and fewer Black and Hispanic pts will be candidates for therapies targeting low level HER2 expression.

Introduction: Breast cancer has pioneered precision medicine with prognostic and predictive subtypes, defined by immunohistochemistry (IHC). Novel therapeutic strategies have led to the emergence of HER2-Low (H2L) as a new entity, defined as tumors with HER2 IHC score of 1+ (>10% cell stained), as well as those with 2+ (>10% cell stained) with paired negative in-situ hybridization (ISH) assay. H2L has been reported to represent up to half of all breast cancer. Further investigation into the mutational landscape of H2L compared to historical subtypes is needed to understand the clinical and biologic factors driving mechanisms of resistance and to consider post-progression treatment options within H2L populations. Methods: The Caris Life Sciences database was used to identify H2L breast tumors by IHC and CISH and evaluated for mutations detected by DNA next-generation sequencing (NextSeq 592-gene panel or NovaSeq whole exome panel). PD-L1 expression was tested by IHC (SP142 IC \geq 1%). Tumor mutational burden (TMB) was measured by totaling somatic mutations per tumor (high \geq 10 mutations per Mb). Statistical significance was determined using Fisher's-Exact/Mann Whitney/X2 test with Benjamini-Hochberg-correction-adjusted p value (q value) of <0.05 . Results: A total of 19789 breast tumors were included in this study. Using standard definitions, 12480 were defined as hormone receptor positive (HR+), 7309 hormone receptors negative (HRneg), 5564 were TNBC, and 1784 HER2 positive (HER2pos). 4349 cases were also identified as H2L, which included 3403 HR+H2L and 946 HRneg H2L. H2L was 22% (4349/19789) of total population; 27% (3403/12480) of the HR+ population and 12.9% (946/7309) of the HRneg population. Within the H2L tumors, when stratified by HR status, we observed in the HR+H2L tumors an increased frequency of amplifications in CCND1 (15.6% vs 5.0%), FGF3 (13.3% vs 4.7%), FGF4 (13.3% vs 4.2%), FGF19 (14.4% vs 4.7%), ZNF703 (15.6% vs 4.4%), NSD3 (12.9% vs 5.2%), ADGRA2 (13.1% vs 5.3%), FGFR1 (11.7% vs 3.6%) and EMSY (5.2% vs 1.4%) compared to the HRnegH2L tumors. TP53 mutations were strikingly higher in the HRnegH2L group (74.4% vs 25.0%) compared to HR+H2L tumors. Markers of IO response also showed elevated positivity in PD-L1 (39.6% vs 19.5%) however, no difference was detected in TMB-H status in HRnegH2L tumors compared to HR+H2L tumors, all $q < 0.05$. The genomic landscape differed when comparing HR+HER2pos tumors to HR+H2L tumors. Significantly more prevalent alterations in HR+HER2pos included amplifications in RNF43 (4.4% vs 1.4%), RARA (13.6% vs 0.1%), MLLT6 (19% vs 0.0%), MYC (6.1% vs 2.7%), DDX5 (10.1% vs 2.0%), CLTC (10.4% vs 3.3%) as well as TP53 (64.0% vs 25.0%) mutations and PD-L1 expression (26.6% vs 19.5%). Furthermore, mutations in PTEN (2.5% vs 7.8%), MAP3K1 (2.8% vs 7.1%), ESR1 (4.4% vs 14.3%), CDH1 (5.2% vs 16.4%), AKT1 (0.0% vs 4.3%) were elevated in the HR+H2L tumors compared to the HR+HER2pos tumors, all $q < 0.05$. Interestingly, when the HRnegH2L tumors were compared to TNBC subtype differences were seen in the mutation rate of PIK3CA (33.5% vs 16.7%; $q < 0.0001$), a master regulator of cell growth, and tumor suppressor gene TP53 (74% vs 86%). Conclusions: With some exceptions, H2L breast cancer shared genomic features with

its more classically defined subset of either HR+ or HRneg disease. Notable differences in PIK3CA (an actionable mutation) and TP53 (a prognostic alteration) warrant additional assessment, as do amplifications variable between HR+H2L and HR+Her2pos groups. Our findings add tremendously to the current understanding of the molecular profile of the H2L subgroup and comparison to the classically defined breast cancer subgroups. Genomic risk assessments after progression on novel therapeutics will be needed to better define implications for mechanisms of resistance.

Background

Based on the results of the DESTINY-Breast04 study, the HER2-targeted antibody-drug conjugate trastuzumab deruxtecan (T-DXd) and the Ventana PATHWAY 4B5 companion diagnostic were recently approved by the US Food and Drug Administration for the treatment and identification of patients with HER2-low (IHC2+/ISH- or IHC1+) (Modi et al. *N Engl J Med* 2022). The efficacy of T-DXd in HER2-low mBC highlights the need to distinguish lower ranges of HER2 IHC expression, which has been reported to be more challenging than scoring high HER2 expression (Fernandez et al. *JAMA Oncol* 2022). Here we report on current real-world HER2-low interpretation proficiency and the impact of training for participating pathologists in HER2-low scoring.

Methods

Pathologists from laboratories across the US, EU, Japan, Australia, and Brazil were invited to use a digital pathology platform (Pathotrainer) to interpret HER2 digital images using ASCO/CAP 2018 scoring criteria. Two whole-slide imaging sample sets of representative study cases were compiled for Ventana PATHWAY 4B5 or Dako HercepTest (HcT) stained tumors. Another sample set (n = 25) was developed for a 4 hour virtual training session based on the ASCO/CAP 2018 guideline with some practical considerations. A steering committee (SC) of 8 pathology experts was formed to guide the study. Pathologists' score was compared with a reference score as determined by independent review of 3 experts in HER2 pathology. Paired study cases (n = 14) considered challenging due to difficult-to-interpret staining patterns were reevaluated by the SC members. Concordance and efficacy of training were measured by Cohen's weighted kappa (κ) coefficient, overall rater agreement (ORA), and receiver operating characteristic curve statistics. The primary endpoint was real-world concordance and ORA. The secondary endpoints were post-training concordance and ORA and correct identification of HER2 IHC 0 and HER2-low.

Results

Pre-training baseline or real-world scores were taken by 77 pathologists in 14 countries (n = 49 for 4B5, n = 28 for HcT) and 74 pathologists completed post-training scores (n = 48 for 4B5, n = 26 for HcT). HER2 scoring proficiency of pathologists was high for both assays when assessed on ASCO/CAP binary HER2-negative and -positive status, irrespective of training (4B5: κ = 0.96, ORA = 98.9%; HcT: κ = 0.84, ORA = 94.3%) Concordance per ORA for the new 3-tier classification (HER2 IHC 0 vs HER2-low [IHC 2+/ISH- or IHC 1+] vs HER2-positive [IHC 3+ or IHC 2+/ISH+]) was greater than 80% for both assays at baseline and after training (see Table). In a subgroup analysis assessing training effect for 4B5 assay, concordance rates for HER2 IHC 0 were 74.6% at baseline and 89.2% after training (P < 0.001), and for HER2-low, NPA was 80.6% before and 91.1% after training (P < 0.001); there were no statistically significant changes after training for HcT (data not shown).

Conclusions

Results from this real-world global study demonstrate that overall score concordance with a new category of HER2-low was above the 80% ORA benchmark for both 4B5 and HcT and is higher than previously reported (Fernandez et al. *JAMA Oncol* 2022). These data demonstrate pathologists' ability to achieve an acceptable level of accuracy for identifying HER2 IHC 0 and HER2-low patients even after short-term training; however, additional training techniques and

experience are needed to further improve accuracy.

Objectives: The concept of human epidermal growth factor receptor 2 (HER2)-low status has been proposed as a potential treatment target for breast cancers previously considered to be HER2-negative. Defined by an immunohistochemistry (IHC) score of 1+ or 2+ and negative fluorescent in situ hybridization (FISH) for HER2, HER2-low status predicts significant clinical benefit from novel therapeutic compounds in recent clinical trials. The prevalence and clinical implications of HER2-low status in patients with early stage invasive lobular carcinoma (ILC) has not been described. We aimed to describe the clinicopathologic features and prevalence of HER2-low status in ILC, and identify any potential differences in clinical outcome. **Methods:** We evaluated stage I-III ILC tumors from a prospectively maintained institutional database of patients where both IHC and FISH testing for HER2 status was performed as standard clinical care. Tumors were classified as HER2 negative (IHC=0), HER2-low (IHC=1+ or 2+ and negative FISH), or HER2 positive (IHC=3+ or FISH ratio =>2). Data were analyzed in Stata 16.1 using chi-squared tests, t-tests, and Cox proportional hazards models for disease free survival (DFS). **Results:** 666 ILC tumors with available HER2 status were available for analysis. The mean age at diagnosis was 59.8 years (range 21-91). The majority of patients had stage I disease (63.1%) with an average follow up time of 6.7 years (standard deviation [5.4]). Overall, 184 (27.6%) tumors were HER2 negative, 434 (65.1%) were HER2-low, and 48 (7.2%) were HER2 positive. There were no associations between HER2 status and age, menopausal status,

body mass index, tumor stage, grade, presence of lymphovascular invasion, or molecular assay results. Hormone receptor status was significantly associated with HER2 status, with HER2 positive tumors significantly less likely to be estrogen receptor (ER) positive than both HER2 negative and HER2-low tumors (89.6% versus 97.3% and 96.8% respectively, $p=0.03$). HER2-low tumors were also significantly more likely to have progesterone receptor (PR) positivity (86.6% compared to 79.9% of HER2 negative and 72.9% of HER2 positive tumors, $p=0.01$). This difference remained significant when comparing just HER2-low to HER2 negative cases ($p=0.034$). While there were no differences in use of neoadjuvant or adjuvant chemotherapy by HER2 status, HER2-low patients were significantly more likely to undergo mastectomy versus lumpectomy when compared to HER2 negative and HER2 positive patients (53.7% versus 38.0% and 43.8% respectively, $p=0.001$). In a multivariable Cox proportional hazards model adjusting for tumor size, number of positive nodes, ER/PR status, and local therapy received, patients with HER2-low status had worse DFS than those with HER2 negative tumors (hazard ratio 2.0, 95% confidence interval 1.0 - 4.1, $p=0.05$). Conclusions: In this analysis of 666 early stage ILC cases, we found that most tumors were HER2-low, and that those with HER2-low disease were significantly more likely to have PR positive tumors and to undergo mastectomy. When adjusting for these variables, we identified a difference in DFS between HER2 negative and HER2-low early stage ILC. These findings support the contention that HER2-low and HER2 negative disease represent two different clinical entities. Further investigation of the potential benefit of HER2 targeted therapy in ILC, which predominately lacks HER2-amplified disease, is needed to ensure optimal outcomes in this understudied tumor type.

Background: About 60% of breast cancers (BCs) traditionally categorized as HER2 negative (HER2-neg; immunohistochemistry [IHC] 0, IHC 1+ or IHC 2+/in situ hybridization [ISH]-) express low levels of HER2 (HER2-low; IHC 1+ or IHC 2+/ISH-; Schettini, NPJ Breast Cancer 2021). In the phase 3 DESTINY-Breast04 trial (NCT03734029), trastuzumab deruxtecan (T-DXd) showed significantly longer progression-free survival and overall survival (OS) vs physician's choice of chemotherapy in patients (pts) with HER2-low metastatic BC (mBC) who previously received chemotherapy (Modi, NEJM 2022). As HER2-low becomes a clinically relevant HER2 status among pts with BC, greater understanding of pts with HER2-low disease is needed, including identification of these pts using conventional IHC assays. Our objectives were to assess the prevalence of HER2-low among HER2-neg mBC based on rescored HER2 IHC slides, to describe characteristics of pts with HER2-low mBC, and to characterize concordance between historical HER2 scores and rescoring. Methods: This global, multicenter, retrospective study (NCT04807595) included pts with confirmed HER2-neg (HER2 IHC 0, 1+, or 2+/ISH-) unresectable/mBC diagnosed from 2014 through 2017. HER2 IHC-stained slides were rescored after training on low-end expression scoring using Ventana 4B5 and other assays by local laboratories at 13 sites in 10 countries blinded to historical HER2 scores. BCs were categorized as HER2-low (IHC 1+ or IHC 2+/ISH-) or HER2 IHC 0 (IHC 0 or >0< 1+). Prevalence of HER2-low and concordance between historical HER2 scores and rescoring were assessed. Demographics, clinicopathological characteristics, treatment patterns, and outcomes were examined via data from medical charts/health records. Results: HER2 rescoring was obtained for 781 pts with HER2-neg mBC. HER2-low prevalence was 67.1% overall; 71.1% in hormone receptor (HR)-positive (HR+) and 52.5% in HR-negative (HR-) subgroups. There were no notable differences in characteristics (Table) or treatment patterns between pts with HER2-low and HER2 IHC 0. The most frequent therapies used in the first treatment in the metastatic setting were endocrine therapy (64.1%) for pts with HR+ mBC and chemotherapy (94.4%) for pts with HR- mBC. Among pts with HR+ mBC, 10.2% received cyclin-dependent kinase 4/6 inhibitors as part of their first treatment. There were no statistically significant differences in clinical outcomes between the HER2-low and HER2 IHC 0 groups within each HR subgroup. For pts with HR+ mBC, median time to first subsequent treatment was 10 and 8 months for the HER2-low and HER2 IHC 0 groups, respectively. Overall, concordance was 81.2% (kappa=0.582). Concordance between historical HER2 scores and rescoring was 87.3%

for HER2-low and 70.1% for HER2 IHC 0 samples. Conclusions: The prevalence of HER2-low (67.1%) among pts previously categorized as HER2-neg mBC in this study was similar to that of an earlier study (\approx 60%). No obvious differences in patient characteristics or clinical presentation were seen between pts with HER2-low and HER2 IHC 0 mBC. Overall percentage agreement between rescored and historical HER2 scores was 81.2%; agreement was numerically greater for HER2-low than HER2 IHC 0. As HER2-targeted therapies such as T-DXd for the treatment of pts with HER2-low BC are emerging, a greater understanding of pts with HER2-low expression who may benefit from these therapies is important.

Background. Trastuzumab deruxtecan (T-DXd) has shown promising activity in patients with HER2-low metastatic breast cancer. As the HER2-status can vary between the primary and its corresponding metastases, treatment decisions should ideally be based on HER2 assessment of a recent biopsy. However, limited data is available on intra-patient inter-metastatic heterogeneity in HER2-status, affecting representability of a single biopsy and potential therapeutic options and outcome. We therefore assessed HER2 status on multiple metastases from patients with primary ER-positive/HER2-non-amplified breast cancer in our prospective post-mortem tissue donation program UPTIDER (NCT04531696). Methods. Ninety-one metastatic samples retrieved during the autopsies of 6 patients (range: 13–16/patient) and their respective primary tumours were immunohistochemically (IHC) stained for HER2 (HercepTest™, RTU, ISO-15189 accredited) in our institution. Consensus scoring was performed between two pathologists according to ASCO/CAP 2018 guidelines. The observers were blinded for patient ID. Reflex fluorescence in situ hybridization (FISH) testing was

performed for samples with IHC score of 2+. HER2 status was categorized as HER2-zero (IHC 0), HER2-low (IHC 1+ or IHC 2+ with negative FISH), or HER2-positive (IHC 3+ or IHC 2+ with positive FISH). To assess stability of the performance of IHC scoring in the post-mortem setting, an additional 13 samples taken from 3 metastases at regular (every 1.5h) time intervals during the autopsy underwent HER2 IHC scoring. Results. Evaluation of HER2-status in the primary tumour showed 2 patients with HER2-zero disease and 4 with HER2-low disease. A discordance between HER2 status of the metastases and their respective primary was seen in all patients. Not a single lesion was found to be HER2-positive. For every patient, at least one HER2-low metastasis was observed, with the percentage being highly variable between patients and ranging between 7 and 100%. No association was observed between HER2 status and organ site: HER2-low as well as HER2-zero lesions were found in all organs evaluated in at least 4 patients (liver, bone, pleura, lymph nodes). For 5 patients, multiple lesions within the liver were evaluated: while HER2-zero versus HER2-low status was concordant in those lesions in 4 patients, a mix of HER2 IHC scores was seen in 3 of them. IHC scores were stable over time for tumour lesions assessed repeatedly. Discussion. Important inter-lesion heterogeneity in terms of HER2-low status was observed in patients with primary ER-positive/HER2-non-amplified breast cancer participating to our post-mortem tissue donation program. This observed heterogeneity is unlikely to be due to post-mortem changes in HER2 expression. HER2-low status was found in at least one distant lesion in all patients, complicating therapeutic decision-making based on a single biopsy. Of note, IHC 1+ and 2+ scores varied between metastases of each patient too, making assessment on a single biopsy less reliable for stratification in clinical trials. Further assessment on samples from UPTIDER-patients with ER-negative disease is currently ongoing and results will be available to be presented.

Background: The HER2 antibody drug conjugate (ADC) fam-trastuzumab deruxtecan-nxki (T-DXd) significantly improves outcomes over standard chemotherapy in pts with HER2-LOW (IHC 1+ and IHC 2+ FISH-) metastatic breast cancer (MBC). Data from the DAISY (NCT04132960) trial in pts with HER2 IHC 0 or “ultra low” MBC revealed median progression-free survival (PFS) of 4.2 mos vs 6.7 mos in HER2-LOW and 11.1 mos in HER2 3+ pts (Diéras V, et al. Cancer Res. 2022;82(4_Suppl):PD8-02). There is an urgent need to develop methods to accurately discern HER2 LOW expression versus HER2 IHC 0/ultra-low expression so appropriate pts may receive T-DXd. We have developed a quantitative HER2 assay using reverse phase protein array (RPPA) technology with laser capture microdissection (LCM) enrichment of tumor epithelium that measures HER2 expression over a 65-fold dynamic range in HER2 IHC 0 to 3+ breast cancers. In I-SPY 1 and 2 trials we found that RPPA-assessed quantitative HER2 and activated/phosphorylated HER2 expression predicted for pathologic complete response in pts with HER2 IHC 0, HER2-LOW and HER2 3+ disease with various HER2 and other targeted agents. We then developed and validated the first CLIA/CAP-accredited quantitative HER2 protein expression and activation assay, and now explore quantitative HER2 expression in

HER2 IHC 0/ultra low disease. Given the recent approval of sacituzumab govitecan-hziy in TNBC and the results of the TROPiCS-02 (NCT03901339), we also evaluated quantitative RPPA-based TROP-2 expression levels in HER2 IHC 0 breast cancer. Methods: LCM-enriched tumor epithelium was obtained from freshly cut FFPE core needle and resected breast cancer samples from 175 pts with pathology-determined HER2 IHC 0 status (N=68 ER+ and N=107 ER-). Quantitative HER2 output is generated as a relative intensity unit (RU) that is interpolated to an internal calibrator curve and a population referent comprised of known HER2+ (IHC 3+ and 2+/FISH+), HER2-LOW and HER2 IHC 0/ultra-low tumors to generate population-based cut-points as a referent. RPPA-based quantitative HER2 expression are reported as one of four levels of expression across the HER2 dynamic range observed: “non/extremely low”, “modest”, “moderate”, and “high”. Quantitative TROP2 protein expression levels were also measured for each case by the RPPA assay on the same lysate using the same adjectival determinants of relative expression as HER2. Results: For the HER2 IHC 0 ER+ cohort, we observed HER2 protein expression over a 25-fold dynamic range and that 57% (N=39) had HER2 non/extremely low, 37% (N=25) modest, and 4 (6%) moderate/high HER2 expression by RPPA. For the HER2 IHC 0 ER- cohort, we observed HER2 protein expression over a 15-fold dynamic range and that 71% (N=76) had non/extremely low, and 31% (N=29%) modest HER2 expression. We observed TROP-2 protein expression over a 35-fold dynamic range across all tumors measured, and it was found to be at least modestly expressed in 95% (37/39) ER+ and 95% (72/76) ER- of the IHC 0/ultra-low tumors that were also found to be HER2 non/extremely low by RPPA. Conclusions: LCM-RPPA quantitative assessment of HER2 expression showed that nearly 40% of ER+ IHC 0 and 30% of ER- IHC 0 “ultra-low” breast cancers actually had modest to moderate HER2 expression. Interestingly, this frequency approximates the response rate of 30% seen with T-DXd in HER2 IHC 0 pts in the DAISY trial. Quantitatively measured TROP2 is at least modestly expressed in the vast majority of RPPA-assessed HER2 IHC 0 cancers regardless of ER status, making a TROP2-directed ADC an attractive therapeutic option for these pts. If validated in larger studies, LCM-RPPA-based HER2 expression could provide a better understanding of the potential for therapeutic efficacy with T-DXd in patients with HER2 IHC “ultra-low” disease, and may better define true ultra-low HER2 expression in HER2 IHC 0 tumor biopsies at baseline and refine the lower limit of the HER2-LOW designation.

Background In DESTINY-Breast04, the HER2-targeted antibody drug conjugate trastuzumab deruxtecan (T-DXd) demonstrated significant survival benefit vs treatment of physician's choice (TPC) in patients (pts) with HER2-low unresectable or metastatic breast cancer (mBC) (Modi et al. N Engl J Med 2022). These results emphasize the importance of accurately identifying HER2 expression in breast tumor tissue. Here, we describe concordance between previously determined (historical) HER2 scores and central HER2 scores, and tumor sample characteristics for pts with mBC screened and enrolled in DESTINY-Breast04. Methods DESTINY-Breast04 was a randomized, open-label, phase 3 study in pts with centrally determined HER2-low (immunohistochemistry [IHC] 1+ or IHC 2+ with negative in situ hybridization [ISH]) mBC who had previously received 1-2 lines of chemotherapy. Pts were randomized 2:1 to T-DXd or TPC. HER2 scores were determined via central testing of tumor specimens by the investigational Ventana PATHWAY 4B5 IHC assay, using the 2018 American Society of Clinical Oncology/College of American Pathologists (ASCO/CAP) testing guidelines HER2 scoring algorithm, and Ventana INFORM HER2 dual ISH assay (as applicable). Results 1340 pts identified as having HER2-low mBC per historical data submitted tumor samples for central HER2-low testing. Of those, 557 pts met all eligibility criteria and were enrolled in

DESTINY-Breast04. The proportion of samples from metastatic vs primary tumors was 59% vs 41% for all submitted tumor samples and 65% vs 35% for enrolled patients. Of those with available data, most were biopsy specimens (995 [74%] vs 344 [26%] resection/excisions) and were submitted as archived formalin-fixed, paraffin-embedded tissue (1183 [88%] vs 157 [12%] freshly collected samples); historical testing dates ranged from 2000-2020. Of samples with data on the historical HER2 IHC test used (31%), most were scored using local Ventana 4B5 (63%) or Agilent HercepTest (32%) assays. Tumor distribution characteristics were similar between screened and enrolled pts. For samples with historical and central HER2 results (N = 1108), 849/1108 (77%) were centrally scored as HER2-low. Of the samples that were not centrally scored as HER2-low, 88% were scored as HER2 IHC 0. Historical and central HER2 score concordance was assessed by sample region of origin (North America, Europe, China, or Asia without China) and collection date (2013 or earlier, 2104-2018, or 2019 or after) and scoring agreement was associated with these factors. Efficacy of T-DXd vs TPC for pts in DESTINY-Breast04 was consistent across all tumor sample characteristics (primary vs metastatic, specimen type, archival vs fresh, and tissue collection date). Conclusions Despite the lack of prior clinical utility and training in distinguishing HER2 IHC 0 from HER2-low (IHC 1+, 2+/ISH-), evolving guidelines since historical HER2 status provision, differences in local testing methods, and differences in key sample characteristics (primary vs metastatic; archived vs fresh; widely variable sample biopsy and testing dates), there was a 77% agreement between historical and central HER2-low status using the Ventana PATHWAY 4B5 IHC assay and Ventana INFORM HER2 Dual ISH assay. This rate is comparable to the reported initial concordance rates for HER2 overexpression IHC testing (range 74-82%; Roche J. Natl Cancer Inst 2002, Perez. J Clin Oncol 2006). Moreover, consistent benefit of T-DXd vs TPC was generally seen across patient groups with various tumor sample characteristics in DESTINY-Breast04. Determination of HER2-low status using the Ventana PATHWAY 4B5 IHC assay (and ISH when applicable) demonstrated the ability of the test, analyzed by pathologists using current ASCO/CAP guidelines, to identify pts who benefit from T-DXd. Funding This study was funded by Daiichi Sankyo and AstraZeneca.

Background:

HER2 low breast cancer, defined as tumors with HER2 IHC expression 1+ or 2+ without HER2 gene amplification, represents a potential new therapeutic subgroup of metastatic breast cancer (BC). However, the clinical significance of HER2 low status in early BC remains unclear. Previously, the RxPONDER trial (NCT01272037), a prospective, randomized trial of endocrine therapy (ET) vs. chemoendocrine therapy (CET) in women with lymph node positive (LN+) BC, demonstrated invasive disease-free survival (IDFS) with ET vs CET varies by menopausal status. We evaluated the impact of HER2 low vs zero status in the RxPONDER trial (SWOG S1007), stratified by menopausal status and treatment groups.

Methods:

Eligibility criteria included women > / 18 years of age with hormone receptor-positive (HR+), HER2-negative (HER2-) BC, Recurrence Score (RS) < / 25, 1-3+ LN and no contraindications to taxane and/or anthracycline based CT. The impact of HER2 low status and other baseline

clinicopathological features on clinical outcomes were evaluated using covariates in Cox regression analysis. HER2 IHC status was per local testing. HER2 low was defined as IHC 1+ or IHC 2+ without HER2 gene amplification, and HER2 zero was defined as IHC 0. The primary endpoint was IDFS, defined as the time from the date of randomization to the date of a first invasive recurrence (local, regional, or distant), a new invasive primary cancer (breast cancer or another type of cancer), or death from any cause. Secondary objectives included distant-relapse free survival (DRFS).

Results:

Among the 4,983 eligible participants, 4,588 had IHC HER2 status available. 52% of 2,052 premenopausal women had HER2 low BC and 57% of 3,042 post-menopausal women had HER2 low BC. There was a small, but statistically significant ($p=0.03$) difference, in RS between HER2 low (mean 14.5) and HER2 zero (mean 14.1) status. The proportion of participants with HER2 low and zero were balanced between treatment group assignment (CET vs ET). Among premenopausal women adjusting for RS, CET led to an observed improvement in IDFS among both HER2 low (HR=0.67; 95% CI 0.43-1.04) and HER2 zero subgroups (HR=0.57; 95% CI 0.36-0.89) (interaction $p=0.55$). Similarly, among post-menopausal women, there was no difference in IDFS between CET vs ET among both HER2 low (HR=0.98; 95% CI 0.75-1.29) and HER2 zero (HR=1.12; 95% CI 0.80-1.56) subgroups (interaction $p=0.57$). In multivariable analysis, adjusting for treatment arm, RS, and menopausal status, HER2 low status was not associated with worse IDFS compared to HER2 zero status (HR=0.93; 95% CI 0.78-1.11). Additionally, no differences were noted in DRFS.

Conclusion:

HER2 low or zero status had no impact on clinical outcomes with CET vs ET among premenopausal or post-menopausal women with HR+/HER- BC with 1-3+ LNs and RS $< / 25$. HER2 low evaluation should not be currently used for CET vs ET clinical decision making among patients with HR+/HER2- breast cancer with 1-3+ LN and RS $< / 25$. Further research on the role of HER2 low status in other settings may be warranted.

Background: Recent studies suggest that enhancer reprogramming underlies heterogeneity and disease progression in estrogen receptor-positive (ER+) BC. Cell-type/state specific transcription is governed by high-order assemblies of master transcription factors (TFs) and epigenetically defined regulatory regions including super-enhancers (SEs). We previously showed that aberrant activation of the pioneer TF FOXA1 promotes enhancer and transcriptional reprogramming in endocrine-resistant BC, involving the ER and the AP-1 FRA1 and c-JUN TFs. As SEs maintain a robust cell-type/state specific core transcriptional regulatory circuitry (CRC) in developmental and tumorigenic processes, we sought to identify key additional TFs in SE/FOXA1-driven CRCs in endocrine resistance, which could serve as attractive therapeutic targets.

Methods: TF binding motif at the shared SEs (mapped by H3K27ac ChIP-seq) between MCF7-parental (P) cells with ectopic FOXA1 overexpression (OE) and the endogenous FOXA1-amplified tamoxifen-resistant (TamR) cells was analyzed by HOMER. ER-bound SEs distinguishing TamR vs. P cells were defined by integrating the SEs with our prior ER ChIP-seq data (PMID 28507152). KLF4 motif within these ER-bound SEs was scanned using FIMO and linked to nearby genes by intersection with the previously defined promoter-tethered regions (PTRs) (PMID 24141950). Differential gene expression in MCF7-TamR cells upon KLF4 knockdown (KD) by 3 unique siRNAs was analyzed using limma from edgeR. The biological and clinical significance of the KLF4-dependent genes was analyzed using Gene Ontology and survival modeling with METABRIC and the ER+ metastatic BC cohort ([SABCS19-GS2-02](#)). Cell migration was assessed by the wound-healing assay.

Country: United Kingdom

Co-expression of hormone receptors (HR) and human epidermal growth factor receptor 2 (HER2) occurs in 10% of all breast cancers, and due to cross-talk mechanisms that influence cell signalling the co-expression of these receptors modulates response of these cancers to both HER2-directed and endocrine therapies. Prior to the advent of HER2 targeted therapies, patients with HR+/HER2+ breast cancer had a significantly worse prognosis compared with HR+/HER2- breast tumours, primarily related to HER2 signalling driving endocrine resistance. Likewise, prior clinical studies in the neoadjuvant setting showed that patients with HR+/HER2+ primary breast cancer had a lower pathological complete response rate to HER2-targeted therapy plus chemotherapy that those with HR-/HER2+ tumours, suggesting a different biology. As such, strategies that combine receptor blockade against HER2 and HR have been developed in metastatic breast cancer (MBC), confirming that combined blockade is better than endocrine therapy (ET) alone, and then that dual HER2 blockade + ET was superior to single HER2 therapy + ET. More recently combinations of a CDK 4/6 inhibitor with ET and HER2 therapy has shown significant clinical efficacy and survival benefit in heavily pre-treated patients, confirming the efficacy for non-chemotherapy targeted combinations in HR+/HER2+ MBC. In the early breast cancer (EBC) setting, most HER2 directed therapy is given in combination with chemotherapy in the neoadjuvant setting, while studies of combined ET and HER2 targeted strategies without chemotherapy work slower with lower pCR rates. As such, the real benefit for combined targeted therapy may be in the adjuvant setting where ET and HER2 therapy are routinely given together following completion of chemotherapy. Furthermore, extended adjuvant ET/HER2 therapy beyond completion of antibody based treatment may also provide extra benefit, and in higher risk patients longer treatment may prove an important consideration.

Sex-hormone driven fundamental programs govern breast physiology and mammary stem and progenitor cell biology. Mammary epithelium is composed of two lineages, basal and luminal. Understanding breast cell heterogeneity in the context of these mammary lineages is essential for designing new classes of drugs aimed at early breast cancer interception and/or treatment. Distinct cell subsets constitute the highly organized epithelial ductal tree and we have been systematically building new knowledge on breast cell composition through multi-modal global profiling, which has pinpointed new mammary cell vulnerabilities. One core pathway is that of lineage-rooted differences in the metabolic programs which can be exploited to suppress unwarranted breast progenitor activity. This lecture will describe our work laying the foundation for breast-progenitor guided new therapeutic opportunities.

Tumor stroma in DCIS progression

Presenting Author(s) and Co-Author(s):

Robert West, MD, PhD - *Stanford University Medical Center*

City: Stanford

State: CA

Country: United States

The interaction between cancer cells and the surrounding stroma plays a significant role in tumor growth and progression. The rapidly growing field of study involving the tumor microenvironment is discovering stromal-specific genes and cells that participate in this process. In invasive breast cancer, transcriptional analysis of stroma derived samples has identified stromal gene expression features that are correlated with clinical outcome with features characteristic of angiogenesis, hypoxia, and inflammation. The role of the microenvironment in DCIS is less well studied and has significant variation across and within DCIS. The basement membrane and myoepithelial cell layers provide a barrier for the interaction between neoplastic cells and the tumor microenvironment. DCIS tumor cells may be variably exposed to the immune environment. An immune infiltration is common in some DCIS, including high grade DCIS with necrosis. How this influences the transition from DCIS to IBC is complex.

Clonal evolution of DCIS to invasion

Presenting Author(s) and Co-Author(s):

Jelle Wesseling, MD, PhD - *Netherlands Cancer Institute*

City: Amsterdam

Country: Netherlands

Clonal evolution of DCIS to invasion

Ductal carcinoma in situ (DCIS) is the most common form of preinvasive breast cancer and, despite treatment, a small fraction (5-10%) of DCIS patients develop subsequent invasive breast cancer (IBC). If not treated, at least 3 out of 4 women with DCIS will not develop IBC¹⁻³. This implies many women with non-progressive, low-risk DCIS are likely to carry the burden of overtreatment. To solve this DCIS dilemma, two fundamental questions need to be answered. The first question is, how the subsequent IBC is related to the initial DCIS lesion. The second question is how to distinguish high- from low-risk DCIS at the time of diagnosis. This is essential to take well-informed DCIS management decisions, i.e., surgery, followed by radiotherapy in case of breast conserving treatment with or without subsequent endocrine treatment, or test whether active surveillance for low-risk DCIS is safe.

How is the subsequent IBC related to the initial DCIS?

The high genomic concordance in DNA aberrations between DCIS and IBC suggest that most driver mutations and CNA events are acquired at the earliest stages of DCIS initiation. It has therefore been assumed that most solid tumours arise from a single cell and that the probability of two independent tumours arising from the same tissue is low⁴⁻⁶. However, lineage tracing and genomic studies strongly suggest both direct and independent clonal lineages during the initiation of DCIS and evolution to IBC. In these processes, mammary stem cells have been implicated in DCIS initiation.

Role of mammary stem cells in DCIS initiation

Lineage tracing mouse model experiments have shown the fate of individual cells and lineages that acquire mutations before a tumour is established⁷⁻⁹. This is also relevant for DCIS initiation^{10,11}, as different pools of MaSCs drive the growth and development of the ductal network and are considered the cell of origin for breast cancers^{9,10}. The ductal trees remain quiescent until puberty, during which extension, branching and termination of terminal end buds (TEBs) leads to its expansion throughout the fat pad^{7,12,13}. Any oncogenic mutation that occurs in a fetal MaSC will spread throughout the ductal network to a large part of the ductal tree, leading to sick lobes⁹. By contrast, oncogenic mutations acquired by a single MaSC during puberty spread to a smaller number of offspring located in small clusters in a part of the ductal network^{8,14}.

Direct lineage models for DCIS progression

Direct lineage models postulate that DCIS has a single cell of origin that acquires mutations and progresses to IBC¹⁵⁻¹⁸. This is also supported by the high genomic concordance of CNAs

and mutations in synchronous DCIS–IBC regions^{6,15,17,19-21} and the results of a recent large longitudinal study that profiled pure DCIS and recurrent IBC using multiple sequencing techniques, which estimated direct clonal lineages in approximately ~80% of patients¹⁸.

Two distinct direct lineage models have been proposed: the evolutionary bottleneck model and the multiclonal invasion model. In the evolutionary bottleneck model, a single clone (or a limited number of clones) with an invasive genotype is selected and breaks through the basement membrane to migrate into surrounding tissues^{15,16,22}, while other clones are unable to escape the ducts²¹⁻²⁸. The multiclonal invasion model posits that most or all subclones can escape the basement membrane, establishing invasive disease^{6,16,17,20}. The multiclonal model has not been studied widely in pure DCIS and recurrent IBC samples.

Independent lineage model for DCIS progression

DCIS lesions and IBCs can arise from different initiating cells in the same breast independently^{5,20,29-32}. An analysis of sequential DCIS–IBC pairs in a unique, large-scale, in-depth study of 95 matched pure DCIS and recurrent IBC showed that ~20% of the IBC recurrences were indeed clonally unrelated to the primary DCIS¹⁸, as is also supported by some mathematical model studies³³.

The potential role of a field effect

IBC can develop in the same breast as an initial DCIS even after treatment, which could be explained by the presence of a field effect³⁴⁻³⁷. Alternatively, the sick lobe hypothesis proposes that a single lobe harbours first-hit mutations, acquired in utero or during early mammary development³⁷⁻⁴². This could also explain the restriction of IBC to the ipsilateral side of the breast^{39,43,44}. Germline mutations may also explain the emergence of independent lineages in DCIS and IBC patients, lowering the threshold for cancer development^{32,43-46}.

Convergent evolution model of DCIS progression

A third model for the emergence of IBC from DCIS is convergent evolution, in which the same mutations and CNA are selected and expanded during tumour growth such that environmental factors fuel competition between distinct clones and push them towards a similar genotype. Ultimately, two independent clonal lineages from different ancestral cells then happen to share multiple genomic aberrations or driver mutations across regions⁴⁷⁻⁴⁹. Although independent lineages are considered uncommon (~20%) in ipsilateral recurrences, they occur at much higher frequencies in contralateral recurrences (>80%), in which single-nucleotide polymorphism and comparative genomic hybridization microarrays show few (or no) genomic alterations shared in tumours from the contralateral breast cancer^{18,50,51}.

How to distinguish high- from low-risk DCIS at the time of diagnosis?

The genomic and transcriptomic profile present at the time of DCIS diagnosis may contain crucial information on the risk of progression of DCIS to IBC. Thus far, it has been unclear whether prognostic gene expression markers can be used to separate indolent DCIS from potentially progressive DCIS. To this end, microarrays and RNA-seq have been applied for the comparison of bulk RNA from microdissected DCIS and IBC tissue. In synchronous DCIS–IBC, a limited number of transcriptional differences have been found and the few events discovered

often varied extensively across different tumours⁵²⁻⁵⁶. Although these differences were strong, the added value of these studies is uncertain as they are often confounded by small sample size, lack of matched receptor status data, and low sample purity. Despite these limitations, these studies have implicated the epithelial-mesenchymal transition (EMT) and extracellular matrix (ECM) remodelling pathways as potentially relevant for the progression of DCIS to IBC⁵⁵⁻⁶².

We studied two large DCIS cohorts: the Sloane cohort, a prospective breast screening cohort from the UK (median follow-up of 12.5 years), and a Dutch population-based cohort (NKI, median follow-up of 13 years). FFPE tissue specimens from patients with pure primary DCIS after breast-conserving surgery (BCS) +/- RT that did develop a subsequent ipsilateral event (DCIS or invasive) were considered as cases, whereas patients that did not develop any form of recurrence up to the last follow-up or death were considered as controls. We performed copy number analysis (CNA) and RNAseq analysis on 229 cases (149 IBC recurrences and 80 DCIS recurrences) and 344 controls.

We classified DCIS into the PAM50 subtypes using RNAseq data which revealed an enrichment of luminal A phenotype in DCIS that did not recur ($P = 0.01$, Fisher Exact test). No single copy number aberration was more common in cases compared to controls. RNAseq data did not reveal any genes significantly over/under expressed in cases versus controls after false discovery rate (FDR) correction. However, by limiting the analysis to samples that had not had RT and excluding pure DCIS recurrences we developed a penalized Cox model from RNAseq data. The model was trained on weighted samples (to correct for the biased sampling of the case control dataset) from the NKI series with double loop cross validation. Using this predicted hazard ratio, the samples were split into high, medium and low risk quantiles, with a recurrence risk of 20%, 9% and 2.5%, respectively at 5 years ($p < 0.001$, Wald test). The NKI-trained predictor was independently validated in the Sloane No RT cohort ($p = 0.02$, Wald test). GSEA analysis revealed proliferation hallmarks enriched in the recurrence predictor (FDR = 0.058). The NKI-RNAseq predictor was more predictive of invasive recurrence than PAM50, clinical features (Grade, Her2 and ER) and the 12-gene Oncotype DCIS score ($p < 0.001$, permutation test using the Wald statistic) in both the NKI and Sloane series.

In the methylation analysis, 50 controls were compared with 35 cases. We could identify Variably Methylation Regions (VMRs) and Differentially Methylated Regions (DMRs) between cases and controls. Interestingly, VMRs were enriched in cell adhesion pathways

Conclusion

The recently acquired knowledge described above on how often the subsequent IBC is directly related to the initial DCIS and on molecular markers predicting the risk of DCIS progression is essential for accurate DCIS risk assessment. This is essential to aid accurate clinical decision making to personalize DCIS management in the near future.

Defining recurrence risk for DCIS: How do we tailor therapy

Presenting Author(s) and Co-Author(s):

Kimberly Van Zee, MS, MD, FACS - *Memorial Sloan Cancer Center*

City: New York

State: NY

Country: United States

In tailoring treatment for DCIS, the goal is to avoid overtreatment while minimizing risk of recurrence. This necessitates estimation of recurrence risk and assessment of efficacy of each intervention in reducing risk. There are several clinicopathologic and treatment factors that have been proven in prospective trials to affect risk. These have been combined into a multivariable nomogram that estimates 10-year risk of recurrence (DCIS Nomogram). It is available online and free-of-charge, and has been validated in at least 5 independent populations with assessments of calibration and discrimination to assess its utility.

There have also been attempts to develop genomic predictors of risk. The Oncotype DCIS score originally was based on a purely genomic analysis, but was "refined" to include clinicopathologic factors. DCISionRT was initially created with the inclusion of clinicopathologic factors. Neither has been prospectively validated and neither has published any assessments of calibration and discrimination. It is unclear what proportion of either risk estimate is due to the inclusion of clinicopathologic factors vs the actual genomic analysis. Both cost thousands of dollars.

Furthermore, neither the refined Oncotype DCIS score nor the DCISionRT score incorporates the use of endocrine therapy. Tamoxifen and aromatase inhibitors have been proven to reduce the risk of recurrence by about 30-50%, and their use should be expected to decrease risk of recurrence. Yet, neither score accounts for this fact, and therefore the risk predictions are too high for those that take endocrine therapy, and too low for those that do not.

In a sample of 59 women age ≥ 50 years old, with DCIS ≤ 2.5 cm in size and clear margins, 10-year recurrence risk estimates from the DCIS Nomogram and refined Oncotype DCIS score (RDS) were compared. Overall, RDS risk estimates were in agreement (within 1-2% of the nomogram risk estimate range, calculated with and without the use of endocrine therapy) in 92% of cases. Among the 5 patients for which the Nomogram and RDS estimates disagreed, all had close margins (≤ 2 mm). Close margins are associated with a statistically significant doubling of risk of recurrence. Nevertheless, the Oncotype DCIS score 10-year recurrence estimate was only 5-8% for these patients with close margins, while the Nomogram estimates were 11-14% (assuming use of endocrine therapy) or 21-27% (without endocrine therapy). From all published data, it seems clear that the refined Oncotype DCIS score markedly underestimates risk for those with close margins. And for those with clear margins, there was excellent (100%) agreement between the Nomogram and the refined Oncotype DCIS score.

Given the need for cost-based value in health care, and given the cost-free availability of a validated predictive online DCIS nomogram, rigorous evaluation of predictive accuracy and proof of significant *added* clinical benefit should be performed and made available before any new expensive commercially available test is adopted for clinical use.

Clinically node positive breast cancer patients often receive neoadjuvant chemotherapy which can eradicate nodal disease. While sentinel node dissection alone has been shown to predict treatment response with a false negative rate of 12-14%, it is possible to increase the accuracy by performing targeted axillary dissection (TAD). To perform TAD, a clip is placed in a node if biopsy confirms disease. The procedure then involves selectively localizing and removing the clipped node in addition to the sentinel nodes. Multiple studies have shown that this approach has a false negative rate of <5%. These studies also show that the clipped node is not retrieved as a sentinel node in > 20% of cases. This means that evaluating the sentinel nodes alone would miss evaluating the node with confirmed disease in a significant proportion of patients. This session will focus on the question of whether there is benefit to placing clips in nodes and ensuring removal after neoadjuvant chemotherapy.

Neoadjuvant chemotherapy (NAC) changed the breast surgery approach and increased indications in recent years. NAC allows to downstage the primary tumor and also may clear the axilla of lymph node metastases in some patients. In fact, NAC allows de-escalation of surgery: not only resulted in an increase in conservative surgery in 40%, which was the initial goal of chemotherapy, but in particular it allows for a reduction in axillary surgery. Furthermore, in relation to the molecular characteristics of the tumors we can have a pathological complete response (pCR) ranging from 20 to 80%. In node-positive patients who converted to cN0 different prospective studies ACOSOG Z1071, SENTINA, SN FNAC and GANEA 2, have demonstrated that the FNR of the SNB was high, more than the acceptable 10%. Therefore, strategies to reduce the FNR treatment in cN+ patients are being investigated: is to remove more than three negative axillary lymph nodes or marking of positive axillary nodes with a tattoo or clip, the so-called target axillary dissection (TAD), to document their removal. But all the effort to reduce the FNR rate do not have clinical prognostic significance. This has already been demonstrated in the literature in different randomized trials with long term follow up. The 10-year follow-up of our study confirmed our preliminary data that the use of standard sentinel node biopsy (SNB) without the use of clip is acceptable in cN1/2 patients who become cN0 after NAT and will not translate into a worse outcome. In fact, the axillary recurrences found were less than 2% in particular in the group that started from a positive axilla were 1.8 %, if we considered that 2 of them had a micrometastatic SN and refused the AD, but if we considered only those with a negative SN the percentage drops to 0.9% Similar positive data with different follow up were also confirmed by other studies that used SNB alone without TAD. All these studies data, with now comforting results on the follow up, confirm that SN surgery alone for selected patients who have an excellent response to NAC is not oncologically inferior to AD during a short- and long-term follow-up.

Patients with hormone-receptor positive, early-stage breast cancer are at considerable risk for late recurrence.

Previous randomized clinical trials have shown that extending adjuvant tamoxifen to ten vs. five years improves disease-free survival (and overall survival in one trial). Adding five years of an aromatase inhibitor (AI) after five years of tamoxifen has also been shown to significantly improve disease-free survival in postmenopausal patients. Benefit from extending adjuvant AI therapy beyond five years in patients who have received five years of an AI or tamoxifen+AI has also been recently demonstrated in several clinical trials but the absolute benefit appears small and the ideal duration of the extended therapy is still a topic of debate.

Over the past decade, efforts have focused on identifying predictors of risk of late recurrence and predictors of benefit from extended endocrine therapy. Clinicopathologic factors and circulating tumor cells can predict risk of late recurrence but not benefit from extended ET. Several commercially available genomic classifiers can further stratify risk of late recurrence, and some have also been found to predict benefit from extended ET. Their clinical utility for tailoring the use of extended endocrine therapy continues to evolve.

Activating a collaborative innate-adaptive immune response to control metastasis

Presenting Author(s) and Co-Author(s):

Mikala Egeblad, PhD, MSC - *Cold Spring Harbor Laboratory*

City: New York

State: NY

Country: United States

Tumor-associated macrophages (TAMs) promote metastasis and inhibit T cells, but we have shown that macrophages isolated from pleural effusions can be polarized to kill breast cancer cells using monophosphoryl lipid A (MPLA) and interferon (IFN) γ . MPLA + IFN γ injected intratumorally or intraperitoneally reduces primary tumor growth and metastasis in breast cancer mouse models. Mechanistically, MPLA + IFN γ stimulates type I IFN signaling, reprograms CD206⁺ TAMs to inducible NO synthase (iNOS)⁺ macrophages, and activates cytotoxic T cells through macrophage-secreted interleukin-12 (IL-12) and tumor necrosis factor alpha (TNF α). MPLA and IFN γ are used individually in clinical practice and together represent a previously unexplored approach for engaging a systemic anti-tumor immune response.

Neutrophil elastase and anti-tumor effects

Presenting Author(s) and Co-Author(s):

Lev Becker, PhD - *The University of Chicago*

City: Chicago

State: IL

Country: United States

Cancer cell genetic variability and similarity to host cells have stymied development of broad anti-cancer therapeutics. Our innate immune system evolved to clear genetically diverse pathogens and limit host toxicity; however, whether/how innate immunity can produce similar effects in cancer is unknown. Here, we show that human, but not murine, neutrophils release catalytically active neutrophil elastase (ELANE) to kill many cancer cell types while sparing non-cancer cells. On a molecular level, ELANE proteolytically liberates the CD95 death domain, which interacts with histone H1 isoforms to selectively eradicate cancer cells. In pre-clinical models, ELANE attenuates primary tumor growth and produces a CD8+ T cell-mediated abscopal effect to attack distant metastases, therapeutic effects that are improved on by porcine pancreatic elastase, an ELANE homolog that better resists protease inhibitors in the tumor microenvironment. Altogether, our studies suggest that ELANE kills genetically diverse cancer cells with minimal toxicity to non-cancer cells, raising the possibility of developing it as a broad anti-cancer therapy.

Despite objective responses to poly(ADP-ribose) polymerase (PARP) inhibition and improvements in progression-free survival (PFS) compared to standard chemotherapy in patients with BRCA-associated triple-negative breast cancer (TNBC), benefits are transitory. Using high-dimensional single-cell profiling of human TNBC, here we demonstrate that macrophages are the predominant infiltrating immune cell type in breast cancer susceptibility (BRCA)-associated TNBC. Macrophages are an innate immune cell that play a critical role in host defense and maintaining tissue homeostasis, however their infiltration into tumors has been associated with disease progression and resistance to therapy. Tumor associated macrophages (TAMs) represent a significant proportion of solid tumors, including breast cancer. TAMs play a major role in tumorigenesis as they can enhance tumor cell growth, angiogenesis and metastasis. In addition, TAMs can inhibit anti-tumor responses of T cells. Our recent work has shown that removal or conversion of TAMs to an anti-tumor phenotype enhances chemo- and immuno-therapy establishing TAMs as targets for anti-cancer therapy. Through multi-omics profiling, we show that PARP inhibitors enhance both anti- and pro-tumor features of macrophages through glucose and lipid metabolic reprogramming, driven by the sterol regulatory element-binding protein 1 (SREBF1, SREBP1) pathway. Combining PARP inhibitor therapy with colony-stimulating factor 1 receptor (CSF1R)-blocking antibodies significantly enhanced innate and adaptive antitumor immunity and extended survival in mice with BRCA-deficient tumors *in vivo*, and this was mediated by CD8+ T cells. Collectively, our results uncover macrophage-mediated immune suppression as a liability of PARP inhibitor treatment and demonstrate that combined PARP inhibition and macrophage-targeting therapy induces a durable reprogramming of the tumor microenvironment (TME), thus constituting a promising therapeutic strategy for TNBC. Therefore, targeting TAMs offers great potential to enhance both chemo- and immuno-therapy. Deep analysis of TAMs in solid tumors has revealed the complexity of TAMs and revealed major gaps in our knowledge of the functional and phenotypic characterization of TAM subsets associated with cancer, before and after treatment. Here we will discuss the complexity of TAMs in solid tumors including characterizing TAM subsets, location, and crosstalk with neighboring cells, as well as novel TAM-modulating strategies and combinations that are likely to enhance current therapies and overcome chemo- and immuno-therapy resistance.

Breast cancer metastasis develops from disseminated cancer cells (DCCs) that leave the primary tumor and seed in distant organs. In those organs, DCCs undergo a period of dormancy during which cancer cells remain occult, in a non-proliferative state, before metastases become detectable. In this seminar I will discuss how disseminated cancer cells enter in dormancy at metastatic sites and the importance of the ECM in this process. We have found that dormant cancer cells express a specific set of ECM genes, "*the matrisome*", that is lost upon break from dormancy. ECM proteomics identify tumor-derived COL3A1 as a key ECM component required for tumor cell dormancy at metastatic organs. Intravital imaging and SHG microscopy reveals that the dormancy-to-reactivation transition is accompanied by changes in collagen three-dimensional architecture. Our data reveal a novel barrier to metastasis through a mechanism by which DCCs depend on the assembly of a pro-quiescence ECM to establish a niche that sustains dormancy.

Implications for clinical care

Presenting Author(s) and Co-Author(s):

Alexandra Thomas, MD, FACP - *Wake Forest Baptist Health*

City: Winston-Salem

State: NC

Country: United States

Late recurrence, commonly considered to be distant recurrence five or more years after initial diagnosis remains a formidable challenge in breast oncology. Current management focuses on slowing the growth of macroscopic recurrent disease which is generally considered incurable. Emerging tools to identify minimal residual disease or tumor dormancy hold great promise to transform the treatment landscape in this space. This mini-symposium discussion will review the scope of the clinical challenge, highlighting the numbers at risk and the timeframe for recurrence risk. Current and emerging tools to assess the risk in individual patients beyond 5 years from diagnosis will be discussed. Evidence and guidelines on the use of clinically available anatomic-based and genomic assay-based late risk assessment tools including Clinical Treatment Score post-5 years (CTS5) and the Breast Cancer Index (BCI) will be highlighted. Current data on the role of circulating biomarkers including ctDNA, to identify at risk patients will be discussed as will open questions on how this might impact treatment approach. Finally, possible therapeutic approaches following the identification minimal residual or dormant disease will be reviewed, as will trial design options in this rapidly evolving space in breast oncology.

Mechanisms of resistance to Antibody Drug Conjugates

Leif W. Ellisen, M.D., Ph.D.

Program Director, Breast Oncology, Mass General Hospital Cancer Center

Professor of Medicine, Harvard Medical School.

Antibody Drug Conjugates (ADCs) are emerging as promising therapeutics for all subtypes of breast cancer. ADCs are composed of a monoclonal antibody directed against a tumor-expressed antibody, conjugated via a variety of linker chemistries to a cytotoxic or other tumor-active payload. Tumor-selective drug delivery via ADCs has the potential to substantially improve the therapeutic window and efficacy for a variety of therapeutic agents. Indeed, recent clinical data have demonstrated significant improvements in overall survival with the use of single-agent ADCs across the spectrum of advanced breast cancer. However, both de novo and acquired resistance to ADCs is common, and may involve a diverse array of potential mechanisms that reflect the complexity of ADC action. These include alteration or downregulation of the ADC target, deregulation of intracellular trafficking or endolysosomal processing of the internalized ADC, and a variety of payload-specific mechanisms of resistance such as induction of drug efflux or activation of cell survival pathways. Which mechanism(s) dominates in a given setting may depend on both ADC-specific and tumor-specific factors. For example, linker design is likely to have a major influence on potential ADC resistance: ADCs with a non-cleavable linker (e.g. trastuzumab emtansine) are dependent upon fusion with acidified lysosomes for degradation and payload release, and attenuated acidification has been demonstrated pre-clinically as a resistance mechanism. In contrast, ADCs with a cleavable peptide linker (e.g. trastuzumab deruxtecan) may not require lysosomal processing for payload release. Furthermore, highly genetically unstable tumors may simultaneously generate multiple types of resistance mechanisms. We recently demonstrated the emergence of distinct acquired resistance mutations to sacituzumab govitecan, involving the ADC antibody target (TROP2) and the payload target (topoisomerase 1), within different metastatic lesions of an individual patient. General strategies to overcome ADC resistance include the sequential use of multiple ADCs, and/or the up-front use of select combination therapies incorporating ADCs. Clearly, the success of these approaches will require a more thorough evaluation and understanding of resistance mechanisms as they occur in patients. Fortunately, the relative success of ADCs for breast cancer treatment to date is spurring the identification of new targets, approaches for linker design, and a wide diversity of payloads that will be instrumental for efforts to overcome resistance.

What are PROs and evidence for benefit?

Presenting Author(s) and Co-Author(s):

Shoshana Rosenberg, ScD, MPH - *Weill Cornell Medicine*

City: New York

State: NY

Country: United States

Patient-reported outcomes (PROs) are self-reported assessments provided directly by patients. PROs can be used for research, to tailor and improve clinical and supportive care, and for quality assessment purposes. It is well-established that PROs, rather than clinician evaluations, better capture the patient experience. Additionally, there is growing evidence supporting the routine incorporation of PROs into clinical practice. In particular, the use of PRO-based interventions is associated with improved symptom management, enhanced patient-provider communication, and better outcomes, including quality of life and survival, in patients with advanced cancer. Among patients in the post-active treatment and survivorship phase of care, PROs are critical in identifying and understanding late and long-term effects of treatment, identifying unmet needs, and determining if survivors are receiving appropriate follow-up care. There are also data in the survivorship setting demonstrating how PROs can predict other outcomes, such as adherence to aromatase inhibitors in breast cancer survivors. Careful consideration of age (e.g., pediatric vs. adult measures), race and ethnicity (e.g., was the measure validated in a diverse and representative population), language (e.g., was the measure validated in other languages), literacy level (e.g., was the measure written for individuals with low literacy levels), mode of delivery (e.g., paper vs. tablet), and participant burden (e.g., does the assessment take a reasonable amount of time) when selecting PROs is critical to ensure that the information learned is generalizable and that the benefit patients can gain through the incorporation of PROs into cancer care is equitable.

How to incorporate PROs into clinical care

Presenting Author(s) and Co-Author(s):

Oluwadamilola (Lola) Fayanju, MD, MA, MPHS, FACS - *Perelman School of Medicine at the University of Pennsylvania*

City: Philadelphia

State: PA

Country: United States

Patient-reported outcomes (PROs) are self-reported assessments of health status that come from the patient's perspective. Communicated without interpretation by a physician, PROs can enhance shared-decision making. When administered in multi-lingual, level-appropriate, and culturally aware formats, PROs can be used to address the individual and collective health status of potentially vulnerable groups including children, older adults, those with disabilities, and those from racial/ethnic minority backgrounds thereby providing an opportunity not only to address the needs of individuals but also identify potential disparities across groups. In her talk, Dr. Fayanju will provide strategies to facilitate incorporation of PROs into routine patient care and describe the benefits and potential challenges associated with doing so.

Where are we going with digital interventions and PROs

Presenting Author(s) and Co-Author(s):

Ines Vaz Luis, PhD - *Gustave Roussy*

City: Villejuif

Country: France

Rational: Lately, digital health has shown potential to facilitate cancer care delivery. We now have data that demonstrated that systems integrating self-reporting of common symptoms during treatment for both adjuvant and metastatic breast cancer treatment and allowing for patient remote monitoring result not only result in better quality of life and less emergency room visits, but, in some settings, also lead to significant survival benefit. In addition, some studies incorporating self-management strategies that do not need heavy clinician involvement have shown promising results to manage acute and long and late term physical, social, and psychological effects of cancer and its treatment.

Objectives: In this talk, we will 1) review data on the existing digital health solutions that can be used in clinical care. In addition, 2) we will reflect on what is next in digital health innovation, particularly a) how the integration of technology, including digital companions facilitating remote monitoring, education and self-management, may serve as a vehicle to promote continuous care b) innovative emerging digital health tools (including, although not limited to wearables and digital therapeutics). Finally, 3) we will examine how digital health can address the needs of every patient, avoid pitfalls such as contributing to health disparities.

Patient Advocate Perspective

Presenting Author(s) and Co-Author(s):

Patty Spears, BS - *University of North Carolina*

City: Chapel Hill

State: NC

Country: United States

Patient reported outcome (PRO) measures can be collected in clinical trials or clinical care through questionnaires. PROs allow a direct measure of how a patient is feeling and functioning, directly from the patient without interpretation by another person or clinician. PROs give patients a voice. Although there are challenges to collecting PROs, these challenges can be overcome. When deciding which measures to collect there are some things to keep in mind. For example, if the questions are relevant and meaningful to what the patient is experiencing they will be more likely to fill them out, providing useful information. The questionnaires can also be given in multiple formats (electronic, paper, telephone) to accommodate the preferences of different patients. However, collecting PROs is not enough, the information collected needs to be used to inform future patients or inform patient care. Additional challenges and benefits of collecting PROs in breast cancer research and clinical care from the patient perspective will be discussed.

Educational Session: Spatial and Single Cell Characterization of Breast Cancer Progression

Presenting Author(s) and Co-Author(s):

Christina Curtis, PhD, MSc - *Stanford University School of Medicine*

City: Stanford

State: CA

Country: United States

Recent years have seen an explosion of single cell and spatial methods to interrogate cellular and tissue biology in native context. This session will highlight recent advances in single cell and spatial profiling of breast cancer. An expert faculty panel will share their experience with different platforms ranging from single cell sequencing (RNA, ATAC, DNA), to multiplexed proteomic profiling and imaging mass cytometry. Speakers will review study design considerations, measurement types and interpretation as well as practical considerations for the implementation of these methods. Focus will be placed on the application of these methods to breast cancer patient cohorts and the types of questions that can be addressed. Lastly, we will close with the future clinical outlook for these approaches.

12/7/2022

Multiplex spatial proteomic profiling

Presenting Author(s) and Co-Author(s):

David Rimm, MD, PhD - *Yale University*

City: New Haven

State: CT

Country: United States

Multiplex spatial analysis is touted as a potential solution for tissue biomarkers for prognostic and companion diagnostic applications. Spatial analysis infers maintaining the location of a biomolecule so that both its amount and context can contribute to the information obtained. Immunohistochemistry (IHC) is the archetypal method of spatial profiling and the only application that has made it to the clinic. In this session, we will discuss technologies based on IHC, but that allow assessment of at least two, and as many as 100 or more proteins within the cell or molecular compartment that maintains spatial context. The simplest and most common approach is multiplex immunofluorescence, followed by a number of next generation techniques that use alternative labeling of the antibodies or cycling strategies or both to generate spatially informed data. Excluding Mass spectrometry-based methods, still in early stages, the highest “plex” method for protein is digital spatial profiling. Digital spatial profiling (DSP) uses a molecular method to define spatial compartments which is different from other high-plex methods that use cell segmentation, an image analysis method that largely depends on the presence of a cell nucleus in the image. As a result, the DSP method allows assessment of both cellular and non-cellular stromal compartments. DSP and other high-plex methods that will be discussed are thought to be best used as biomarker discovery tools, that might find biomarkers that can be measured with a more traditional approach for assessment in the clinic.

Beyond the lab: Clinical implications

Presenting Author(s) and Co-Author(s):

Christina Curtis, PhD, MSc - *Stanford University School of Medicine*

City: Stanford

State: CA

Country: United States

During this talk, I will review the ever expanding repertoire of single cell and spatially resolved profiling techniques which enable the interrogation breast cancer pathology, immuno-biology and treatment response at unprecedented resolution. I will outline considerations for throughput, plex and resolution across different methods before providing several case studies in their application. As one example, I will outline the use of multi-omic single cell profiling and spatial proteomic profiling to characterize changes throughout the course of neoadjuvant Her2-targeted therapy and leading to the identification of candidate predictive biomarkers. I will go on to discuss translational and potential clinical applications of these techniques.

12/7/2022

3:00 PM - 3:30 PM

Beyond anthracyclines and trastuzumab: Cardiotoxicity of novel agents

Presenting Author(s) and Co-Author(s):

Susan Dent, MD - *Duke University*

City: Durham

State: NC

Country: United States

Breast cancer treatment can have a diverse array of delayed and long-term effects, including cardiovascular events such as heart failure, valvular damage, coronary artery disease, arrhythmias, and cardiac dysfunction. The adverse cardiovascular effects of anthracyclines and trastuzumab in the treatment of early and advanced breast cancer have been well elucidated with the literature; however, there is less understanding of the potential cardiovascular impact of more recent novel breast cancer therapies. Dual HER2 targeted therapy (pertuzumab/trastuzumab) is now standard of care for neoadjuvant and adjuvant treatment, particularly in the setting of lymph node involvement, but is there a higher risk of cardiotoxicity? There is a limited understanding of the potential short- and long-term cardiovascular toxicity associated with antibody-drug conjugates, such as T-DM1 and fam-trastuzumab deruxtecan, and well as oral anti-HER2 tyrosine kinase inhibitors such as lapatinib, neratinib, and more recently tucatinib. CDK4/6 inhibitors (eg ribociclib) combined with endocrine therapy have significantly improved clinical outcomes for individuals with hormone receptor positive, HER-2 advanced breast cancer but are associated with an increased risk of QTc prolongation, which can be compounded by electrolyte abnormalities and drug-drug interactions. Immune checkpoint inhibitors (pembrolizumab) are approved in the neoadjuvant (high risk) and advanced setting (PDL-1 positive) for triple negative breast cancer but are associated with several toxicities including endocrinopathies and rarely fatal myocarditis. The goal of this session is to improve the awareness and understanding of the potential cardiovascular toxicities associated with modern anti-cancer therapies used in the treatment of breast cancer.

Cardiovascular toxicity and breast cancer: Detection and prevention strategies

Presenting Author(s) and Co-Author(s):

Dinesh Thavendiranathan, MD, MSc - *Peter Munk Cardiac Center, Toronto General Hospital, University of Toronto*

City: Toronto

Country: Canada

The presentation will discuss the potential cardiovascular toxicities (e.g., heart failure, coronary artery disease, arrhythmias) that are seen in women with breast cancer with a particular focus on those receiving cancer therapy. It will discuss the associated drugs, timing, the severity, and treatment options. The presentation will also include strategies that could be considered for risk stratification of patients prior to initiation of cancer therapy, methods to identify early cardiovascular injury, and primary prevention options. Recent guidelines including the ESC cardio-oncology guidelines and the prior ASCO guidelines will be highlighted. Practical approaches to assessment and management of cardiovascular toxicities will also be discussed. The presentation will wrap up providing potential future directions in the field.

BACKGROUND: Cyclin-dependent kinase 4/6 (CDK4/6) inhibitors combined with endocrine therapy are the recommended first-line standard-of-care (SOC) treatment for estrogen receptor (ER)-positive, human epidermal growth factor receptor 2 (HER2)-negative metastatic breast cancer (MBC) patients. After progression on first-line treatment, current clinical practice guidelines (NCCN, ESMO) recommend to sequence endocrine therapy (in absence of visceral crisis) until there is no clinical benefit after up to 3 regimens, and subsequently initiate chemotherapy regimens. However, clinical benefit for endocrine monotherapy after progression on first-line standard-of-care is limited, with median progression-free survival (PFS) of 2-5 months. Multiple factors can contribute to endocrine therapy resistance, including changes in ER expression, (epi)genetic mutations, and/or clonal selection under therapeutic pressure. ER heterogeneity can occur over time (temporal) as well as between lesions in a patient (spatial). As confirmed by tissue biopsy, greater than 20% of MBC patients have discordance in ER expression between their primary tumor and a metastatic lesion. Measuring total ER heterogeneity in a patient – the variation in ER expression at whole body level across all MBC lesions – is not clinically feasible by tissue biopsy alone. Fluoroestradiol F18 (Cerianna), also called 18F-FES, is a radioactive diagnostic agent that can be used with PET/CT for in vivo detection of ER-positive lesions in MBC with high accuracy. Results from 18F-FES PET/CT studies have shown that ER expression across MBC lesions at whole body level is heterogeneous in approximately half of ER-positive, HER2-negative MBC patients. In this study, we aim to evaluate the clinical utility of 18F-FES PET/CT to guide second-line treatment decision in ER-positive, HER2-negative MBC patients with progressive disease on first-line SOC hormonal therapy. **METHODS:** Fluoroestradiol F18 (Cerianna) is being evaluated in a phase 4, open-label, prospective cohort study enrolling 206 patients at 20-30 centers in the United States. Patients diagnosed with ER-positive, HER2-negative MBC who have progressive disease on first-line aromatase inhibitor therapy with or without CDK4/6 inhibitor

will be included in the study; patients with isolated hepatic metastases will be excluded. All patients will undergo an 18F-FES PET/CT scan. The treating physician will complete a standardized questionnaire to indicate the second-line therapeutic management plan before the scheduled 18F-FES PET/CT. After interpretation of 18F-FES PET/CT by local radiologist or nuclear medicine physician, imaging results will be provided to the treating physician who will then fill out a similar questionnaire to specify the final therapeutic decision. The proportion of patients with a change in therapeutic management plan based on incorporation of 18F-FES PET/CT results will be the primary endpoint. During the study follow-up period of 18 months, data on SOC imaging, treatments/procedures received, and clinical outcomes will be collected. Secondary endpoints include visual and quantitative heterogeneity assessment of tumor 18F-FES uptake, and PFS rates at 6 months and 18 months after 18F-FES PET/CT, which will be assessed between patients with and without a change in therapeutic management plan. The trial is planned to begin enrollment in Q3 2022. Clinical trial information: NCT05068726

Background Antiprogestins, including selective progesterone receptor (PgR) modulators (SPRMs) that act as PgR antagonists, are a promising class of therapeutics for overcoming endocrine resistance including in patients who develop activating estrogen receptor alpha (ESR1) mutations after prior endocrine therapy (ET). The SMILE study is a multi-institutional phase II clinical trial to determine the efficacy and safety of an antiprogestin, onapristone in combination with fulvestrant as second-line therapy for patients with ER+,PgR+/-, HER2 - metastatic breast cancer (MBC). Methods Patients with locally advanced or MBC who progress on ≥ 2 lines of prior therapy with ET as a single agent or in combination with CDK4/6 inhibitors, mTOR inhibitors and one line of chemotherapy in the metastatic setting are eligible. Other criteria include ECOG performance status ≤ 2 , measurable disease per RECIST 1.1 criteria, adequate organ function, availability of an archived tumor biopsy block confirming the diagnosis of MBC, optional biopsy at disease progression on trial, and optional 18F-fluorofuranylnorprogesterone (18F-FFNP) PET/CT imaging. Ovarian suppression is allowed. Prior ET with tamoxifen or aromatase inhibitor therapy in the adjuvant or metastatic setting is allowed. Patients with prior exposure to fulvestrant, antiprogestins, or CDK inhibitors in the adjuvant setting are ineligible. Following consent, all subjects will receive fulvestrant at the recommended dosing schedule plus onapristone 50 mg orally, twice daily, until disease progression, unacceptable toxicity, or discontinuation for any other reason. Using the Simon Two-Stage design, a total of 39 patients will be enrolled over two years from 6-8 sites within Wisconsin Oncology Network (WON); study enrollment began in November 2021. In the first stage of the trial, thus far, nine patients were accrued who are tolerating the trial regimen well with no reported toxicities or serious events. The safety monitoring is planned when the cohort size reaches eleven patients, and interim analysis at 21 patients; if ≥ 2 responses are observed, then 18 additional subjects will be enrolled in the second stage. This design yields a one-sided type I error rate of 5% if the ORR is 7% and power of 80% when the combination's true response rate is 20%. The primary objective is to evaluate the objective response rate; secondary objectives include safety and tolerability, progression-free survival, disease control

rate, and duration of response. Other correlates include optional functional imaging of PgR binding with 18F-FFNP PET/CT and biomarker analysis (ER, total PgR, HER2, Ki67, CD24, CD44, LDH1, KLF4, CK 5/6, PhosphoSer294-PgR on tissue samples, ESR1 mutations, and circulating tumor DNA analysis).

Background: Elacestrant demonstrated significantly prolonged progression-free survival (PFS) and a manageable safety profile compared with standard of care endocrine therapy in the phase 3 EMERALD trial that enrolled patients with estrogen-receptor positive (ER+)/HER2– mBC following disease progression on prior endocrine and cyclin-dependent kinase 4/6 inhibitor (CDK4/6i) therapy. Benefit was observed in the overall population and in patients with ESR1 mutations. Combining elacestrant with targeted agents utilized in combination with endocrine therapy in mBC is of therapeutic interest. Methods: ELEVATE is a phase 1b/2 trial designed to evaluate the combination of elacestrant with alpelisib, everolimus, palbociclib, abemaciclib, or ribociclib. Eligible patients (pts) are women or men with ER+/HER2– locally advanced or mBC, measurable disease per RECIST v1.1 or ≥ 1 lytic or mainly lytic bone lesion, ECOG PS ≤ 1 , no inflammatory breast cancer or uncontrolled central nervous system metastases, in addition to treatment-arm specific eligibility criteria as detailed below. In the phase 1b portion, pts who have received prior aromatase inhibitor (AI) and CDK4/6i will be enrolled in three 6-patient cohorts for each combination except abemaciclib (under study in a separate trial). Patients will receive elacestrant with the targeted agent at reduced or full doses. The primary endpoint of phase 1b is to determine the recommended phase 2 dose for each combination. Secondary endpoints are safety, pharmacokinetics, pharmacodynamics, and efficacy (objective response rate [ORR], duration of response [DoR], clinical benefit rate [CBR], PFS, and overall survival [OS]). The phase 2 portion will enroll 5 separate arms: A) pts with PIK3CA mutation(s) and prior AI + CDK4/6i: alpelisib + elacestrant, n=50; B) pts with prior AI + CDK4/6i: everolimus + elacestrant, n=50; C) pts with prior AI + CDK4/6i: abemaciclib or ribociclib (investigator's [inv] choice) + elacestrant, n=60 (30 per combination); D) pts with prior AI only (no CDK4/6i): palbociclib, abemaciclib or ribociclib (inv choice) + elacestrant, n=90 (n=30 per combination); E) pts with no prior systemic therapy: palbociclib or ribociclib (inv choice) + elacestrant, n=90 (n=45 per combination). No prior fulvestrant or chemotherapy is allowed in any arm and no more than 2 prior hormonal therapies are permitted in arms A-D. Prior therapy restrictions apply to the mBC setting or within 12 months of adjuvant therapy. The primary endpoint for the phase 2 portion is the estimation of PFS at 6 months in arms A, B, and C and at 12 months in arms D and E. Secondary endpoints will include ORR, DoR, CBR, PFS, OS, and safety. The Kaplan-Meier method will be used to estimate PFS. Descriptive statistics will be used to evaluate response and safety.

Objectives: The addition of a CDK 4/6 inhibitors to endocrine therapy, in the first or second line setting, provides a significant improvement in progression free survival (PFS), and in some cases in overall survival (OS), with a tolerable toxicity profile. Regardless, most patients experience disease progression on these agents and ultimately develop endocrine resistance, thus, emphasizing the critical need for novel treatments. Elacestrant showed a statistically significant improvement in PFS when compared to standard of care endocrine therapy after progression on CDK4/6 inhibitors in combination with endocrine therapy (Bidard et al, 2022). Onapristone is a type I antiprogestin which prevents the progesterone receptor (PgR) from
