Title: Whole exome and transcriptome sequencing of resistant ER+ metastatic breast cancer

Body: Background: While great strides have been made in the treatment of estrogen receptor-positive (ER+) metastatic breast cancer (MBC), therapeutic resistance invariably occurs. A better understanding of the underlying resistance mechanisms is critical to enable durable control of this disease.

Methods: We performed whole exome sequencing (WES) and transcriptome sequencing (RNA-seq) on metastatic tumor biopsies from 88 patients with ER+ MBC who had developed resistance to one or more ER-directed therapies. For 27 of these patients, we sequenced the treatment-naive primary tumors for comparison to the resistant specimens. Tumors were analyzed for point mutations, insertions/deletions, copy number alterations, translocations, and gene expression. Detailed clinicopathologic data was collected for each patient and linked to the genomic information.

Results: WES of all metastatic samples demonstrated several recurrently altered genes whose incidence differed significantly from primary, treatment-naive ER+ breast cancers sequenced in the TCGA study (TCGA). These include ESR1 mutations (n=17, 19.3%; 32.86 fold enrichment, q.value<7.5e-12), CCND1 amplification (n=52, 59.1%; 2.3 fold enrichment, q.value<0.0073), and MAP2K4 biallelic inactivation (n=14, 15.9%; 3.04 fold enrichment, q.value<0.054). Comparing to matched primary samples from the same patient, many alterations were found to be acquired in several cases, including for ESR1, ERBB2, PIK3CA, PTEN, RB1, AKT1, and others. Initial analysis of RNA-seq data from metastatic samples (n=59) allowed classification of individual resistance mechanisms into broader resistance modes based on the observed transcriptional state.

Conclusions: We present a genomic landscape of resistant ER+ MBC using WES and RNA-seq. Multiple genes were recurrently altered in these tumors at significantly higher rates than in ER+ primary breast cancer. When compared with matched primary tumors from the same patient, alterations in these and other genes were often found to be acquired after treatment, suggesting a role in resistance to ER-directed therapies and/or metastasis. Potential resistance mechanisms appear to fall into several categories; integrating RNA-seq data may enhance the ability to identify these categories even when genomic alterations are not identified. Multiple clinically relevant genomic and molecular alterations are identified in metastatic biopsies—with implications for choice of next therapy, clinical trial eligibility, and novel drug targets.

Title: PrECOG 0102: A randomized, double-blind, phase II trial of fulvestrant plus everolimus or placebo in post-menopausal women with hormone receptor (HR)-positive, HER2-negative metastatic breast cancer (MBC) resistant to aromatase inhibitor (AI) therapy

Kornblum NS S, Manola J, Klein P, Ramaswamy B, Brufsky A, Stella PJ J, Burnette B, Telli M, Makower DF F, Leach J, Truica CI, Wolff AC C, Soori GS S, Haley B, Nagarajan A, Wassenaar TR R, Goldstein L, Miller KD D and Sparano JA A. Montefiore-Einstein Center for Cancer Care, Bronx, NY; Dana-Farber Cancer Institute, Boston, MA; Mount Sinai Beth Israel Comprehensive Cancer Center, New York, NY; Ohio State University Comprehensive Cancer Center, Columbus, OH; University of Pittsburgh, Pittsburgh, PA; Saint Joseph Mercy (Michigan Cancer Consortium), Ann Arbor, MI; Saint Vincent Hospital, Green Bay, WI; Stanford University Medical Center, Stanford, CA; Fox Chase Cancer Center, Philadelphia, PA; Minnesota Oncology, Saint Louis Park, MN; Penn State Hershey Cancer Institute, Hershey, PA; Johns Hopkins Sidney Kimmel Comprehensive Cancer Center, Baltimore, MD; Missouri Valley Cancer Consortium, Omaha, NE; UT Southwestern Medical Center, Dallas, TX; CAMC Health System, Charleston, WV; Pro Health Care, Waukesha, WI and Indiana University School of Medicine, Indianapolis, IN.

Body: Background: Although AIs are an effective treatment for HR-positive MBC, whether used alone or in combination with CDK4/6 inhibitors, resistance to therapy and disease progression invariably develops. Therapeutic options for AI-resistant disease include the m-TOR inhibitor everolimus in combination with the steroidal AI exemestane, or the selective estrogen receptor downregulator (SERD) fulvestrant alone. We hypothesized that the combination of fulvestrant and everolimus would be more effective than fulvestrant alone in AI-resistant MBC.

Methods: Major eligibility criteria included post-menopausal women with HR-positive, HER2-negative MBC, recurrence or progression while receiving prior non-steroidal or steroidal AI therapy, ECOG PS 0-1, and ≤1 prior chemotherapy regimen for metastases. All patients received fulvestrant (500mg IM q2 weeks for 3 doses, then q4 weeks) plus oral everolimus (10mg) or placebo (1:1 randomization). Prophylactic corticosteroid mouthwash was not used. Tumor assessment was performed at baseline and every 12 weeks. Treatment continued until progressive disease (PD) by RECIST 1.1 criteria. Patients who discontinued everolimus/placebo due to toxicity continued fulvestrant until PD. The primary endpoint was progression-free survival (PFS), defined as time from start of treatment until progression or death. With accrual of 130 patients (120 eligible), the trial had 90% power to detect an improvement in median PFS from 5.4 months to 9.2 months (1-sided stratified log-rank test, type I error rate10%), with analysis planned after 98 PFS events.

Results: Of 130 patients treated (64 everolimus, 66 placebo), median age was 61 years (range 35-92), and treatment arms were balanced for stratification factors used in randomization, including ECOG PS 0 vs. 1 (59%/41%), measurable disease (66%), and prior chemotherapy for metastasis (17%). Grade 3/4 AEs were more common in the everolimus arm (53%/3% vs. 23%/3%), including hyperglycemia (16%/0% vs. 0%), stomatitis (11%/0% vs. 0%), hypertriglyceridemia (9%/2% vs. 0%), lymphopenia (9%/0% vs. 0%), and pneumonitis (6%/2% vs. 0%). There were 3 grade 5 events (2 everolimus, 1 placebo arm), none of which were attributed to therapy. Selected grade 2 events of interest included fatigue (17% vs. 6%), hyperglycemia (6% vs. 0%), and stomatitis (6% vs. 0%). Everolimus/placebo was discontinued for adverse events, patient withdrawal, or physician discretion in 39% in the everolimus arm and 21% in the placebo arm. After 98 PFS events, median PFS was 10.4 months in the everolimus arm versus 5.1 months in the placebo arm (hazard ratio: 0.61, 95% C.I. 0.40 – 0.92; stratified logrank p= 0.02).

Conclusions: The addition of everolimus to fulvestrant significantly improved PFS in post-menopausal women with AI-resistant MBC. Everolimus used without prophylactic corticosteroid mouthwash exhibited a similar rate of oral mucositis and overall AE profile when combined with fulvestrant as when combined with exemestane.

Title: First results from the multicenter phase III DATA study comparing 3 versus 6 years of anastrozole after 2-3 years of tamoxifen in postmenopausal women with hormone receptor-positive early breast cancer

Tjan-Heijnen VC C, Van Hellemond IE E, Peer PG G, Swinkels AC C, Smorenburg CH H, Van der Sangen M, Kroep JR R, De Graaf H, Honkoop AH H, Erdkamp F, Van den Berkmortel FW W, Kitzen JJ J, De Boer M, De Roos WK K, Linn SC C, Imholz AL L and Seynaeve C. Maastricht University Medical Centre, Netherlands; Radboud University Medical Centre, Netherlands; Netherlands Comprehensive Cancer Organisation IKNL, Netherlands; Medical Centre Alkmaar, Netherlands; Catharina Hospital, Netherlands; Leiden University Medical Centre, Netherlands; Medical Centre Leeuwarden, Netherlands; Isala Clinics, Netherlands; Zuyderland Medical Centre, Sittard, Netherlands; Zuyderland Medical Centre, Heerlen, Netherlands; Albert Schweitzer Hospital, Netherlands; Gelderse Vallei Hospital, Netherlands; Netherlands Cancer Institute, Netherlands; Deventer Hospital, Netherlands and Erasmus MC Cancer Institute, Netherlands.

Body: Background. Even in view of the recent findings of the MA.17R trial, the impact of prolonged aromatase inhibitor (AI) therapy after prior tamoxifen in hormone receptor-positive early breast cancer remains insufficiently clear.

Methods. In this open-label phase III study, we randomly assigned 1912 postmenopausal women with hormone receptor-positive breast cancer after 2-3 years of adjuvant tamoxifen to either 3 or 6 years of anastrozole therapy. The primary endpoint was the adapted disease-free survival (ADFS). This was defined as the DFS beyond 3 years after randomization to AI therapy because initially all patients received the same AI therapy for 3 years. ADFS events included (non-) invasive breast cancer recurrences (local, regional, distant), second primary (non-) invasive (breast) cancers, and death of any cause. The study was designed to detect an increase of the ADFS in the 6-year versus the 3-year anastrozole group corresponding with a hazard ratio (HR) of 0.60. The HRs and the corresponding 95% confidence intervals (CIs) were estimated with stratified Cox proportional-hazard models according to intention-to-treat.

Results. Patients were randomized from July 2006 till August 2009. Three years after randomization 1663 patients had no DFS events, with an equal distribution between the treatment arms. The patient and tumor characteristics were well balanced. The median age at randomization was 57 years (P_5 = 45 years, P_95 = 76 years), the median primary tumor size was 21 mm (P_5 = 10 mm, P_95 = 50 mm), 67% of the patients had node-positive disease, and in 2% the tumor was HER2-positive (14% unknown); 64% of the patients had received adjuvant chemotherapy and <1% adjuvant trastuzumab. The median adapted follow-up was 4.1 years (P_5 = 2.9 years, P_95 = 5.8 years). No unexpected safety issues were seen. The 5-year ADFS was 79% in the 3-year and 83% in the 6-year anastrozole treatment group, yielding a HR for ADFS-event of 0.78 (95% CI 0.61 to 1.00; p = 0.0528). In patients with node-positive disease (N = 1117), the HR for ADFS-event was 0.71 (95% CI 0.53 to 0.96; p=0.0232), in N0 disease (N=546) 1.01 (95% CI 0.62 to 1.63; p=0.9817) and in patients with both ER and PR positive breast cancer (N = 1264) 0.68 (95% CI 0.51 to 0.90; p=0.0072). The 5-year adapted overall survival was not different between the treatment groups.

Conclusion. These findings do not yet support the use of extended adjuvant AI prescription after 5 years of sequential endocrine therapy for postmenopausal patients with hormone receptor-positive breast cancer, but suggest benefit for a selected group of patients. Continued follow-up is needed to assess long-term efficacy and safety.

Title: Optimal duration of extended letrozole treatment after 5 years of adjuvant endocrine therapy; results of the randomized phase III IDEAL trial (BOOG 2006-05)

Blokh EJ J, van de Velde CJH JH, Meershoek-Klein Kranenbarg EM M, Putter H, van den Bosch J, Maartense E, van Leeuwen-Stok AE, Liefers G-J, Nortier JWR WR, Rutgers EJT JTh and Kroep JR R. Leiden University Medical Center, Leiden, Netherlands; Leiden University Medical Center, Leiden, Netherlands; Leiden University Medical Center, Leiden, Netherlands; Albert Schweitzer Hospital, Dordrecht, Netherlands; Reinier de Graaff Hospital, Delft, Netherlands; Dutch Breast Cancer Research Group, Utrecht, Netherlands and Netherlands Cancer Institute, Amsterdam, Netherlands.

Body: Despite the success of adjuvant endocrine therapy in early breast cancer, approximately 50% of all recurrences still occur after the initial 5 years of follow-up. Earlier studies confirmed that endocrine therapy extension after 5 years of adjuvant tamoxifen with either tamoxifen or aromatase inhibitors up to 10 years leads to an improvement in survival. However, aromatase inhibitors are currently standard of care in the initial 5 years of adjuvant therapy, and the benefit of extended use beyond 5 years of AI based therapy is still debated. The randomized phase III IDEAL trial was designed to study the optimal duration of extended adjuvant endocrine therapy after the initial 5 years of any endocrine therapy. Between April 2007 and November 2011, 1824 postmenopausal, HR-positive early breast cancer patients were included by 74 hospitals in the Netherlands. Enrolled patients earlier received 5 years of any endocrine therapy (87.9% AI based), completed this treatment no longer than 2 years before randomization, and did not have any recurrence at the moment of inclusion. The included patients were randomly allocated to either 2.5 or 5 years of extended letrozole (daily 2.5mg). Primary outcome was disease free survival (DFS), secondary endpoints were overall survival (OS), distant disease free survival (DDFS), contralateral breast cancer and safety.

Results & Discussion: Results will become available soon.
Title: A randomized, double-blinded, placebo-controlled clinical trial of extended adjuvant endocrine therapy (tx) with letrozole (L) in postmenopausal women with hormone-receptor (+) breast cancer (BC) who have completed previous adjuvant tx with an aromatase inhibitor (AI): Results from NRG Oncology/NSABP B-42

Mamounas EP P, Bandos H, Lembersky BC C, Geyer, Jr CE E, Fehrenbacher L, Graham ML L, Chia SL L, Brufsky AM M, Hennessy BT T, Soori GS S, Dakil SR R, Seay TE E, Wade, III JL L, McCarron EC C, Paik S, Swain SM M, Wickerham DL and Wolmark N. NRG Oncology/NSABP (NSABP Legacy Trials Are Now Part of the NRG Oncology Portfolio), Pittsburgh, PA; UF Cancer Center at Orlando Health, Orlando, FL; University of Pittsburgh, Pittsburgh, PA; The University of Pittsburgh Cancer Institute, Pittsburgh, PA; Massey Cancer Center, Virginia Commonwealth University, Richmond, VA; Kaiser Permanente Oncology Clinical Trials Northern California - Vallejo, Vallejo, CA; Southeast Cancer Control Consortium, Goldsboro, NC; British Columbia Cancer Agency (BCCA), Vancouver, BC, Canada; Cancer Trials Ireland (Formerly known as Irish Clinical Oncology Research Group - ICORG), Dublin, Ireland; Missouri Valley Cancer Consortium, Omaha, NE; CCCOP, Wichita Cancer Center of Kansas, Wichita, KS; Georgia NCI Community Oncology Research Program, Atlanta, GA; CCOP, Central Illinois, Decatur, IL; MedStar Franklin Square Medical Center, Weinberg Cancer Institute, Baltimore, MD; Severance Biomedical Science Institute and Yonsei University College of Medicine, Seoul, Korea; Lombardi Comprehensive Cancer Center, Georgetown University Medical Center, Washington, DC and Allegheny Health Network Cancer Institute, Pittsburgh, PA.

Body: Background: Extending adjuvant endocrine therapy (tx) after 5 yrs of tamoxifen (Tam) with either Tam or an AI improves disease-free survival (DFS) in early-stage breast cancer (BC). However, optimal duration of adjuvant AI tx beyond 5 yrs is unknown. NSABP B-42 aimed to determine whether 5 yrs of letrozole (L) v placebo (P) improves DFS in patients (pts) who have completed 5 yrs of hormonal tx (with either AI or TAM→AI).

Methods: Postmenopausal pts with stage I-III, hormone-receptor (+) BC, disease-free after 5 yrs of either AI or Tam for ≤3 years→AI for the remainder of 5 yrs, were randomized to L 2.5 mg or P daily for an additional 5 yrs. Stratification was by pathological nodal status, prior adjuvant Tam or not, and baseline dexa T scores (>2.0, ≤2.0 SD). Primary endpoint was DFS including local, regional, distant recurrence (DR), secondary primary cancers, and deaths from any cause as first event. Secondary endpoints included overall survival (OS), BC-free interval (BCFI including recurrence or contralateral BC as first event), DR, osteoporotic fractures (OF), and arterial thrombotic (AT) events. Differences in DFS, OS, BCFI, DR, OF, and AT between L and P were assessed by the stratified log-rank tests and Cox proportional hazards models. Statistical significance level for DFS was set at 0.0418 as per statistical plan.

Results: From 9/06-1/10, 3966 pts were randomized (34% were <60 yrs, 57% were node-negative, 39% received prior TAM, 14% were HER-2 neu positive). Median follow-up for 3923 pts included in efficacy analyses was 6.9 years. As of 8/16, 631 DFS events occurred (L=292, P=339); L did not result in statistically significant increase in DFS v P (HR=0.85; 95% CI 0.73, 0.99; P=0.048), even after adjusting for age or surgery type; 7-yr DFS was L=84.7% and P=81.3%. There were no significant interactions between treatment and stratification variables. 310 deaths occurred (L=164, P=146); there was no statistically significant difference in OS with L or P (HR=1.15, 95% CI 0.92, 1.44; P=0.22); 7-yr OS was L=91.8% and P=92.3%; 306 BCFI events occurred (L=127, P=179); L v P resulted in a statistically significant 29% decrease in BCFI events (HR=0.71, 95% CI 0.56, 0.89; P=0.003); 7-yr cumulative incidence (Cln) of BCFI was L=6.7% v P=10%; 175 DRs occurred (L=73, P=102); L v P resulted in a statistically significant 28% reduction in DR (HR=0.72, 95% CI 0.53, 0.97; P=0.03). There were 169 OF (L=91, P=78). There were no significant differences in time to OF with L v P (P=0.27). Cln of OF through 7 yrs was L=5.4% v P=4.8%. There were 127 AT events (L=69, P=58). Treatment with L did not result in an overall statistically significant increase in AT events compared to P (P=0.33). Cln of AT through 7 yrs was L=3.9% v P=3.3%.

Conclusions: After 5 yrs of an AI or TAM→AI, the beneficial effect of extended tx with 5 yrs of L on DFS did not reach statistical significance. There was no significant improvement in OS with L but L provided a significant improvement in BCFI and DR.

Title: Immune sculpting of the triple negative breast cancer genome

Karn T, Jiang T, Hatzis C, El-Balat A, Holtrich U, Becker S, Bianchini G and Pusztai L. Goethe University, Frankfurt, Germany; Yale Cancer Center, New Haven, CT and San Raffaele Scientific Institute, Milan, Italy.

Body: Background: Tumors with infiltrating lymphocytes (TIL) demonstrate a better prognosis particularly in TNBC and HER2 positive breast cancer. Two competing hypothesis predict contrasting relationships of TILs and genomic heterogeneity. On one hand, a strong immune response may lead to “pruning” of intratumor heterogeneity by eliminating immunogenic clones resulting in a near equilibrium, hence better prognosis, while cancers that escape the surveillance may evolve towards greater clonal heterogeneity and genomic complexity. In some cancers, the predicted neoantigens are less frequent than expected by chance also suggesting immune mediated elimination of neoplastic clones (Rooney et al. 2015). Studies also showed an inverse association between immune cell infiltration and intratumor clonal heterogeneity (Morris et al. 2016). On the other hand, cancers with greater genomic instability and mutational burden will have larger clonal heterogeneity and therefore more neoantigens and greater immune infiltration. Indeed, a positive correlation between overall mutation load and immune activity in the tumor microenvironment was observed in pooled data across a broad range of cancer types (Brown et al. 2014, Rooney et al. 2015, Schumacher and Schreiber 2015).

Methods: We assessed these two competing hypothesis and examined the relationship between genomic complexity and immune gene expression in different breast cancer subtypes. We used previously described immune metagene expression (DNA microarray n=655) as measures of immune infiltration in the TCGA data set (RNA-Seq n=1215). We compared somatic mutations, mutation count, neoantigen load, clonal heterogeneity metrics and the distribution of mutations in 119 canonical cancer genes and 12 cancer pathways between good and poor prognosis TNBC (n=208) corresponding to high and low immune infiltration.

Results: A positive but weak correlation between mutation count and immune metagene expression was observed when all breast cancer subtypes were analyzed together (P=0.08). This was driven by the generally higher mutation count and immune infiltration in TNBC. When TNBC was analyzed separately, good prognosis TNBC with high immune infiltration had lower total mutation count (P=0.021) and predicted neo-antigen count (P=0.035). Clonal heterogeneity was also lower in good prognosis TNBC (P=0.001). There was a strong inverse relationship of dispersion in mutation variant allele frequencies and immune metagene expression. CASP8 was the top enriched mutation in TNBC with high immune infiltration (P=0.007 with no adjustment for multiple testing).

Conclusions: High immune infiltration is associated with reduced intratumor heterogeneity in TNBC suggesting immune sculpting of the tumor and a near equilibrium between the cancer and immune surveillance. Surgical resection of the primary tumor may tilt the balance towards the immune system resulting in the better prognosis of high-TIL TNBC. TNBC with low immune infiltration has greater clonal heterogeneity and mutation load and may represent the consequence of escape from immune surveillance. Mutation of CASP8 may be one way to evade tumor cell killing in high-TIL TNBC as previously noted.

Title: Prognostic associations of tumor-infiltrating lymphocytes (TIL) in metastatic HER2-positive breast cancer (BC) treated with trastuzumab and pertuzumab: A secondary analysis of the CLEOPATRA study

Luen S, Salgado R, Stephen F, Peter S, Jennifer E-W, Emma C, Astrid K, Sandra SM M, Jose B, Stefan M and Sherene L. Peter MacCallum Cancer Centre, University of Melbourne, Melbourne, Victoria, Australia; Institut Jules Bordet, Brussels, Belgium; Gustave Roussy, Villejuif, France; Washington Cancer Institute, Georgetown University, Washington DC; Memorial Sloan Kettering Cancer Centre, New York; Roche Products, Welwyn, United Kingdom; Genentech, South San Francisco and Oncology Biomarker Development, Roche, Basel, Switzerland.

Body: Background
The presence of stromal TILs (sTILs) is associated with a better prognosis with anti-HER2 therapy in primary HER2-positive BC. The prognostic value of TILs in the advanced setting with pertuzumab-based therapy is unknown.

Methods
The CLEOPATRA trial randomly assigned 808 patients with metastatic HER2-positive BC to receive pertuzumab or placebo in combination with trastuzumab and docetaxel. We evaluated %TILs using our previously described method. For concordance evaluation, 40 slides from metastatic samples were independently analysed by two pathologists. TILs were examined for associations with clinicopathological factors, progression-free survival (PFS), overall survival (OS), and treatment interactions using Cox regression models fitting sTILs as a continuous variable (per 10%) adjusting for treatment arm, age, estrogen receptor (ER) status, PIK3CA genotype, and visceral vs. non-visceral disease at screening.

Results
Tumour samples from 678 (84%) participants were available. 519 (76.5%) were archival and 155 (22.9%) were obtained fresh, ≤45 days prior to study treatment start. Median follow-up for OS was 50 months, with 519 PFS events and 358 deaths. 54% of patients were treatment naïve i.e. had not received prior chemotherapy nor trastuzumab. The median sTIL level was 10% (1-95%). sTIL evaluation was highly concordant between pathologists (R=0.93). Fresh vs. archival samples had significantly lower sTILs (10% vs 15%, p=0.0004). sTIL levels significantly differed by ethnicity (15% Asians, 10% white, 5% African-Americans, p=0.0007), but not age (p=0.26). Higher sTILs were observed in ER-negative vs. ER-positive tumors (15% vs 10%, p<0.001).

In the whole cohort for PFS, higher sTIL levels trended towards a better outcome independent of treatment (adjusted HR:0.95, 95%CI:0.90-1.00, p=0.06). For OS, the prognostic effect of sTILs reached statistical significance, with each 10% increase in sTILs associated with an 11% reduction in the risk of death (adjusted HR:0.89, 95%CI:0.83-0.96, p=0.001). The prognostic effect was observed independent of treatment arm, ER status, PIK3CA genotype, prior treatment or presence of visceral disease at screening, and in both fresh and archival tissue samples.

There was no significant interaction (int) between pertuzumab and sTILs for PFS (Pint=0.4) nor OS (Pint=0.6). There were no significant interactions between pertuzumab and sTILs for OS in subgroups of PIK3CA mutated (Pint=0.2) or PIK3CA WT (Pint=0.2), nor treatment naive (Pint=0.3) vs prior treatment (Pint=0.5).

The 5-year estimates of OS according to median ≤10% vs >10% sTILs in the placebo arm were 26% (95%CI:19-37) vs. 39% (95%CI:32-48), while in the pertuzumab arm 42% (95%CI:33-53) vs. 56% (95%CI:47-66) respectively.

Conclusion
In advanced HER2-positive disease, sTILs are still evident, though at lower levels, but are nevertheless significantly associated with prognosis, with effects stronger for OS than PFS. This suggests that the influence of anti-tumour immunity persists in the advanced first line setting and that enhancement by immunotherapeutic approaches could potentially further improve survival.
Title: Evaluation of tumor-infiltrating lymphocytes (TILs) as predictive and prognostic biomarker in different subtypes of breast cancer treated with neoadjuvant therapy - A metaanalysis of 3771 patients

Body: Background: Tumor-infiltrating lymphocytes (TILs) have been shown to be predictive for response to neoadjuvant therapy, in particular in triple-negative and HER2 positive breast cancer, suggesting that subtypes of breast cancer are immunogenic. The role of TILs in luminal breast cancer as well as the impact on prognosis in the different subtypes is less clear. In this study we evaluated TILs in a total of 3771 breast carcinomas from 6 prospective neoadjuvant clinical trials and evaluated their relevance for pCR, DFS and OS in different molecular subtypes.

Methods: A total of 3771 tumors from the clinical studies GeparDuo, GeparTrio, GeparQuattro, GeparQuinto, GeparSixto, GeparSepto were evaluated for stromal TILs by standardized methodology. Data on pCR were available for all tumors, DFS and OS was available for 2560 tumors. Logistic regressions, Cox regressions and Kaplan-Meier analyses were performed. In addition, a combined analysis of pCR, survival and TILs in different subtypes was performed.

Results: In the complete cohort of 3771 tumors, increased TILs (>=60%) were observed in 19% of tumors, these tumors with >=60% TILs had a pCR rate of 44% (p<0.0005). Increased stromal TILs (>=60%) were observed in 30% of TNBC (n=906), in 19% of HER2+ tumors (n=1379) and in 13% of HR+/HER2- tumors (n=1366). In all three subtypes, increased TILs were significantly associated with increased pCR rates (p<0.0005). In univariate logistic regression analysis of stromal TILs as a continuous variable, a 10% increase in TILs increased the probability to achieve a pCR by 16% in TNBC (OR 1.16), 13% in HER2+ (OR 1.13) and 33% in HR+/HER2- (OR 1.31, p<0.0005 for all three groups). Similar results were observed in multivariate logistic regression (p<0.0005 for all three groups). In univariate Cox regression, increased TILs were associated with improved DFS survival in TNBC (HR 0.93 per 10% TILs, p=0.01) and HER2+ BC (HR 0.93 per 10% TILs, p=0.02). In luminal (HR+/HER-) tumors there was no effect of TILs observed on DFS (p=0.46). In the luminal group increased TILs were associated with reduced OS (HR 1.10 per 10% increase in TILs, p=0.01), and increased TILs (>=60%) were associated with worse survival in Kaplan-Meier analysis in luminal tumors (DFS: p=0.04, OS: p<0.0005). A detailed analysis of subgroups of luminal BC as well as the link to pCR will be presented.

Conclusion: Our results suggest that tumor-infiltrating lymphocytes are a strong predictive marker for response to neoadjuvant chemotherapy in all molecular subtypes, and this predictive effect is translated into a survival benefit in HER2+ BC and TNBC. In contrast, a survival benefit is not observed in luminal BC, suggesting a different biology of the immunological infiltrate in this subtype.
**Title:** Clinical implications of somatic mutations in post-menopausal early-stage estrogen receptor (ER)-positive HER2-negative breast cancer (BC): Results from the BIG 1-98 study

Loi S, Asher R, Lee CK K, Luen S, Savas P, Kammler R, Dell'Orto P, Blasi OM M, Demanse D, JeBailley L, Dolan S, Hackl W, Thuerlimann B, Viale G, Regan M and Colleoni MA A. Peter MacCallum Cancer Centre, Melbourne, Victoria, Australia; NHMRC Clinical Trials Centre, University of Sydney, Sydney, NSW, Australia; International Breast Cancer Study Group (IBSCG), Bern, Switzerland; European Institute of Oncology, Milan, Italy and Novartis Institute for BioMedical Research, Cambridge, MA.

**Body: Background**
Next generation sequencing (NGS) has revealed that ER+/HER2- BCs have diverse somatic copy number and mutation profiles but thus far the clinical relevance of such findings is unknown. We characterized the molecular alterations in post-menopausal primary BC patients treated in the BIG 1-98 adjuvant letrozole and tamoxifen study and evaluated their associations with prognosis.

**Materials and Methods**
NGS was used to genotype DNA from archival primary tumor blocks for 286 cancer-related genes. From 2706 available eligible samples (confirmed ER+, excluding HER2-positivity or neoadjuvant treatment, adequate DNA quality/quantity), a case-cohort design selected 764 samples: all distant relapses and a stratified sampling of non-relapses after 8yr median follow-up. Mutation prevalence and associations with clinicopathological factors (CP) as well as distant recurrence-free interval (DRFS) were analyzed using weighted tests and Cox regression models, with sampling weights to represent the ER+/HER2-negative trial population. Multivariable analyses were adjusted for tumor size, nodal status, grade and age.

**Results**
NGS data was available from 538/764 samples (70%), there were 140 (26%) distant relapses. Median sequencing depth was 483x. There was a mean of 11 mutations (1-46) per sample, with 25% having 13 or more mutations and no tumors without a mutation.

Overall 28 genes were altered at a frequency of >10%. The most commonly mutated genes were *PIK3CA* (49.3%), *NCOR1* (27.2%), *MAP3K1* (23.8%) *TP53* (16.6%), *CCND1* (17.8%) and *GATA3* (17.1%).

Alterations that were significantly associated with both Luminal B (Ki67 >14%) and grade 3 included *TP53* mutations (p<0.001), *FGFR1* (p=0.001) and *MYC* amplifications (p=0.004).

Gene alterations that were significantly associated with shorter DRFS included *TP53* (HR:2.16), *ARID1A* (HR:2.43), *CHEK2* (HR:2.54), *BRCA2* (HR:1.93), *PTEN* (HR:2.03), *CCND1* (HR:1.82) and *FGFR1* (HR:1.78). *PIK3CA* was significantly associated with lower risk of distant relapse (HR:0.64; 0.43-0.97). Increasing number of total mutations was significantly associated with shorter DRFS (HR:1.04; 95% CI 1.01-1.07; p=0.006). In the multivariable model adjusted for CP factors, *ARID1A*, *BRCA2*, *CCND1*, *CHEK2* and *PTEN* remained independent for shorter DRFS.

Greater than 90% of *PIK3CA* mutations co-existed with another alteration, most common being *NCOR1* (29%), *MAP3K1* (24%), *CDH1* (16%), *GATA3* (16%), *TP53* (14%) and *CCND1* (13%). Patients with a *PIK3CA* mutation had greater benefit with letrozole over tamoxifen monotherapy (HR 0.32; 0.13-0.8) than those without (HR:0.70; 0.33-1.48) (Pint=0.06). This effect was strongest in the subgroup of *PIK3CA* mutant patients who were *CCND1* and *TP53* wild-type (HR:0.24, 0.12-0.48; Pint=0.02) with only 1% relapsing at 5 years.

**Conclusion:**
For the first time, we report the prognostic relevance of oncogenic mutations in ER+/HER2- postmenopausal early-stage BCs from a clinical trial. Tumors with *PIK3CA* mutations derived greater benefit from letrozole over tamoxifen monotherapy, especially if wild-type for *CCND1* and *TP53*. These findings could significantly improve prognostic risk classification and guide future clinical trials of targeted therapies in ER+/HER2- BCs.
Title: Breast cancer risks associated with mutations in cancer predisposition genes identified by clinical genetic testing of 60,000 breast cancer patients

Body: Clinical genetic testing panels are broadly used to gather information about cancer predisposition in individuals with personal and/or family history of breast cancer. However, the involvement of several of the genes on clinical testing panels in predisposition to breast cancer, such as MRE11A and RAD50, has recently come into question. In addition, accurate risk estimates for breast and other cancer are not well defined for the majority of genes on testing panels. We studied 60,000 women diagnosed with breast cancer who were tested for germline cancer predisposing mutations using hereditary cancer gene panels. Information on personal and family cancer history, age of diagnosis, and ethnicity of patients was obtained from test requisition forms. Greater than 90% met National Comprehensive Cancer Network HBOC testing criteria. To estimate gene-specific risks for breast cancer, case-control analyses were performed comparing the frequencies of pathogenic mutations from Caucasian cancer cases with frequencies from Caucasian, non-Finnish, non-TCGA controls from the Exome Aggregation Consortium (ExAC) database. Mutations were detected in 9% of breast cancer patients. Twelve genes displayed a significant association (p<0.05) with breast cancer. Nine of these genes, including ATM, RAD51D, NF1, and MSH6, were associated with moderate risk (RR>2.0) of breast cancer and three genes (BRCA1, BRCA2, PALB2) were associated with high risk (RR>5.0) of breast cancer. Cumulative age-dependent risk models were developed for each gene. This large clinical testing dataset of 60,000 women with breast cancer provides useful data for many predisposition genes previously lacking risk estimates, and should prove useful for clinical risk management of patients with inherited mutations in these genes.
Title: The landscape of somatic genetic alterations in BRCA1 and BRCA2 breast cancers

Introduction: Women carrying BRCA1 or BRCA2 germline mutations have a 45-80% lifetime risk of developing breast cancer (BC). BRCA1 and BRCA2 are perceived as bona fide tumor suppressor genes, whereby bi-allelic inactivation in tumor cells is required for tumorigenesis. Recent studies have indicated that loss of heterozygosity (LOH) of the wild-type allele of BRCA1 may be heterogeneous and constitute a late event. Therefore, additional somatic events prior to full BRCA1/2 inactivation may be required for tumorigenesis. Given that the somatic events that result in the development of BRCA1/2-BCs and their chronology are not understood, here we sought to define the genomic landscape of BRCA1/2-BCs and whether LOH of BRCA1/2 wild-type allele and/or mutations affecting additional tumor suppressor genes would be clonal or subclonal in these cancers.

Methods: We retrieved 29 BRCA1-BCs and 10 BRCA2-BCs from the Pathology Departments of the authors’ institutions. DNA extracted from microdissected tumor and normal breast samples was subjected to targeted capture massively parallel sequencing using either the MSK-IMPACT assay or an assay targeting all exons of 254 genes recurrently mutated in BC or related to DNA repair. Somatic single nucleotide variants, small insertions and deletions and copy number alterations affecting genes present in both sequencing assays (111 genes) were defined using state-of-the-art bioinformatics algorithms. ABSOLUTE and FACETS were employed to define clonal (i.e. present virtually in 100% of the cancer cells of a given case) and subclonal mutations and the presence of LOH of the BRCA1 and BRCA2 wild-type alleles.

Results: Our analysis revealed bi-allelic inactivation of BRCA1 in 28 of 29 BRCA1-BCs (93% harbored LOH of the BRCA1 wild-type allele and 3% harbored a second somatic BRCA1 pathogenic mutation). The only BRCA1-BC lacking bi-allelic inactivation of BRCA1 was an estrogen receptor-positive lobular carcinoma, lacking genomic features consistent with homologous recombination DNA repair defects, diagnosed at 62 years of age. Bi-allelic inactivation of BRCA2 was found in all cases (100% of harbored LOH of the BRCA2 wild-type allele). A clonal somatic 'second hit' resulting in bi-allelic inactivation of BRCA1 or BRCA2 was detected in 76% and 100% of BRCA1-BCs and BRCA2-BCs, respectively. In BRCA1-BCs, TP53 mutations were detected in 76% of cases, and these mutations were found to be clonal in 58% of cases. The repertoire of somatic mutations affecting BRCA1-BCs included clonal somatic mutations or homozygous deletions of known tumor suppressor genes, such as PTEN, RB1, CDKN2A and NF1. In contrast, only 10% of the BRCA2-BCs harbored TP53 somatic mutations. Though clonal somatic mutations in several cancer genes were detected, 40% of BRCA2-BCs had no mutations affecting the cancer genes analyzed.

Conclusions: Bi-allelic inactivation of BRCA1 and BRCA2 are frequent events in BRCA1-BCs and BRCA2-BCs, respectively. In a subset of BRCA1-BCs, however, the second 'hit' appeared to be subclonal, whereas mutations affecting TP53 and other tumor suppressor genes were clonal, supporting the notion that at least in a subset of these tumors, loss of the wild-type allele of BRCA1 may be preceded by inactivation of another tumor suppressor gene.
Title: Does BRCA status affect outcome in young breast cancer patients? Results from the prospective study of outcomes in sporadic and hereditary breast cancer (POSH)

Eccles DM M, Copson ER R, Maishman T, Tapper W, Cutress R, Gerty S, Stanton L, Altman DG G, Durcan L, Simmonds P, Decker B, Allen J, Luccarini C, Easton D, Dunning A and POSH Steering Group and Collaborators. Cancer Sciences Academic Unit and Southampton Clinical Trials Unit, Faculty of Medicine, University of Southampton and University Hospital Southampton Foundation Trust, Southampton, United Kingdom; Centre for Statistics in Medicine, University of Oxford, Oxford, United Kingdom; Strangeways Research Laboratories, Cambridge University, Cambridge, United Kingdom and POSH Steering Group and Collaborators.

Body: Background

Germline mutations in BRCA1/2 account for ~3% of breast cancer cases but >10% of young patients who present with triple negative (TN) breast cancer. Young age at diagnosis is also associated with an increased risk of recurrence and inferior survival compared to older patients. Numerous publications describe an increased incidence of adverse biological features in tumours from young breast cancer patients; however it is unclear whether these fully explain the poor outcome.

The effect of carrying a BRCA1/2 mutation on the prognosis of breast cancer remains controversial with retrospective studies reporting better, similar and worse outcomes for mutation carriers compared to patients with sporadic tumours. BRCA carriers could feasibly have enhanced or reduced sensitivity to certain chemotherapeutics; however retrospective studies are problematic due to missing data and biased ascertainment. POSH is multicentre prospective observational cohort study designed to investigate factors which affect prognosis in young breast cancer patients (Copson et al, JNCI, 2013). Here we report the pathology, treatment and outcome of patients with TN tumours as a preliminary analysis to determine the impact of a germline BRCA1 mutation on survival. The whole cohort analysis including BRCA1 and BRCA2 is in progress.

Methods

2956 patients aged ≤40 at breast cancer diagnosis were recruited from 127 UK oncology centres between 2000 and 2008. Patient characteristics, family history, risk factors, tumour pathology and treatment information, and blood DNA were collected at recruitment. Follow-up data were collected at 6 and 12 months, then annually. Summary statistics were used to describe patients by BRCA1 status. Kaplan-Meier estimates were used to describe univariate survival data.

Results

BRCA1 status is currently available for 542 patients with TN tumours. Pathogenic BRCA1 mutations were identified in 122 patients (BRCA1+); 420 had no BRCA1 mutation (BRCA1-). BRCA1+ were younger than BRCA1- (median age 34 vs 36 years, p<0.001) and more likely to have a positive family history (p<0.001). There were no significant differences between BRCA1+ vs BRCA1- for: median tumour size (20.8mm vs 23.0mm); tumour grade distribution (95.8% grade 3 vs 93.6%); nodal involvement (35.2% node positive vs 39.9%); or presence of metastases at diagnosis (0.0% vs 1.0%).

Median follow-up was 7.3 years. Overall survival of patients with stage 1-3 disease treated with anthracycline +/- taxane neoadjuvant chemotherapy (n=538; 151 deaths) was better for BRCA1+ vs BRCA1- (79.1% vs 73.6% at 5-yrs; HR[95%CI]=0.84[0.57,1.25], p=0.388). Distant disease-free survival (DDFS) was also higher for BRCA1+ (5-yr DDFS 76.1% vs 71.5%; HR[CI]=0.92[0.63,1.35], p=0.682). Moreover, survival after first distant relapse was better for BRCA1+ patients (41.9% vs 36.8% at 1-yr; HR[CI]=0.78[0.51,1.18], p=0.233).

Conclusions

Our prospective data show better survival in young BRCA1+ patients with early TN breast cancer treated with anthracycline/-taxane chemotherapy than BRCA1- patients. However, the difference between the groups was not significant in this partial sample. Results for the whole cohort will be available by the time of the meeting.
Title: RANK ligand as a target for breast cancer prevention in BRCA1 mutation carriers

Lindeman GJ J, Nolan E, Vaillant F, Branstetter D, Pal B, Giner G, Whitehead L, Lok SW W, Mann GB B, kConFab Consortium, Rohrbach K, Huang L-Y, Soriano R, Smyth GK K, Dougall WC C and Visvader JE E. The Walter and Eliza Hall Institute of Medical Research, Melbourne, VIC, Australia; The Royal Melbourne Hospital, Melbourne, VIC, Australia; The Victorian Comprehensive Cancer Centre, Melbourne, VIC, Australia; The University of Melbourne, Melbourne, VIC, Australia; Amgen Inc, CA; The Royal Women's Hospital, Melbourne, VIC, Australia; kConFab, Australia and QIMR Berghofer Medical Research Institute, Brisbane, QLD, Australia.

Body: Background: BRCA1 mutation carriers commonly undergo prophylactic mastectomy to reduce their risk of breast cancer. The precise role of chemoprevention with tamoxifen, which reduces the incidence of ER-positive breast cancer in the general population, is uncertain for BRCA1 mutation carriers, where uptake has been modest. The identification of an effective and acceptable prevention therapy therefore remains a 'holy grail' for the field. Precancerous BRCA1mut/+ tissue harbors an aberrant population of luminal progenitor cells and deregulated progesterone signaling has been implicated in BRCA1-associated oncogenesis. Since Receptor Activator of Nuclear Factor-kappa B ligand (RANKL) is a key paracrine effector of progesterone signaling, and RANKL and its receptor RANK contribute to mammary tumorigenesis, we investigated a role for this pathway in the preneoplastic phase of BRCA1 mutation carriers.

Methods: We explored a role for the RANK/RANKL pathway during the preneoplastic phase in freshly isolated (histologically normal) patient specimens from BRCA1 mutation carriers using several approaches. RANK and RANKL expression in breast cancer was evaluated in formalin fixed paraffin embedded (FFPE) archival sections by IHC from the kConFab and the Amgen Tissue Banks. All samples were obtained with patient consent and relevant IRB approval. A role for RANKL inhibition in attenuating tumor onset was studied using the MMTV-cre/Brca1fl/fl/p53+/- mouse model that recapitulates human basal-like breast cancer.

Results: We identified two subsets of luminal progenitors (RANK+ and RANK-) in histologically normal tissue of BRCA1 mutation carriers and found that RANK+ cells are highly proliferative, exhibit grossly aberrant DNA repair and bear a molecular signature similar to that of basal-like breast cancer. Moreover, high levels of RANK expression prevailed in established BRCA1-associated tumors. These data suggest that RANK+ and not RANK- progenitors are a key target population in these women. Notably, inhibition of RANKL signaling by denosumab in 3D breast organoids derived from pre-neoplastic BRCA1mut/+ tissue attenuated progesterone-induced proliferation. Furthermore, inhibition of RANKL with either the RANKL inhibitor OPG-Fc or a RANKL monoclonal antibody in a Brca1-deficient mouse model significantly curtailed mammary tumorigenesis, when compared to controls (p<0.001).

Conclusions: Together these findings identify a targetable pathway in a putative cell of origin population in BRCA1 mutation carriers and implicate RANKL blockade as a promising breast cancer prevention strategy.
Title: Efficacy and tolerability of veliparib (V; ABT-888) in combination with carboplatin (C) and paclitaxel (P) vs placebo (Plc)+C/P in patients (pts) with BRCA1 or BRCA2 mutations and metastatic breast cancer: A randomized, phase 2 study

Han HS Sook, Diéras V, Robson ME E, Palácová M, Marcom PK Kelly, Jager A, Bondarenko I, Citrin D, Campone M, Telll ML L, Domchek SM M, Friedlander M, Kaufman B, Ratajczak C, Coates A, Bonnet P, Qin Q, Qian J, Giranda VL L, Shepherd SP P, Isakoff SJ J and Puhalla S. Moffitt Cancer Center, Tampa, FL; Institut Curie, Paris, France; Memorial Sloan Kettering Cancer Center, New York, NY; Masarykův Onkologický ústav, Brno, Czech Republic; Duke University, Durham, NC; Erasmus MC Cancer Institute, Rotterdam, Netherlands; Dnepropetrovsk City Hospital, Dnepropetrovsk, Ukraine; Midwestern Regional Medical Center, Zion, IL; Institut de Cancérologie de l’Ouest, Saint Herblain, France; Stanford University School of Medicine, Stanford, CA; University of Pennsylvania, Philadelphia, PA; Prince of Wales Hospital, Sydney, NSW, Australia; Sheba Medical Center, Tel Hashomer, Israel; AbbVie, Inc, Chicago, IL; Massachusetts General Hospital, Boston, MA and University of Pittsburgh Cancer Institute, Pittsburgh, PA.

Body: Background: Poly(ADP-ribose) polymerase (PARP) inhibitors block DNA damage repair and may thereby enhance the clinical activity of DNA-damaging chemotherapy. Homologous recombination is defective in BRCA1/2-mutated tumors, leading to more error-prone mechanisms of DNA repair and increased sensitivity to PARP inhibition. V is a potent PARP inhibitor that enhances the antitumor activity of platinum agents in preclinical models. This phase 2 trial (NCT01506609) investigated the safety and efficacy of V+C/P or V+ temozolomide (TMZ) vs Plc+C/P in pts with locally recurrent or metastatic breast cancer harboring a BRCA1 or BRCA2 mutation. Results of the V+C/P and Plc+C/P arms are presented; V+TMZ results will be presented separately.

Methods: Pts ≥18 years with histologically confirmed locally recurrent or metastatic breast cancer were randomized 1:1:1 to: 1) V 40 mg BID D1–7+TMZ, 28-D cycle; 2) V 120 mg BID D1–7+C AUC 6, D3 and P 175 mg/m², D3, 21-D cycle; or 3) Plc BID D1–7+C/P. Key eligibility criteria included deleterious BRCA1/2 mutation, ≤2 prior chemotherapies for metastatic disease, no prior platinum agent, and no CNS metastases. Randomization was stratified by hormone receptor status, prior cytotoxic therapy, and ECOG PS. The primary endpoint was progression-free survival (PFS) per RECIST 1.1 of each V arm vs Plc+C/P by independent review. Primary analysis occurred at the 112th PFS event in the V+C/P and Plc+C/P arms. Overall survival (OS), objective response rate (ORR), tolerability, and quality of life were also evaluated.

Results: A total of 196 pts (193 BRCA+ per central lab) were randomized to receive double-blinded V+C/P (n=97) or Plc+C/P (n=99). Baseline demographics and disease characteristics were balanced across all treatment arms. Median study drug exposure was 10 cycles for Plc+C/P and 12 cycles for V+C/P. The V+C/P arm demonstrated numeric improvements for both PFS and OS compared to the Plc+C/P arm; improvement in ORR was statistically significant (Table 1). There was no meaningful increase of toxicity with addition of V. The most common treatment-emergent adverse events (AEs) with Plc+C/P or V+C/P were neutropenia (74%/74%), thrombocytopenia (70%/71%), and nausea (58%/71%). Grade ≥3 AEs in ≥30% of pts were neutropenia (55%/56%) and thrombocytopenia (26%/31%), respectively. There was no difference in the use of G-CSF with addition of V. Significant improvements in fatigue, pain, and insomnia (all P<0.05) were observed with V+C/P vs Plc+C/P.

Conclusions: This is the first randomized phase 2 trial of a PARP inhibitor in combination with platinum-based therapy for treatment of BRCA1/2-mutated advanced breast cancer. V+C/P demonstrated significantly higher ORR and symptom improvement compared to Plc+C/P, with nonsignificant trends for improved OS and PFS. Phase 3 trials are ongoing.

**Title:** DNA repair deficiency biomarkers and MammaPrint high1/(ultra)high2 risk as predictors of veliparib/carboplatin response: Results from the neoadjuvant I-SPY 2 trial for high risk breast cancer

**Body:**

**Background:** The PARP inhibitor veliparib in combination with carboplatin (VC) was one of the experimental regimens evaluated in the phase 2 neoadjuvant I-SPY 2 standing trial for high risk breast cancer patients. VC graduated in the triple negative (TN) signature. However, not all TN patients achieved pathologic complete response (pCR) and some HR+/HER2- patients responded. The I-SPY 2 biomarker component provides a platform for rigorous evaluation of mechanism-of-action-based markers in the context of established biomarkers (HR, HER2, MammaPrint) within the trial. Here, we report results from 5 investigator-submitted biomarker proposals and the MammaPrint High1/High 2 (MP1/2) classification as specific predictors of VC response.

**Methods:** Data from 116 HER2- patients (VC: 72 and concurrent controls: 44) were available. BRCA1/2 germline mutation was assessed by Myriad Genetics. 3 expression signatures relating to DNA damage repair deficiency (PARPi-7, BRCAness and CIN70) and MP1/2 classification were evaluated on Agilent 44K arrays. PARP1 levels were measured using reverse phase protein arrays. We used logistic modeling to assess biomarker performance. A biomarker is considered a specific predictor of VC response if it associates with response in the V/C arm but not the control arm, and if the biomarker x treatment interaction is significant (likelihood ratio test, p<0.05). In an exploratory analysis, we combined successful biomarkers to refine the ‘predicted sensitive’ group and used Bayesian modeling to estimate the pCR rates of ‘predicted sensitive’ TN and HR+/HER2- patients in each arm.

**Results:** BRCA1/2 germline mutation status associates with VC response, but its low prevalence in the control arm precludes further evaluation. Of the biomarkers evaluated, three (PARPi-7, BRCAness, and MP1/2) associate with response in the VC arm but not the control arm, and have biomarker x treatment interactions with p < 0.05 that retains significance upon adjusting for HR status. These signatures are only moderately correlated. When we combined the PARPi-7 and MP1/2 classifications using a simple voting scheme, the 40% of TN patients who are PARPi7-high and MP2 have an estimated pCR rate of 79% in the VC arm. In contrast, TN patients negative for at least one of these signatures (PARPi7-low and/or MP1) only have an estimated pCR rate of 35%. Only 9% of HR+/HER2- patients are PARPi7-high and MP2; but these patients also appear more responsive to VC with estimated pCR rates of 49%, compared to 13% in ‘biomarker-negative’ HR+/HER2- patients.

**Conclusion:** If verified in a larger trial, PARPi7, BRCAness and MP1/2 signatures may help refine predictions of VC response, thereby improving patient care. Evaluation of the combined signature for patients treated with platinum-based chemotherapy is ongoing.
Title: Sentinel node detection after neoadjuvant chemotherapy in patient without previous axillary node involvement (GANEA 2 trial): Follow-up of a prospective multi-institutional cohort

Classé J-M, Loaec C, Alran S, Paillocher N, Tunon-Lara C, Gimbergues P, Faure-Virelizier C, Chauvet M-P, Lasry S, Dupre P-F, Verhaeghe J-L, De Blaye P, Gutowski M, Barranger E, Lecuru F, Lefevre Lacoeuille C, Loussert L, Lambaudie E, Ferron G and Campion L. Institut Cancérologie de l'Ouest Centre Gauducheau, Saint Herblain, France; Institut Curie, Paris, France; Institut Cancérologie de l'Ouest Centre Papin, Angers, France; Institut Bergonié, Bordeaux, France; Centre Jean Perrin, Clermont Ferrand, France; Centre Leon Berard, Lyon, France; Centre Oscar Lambret, Lille, France; Institut Curie, Saint Cloud, France; Centre Hospitalier Universitaire Morvan, Brest, France; Institut de Cancerologie de Lorraine, Nancy, France; Centre Hospitalier Les Oudairies, La Roche sur Yon, France; Centre Val d'Aurelle, Montpellier, France; Centre Lacassagne, Nice, France; Centre Hospitalier Europeen Pompidou, Paris, France; Centre Hospitalier Universitaire, Angers, France; Centre Paul Stauss, Strasbourg, France; Institut Paoli Calmettes, Marseille, France and Institut Universitaire de Cancerologie Claudius Regaud, Toulouse, France.

Body: Background
Half of the patient treated with neoadjuvant chemotherapy (NAC) for a large operable breast cancer has no axillary lymph node involvement at the time of surgery. Sentinel lymph node detection (SLND), after NAC, is aimed to select patient who should be safely spared of an axillary lymphadenectomy (ALND). GANEA 2 is a French prospective multi institutional trial, aimed to assess SLND after NAC.

Objective
To assess the risk of relapse for patients without previous axillary node involvement treated with NAC followed with a SLND without a systematic lymphadenectomy.

Patients and Method
Inclusion: FIGO stage T1-T3 infiltrating breast carcinoma, indication of NAC.
Exclusion: inflammatory cancer, local relapse, contra-indication to NAC, NAC interrupted due to progressive disease.
Design: indication to plan a NAC, axillary sonography with fine needle cytology before NAC to select patients without lymph node involvement, SLND after NAC. ALND was mandatory in case of SLN involvement (macro or micro-metastasis) or SLND failure. Follow-up was scheduled with a medical visit / 6 months with axillary assessment and a mammography each year. Follow-up results are updated every 6 months.
Pathological analysis were carried out according to standard methods and classified according to the last American Joint Committee staging system.
Studied parameters were SLND detection rate, pathological results on breast specimen and nodes, rate of relapse (axilla, breast, metastasis), and survival.

Results
From July 2010 to February 2014, 587 patients were enrolled, from 17 institutions, and experienced breast tumor surgery and a SLND after NAC.
Each patient experienced breast surgery. A breast tumour pathological complete response was found in 21.3% (125/587). SLND rate was 97% (570/587), with a median number of 2 sentinel nodes (1-9).
Patients with a sentinel detection failure (n=17) experienced a systematic lymphadenectomy, without any involvement (n=13), a micro-metastasis (n=2) and a macro-metastasis (n=2).
A total of 140 patients had at least one sentinel node involved: macro-metastasis (n=86), micro-metastasis (n=54). A lymphadenectomy was performed in 128 cases: metastasis free (n=100), macro-metastasis (n=17), micro-metastasis (n=11).
A total of 430 patients had a SLN metastasis free (75% ;430/570). A not mandatory lymphadenectomy was performed (n=14): metastasis free (n=11), macro-metastasis (n=2) and micro-metastasis (n=1). 17 patients were lost to follow-up.
A total of 399 patients without sentinel node involvement were followed 2.3 years (from 0.5 to 5.6 yrs). At 3 years overall survival was 97.8% [94.9-99.1], disease free survival was 94.8% [91.0-97.1%]. Six patients died. Fifteen patients experienced a relapse: 8 metastasis, 4 homolateral breast, 2 contralateral breast, 1 homolateral axillary relapse.

Conclusion
This is the most important series of patients followed 2.3 years after SLND without axillary lymphadenectomy after NAC for an advanced breast cancer, showing acceptable results. The current series validate the safety of this conservative strategies avoiding systematic lymphadenectomy to patients without initially involved axillary node treated with NAC.
Title: A phase II, open-label, multicenter, translational study for biomarkers of eribulin mesylate: Evaluation of the utility of monitoring epithelial-to-mesenchymal transition (EMT) markers on tumor cells in the malignant plural effusion of patients with metastatic breast cancer (EXPECT-study)

Watanabe J, Ohtani S, Ikeda M, Takahashi M and Moriya T. Shizuoka Cancer Center, Shizuoka, Japan; Hiroshima City Hiroshima Citizens Hospital, Hiroshima, Japan; Fukuyama City Hospital, Fukuyama, Hiroshima, Japan; NHO Hokkaido Cancer Center, Sapporo, Hokkaido, Japan and Kawasaki Medical School, Kurashiki, Okayama, Japan.

Body: Background: Epithelial-mesenchymal transition (EMT) is considered a possible mechanism of distant metastasis or resistance of cancer cells to anticancer drugs. Several reports suggest that eribulin methylate (eribulin) promotes mesenchymal-epithelial transition (MET) both in vitro and in vivo and have shown its inhibition of distant metastasis of engrafted carcinoma. However, no reports have examined the effects of eribulin in a clinical setting. The EXPECT-study investigates EMT/MET markers in metastatic breast cancer (MBC) patients using pleural effusion as a method of liquid biopsy.

Objectives: In MBC patients with malignant pleural effusion, we attempted to establish EMT/MET markers using the cancer cells in the pleural effusion, to assess the efficacy and safety of eribulin monotherapy, and to verify the EMT/MET markers as biomarkers in eribulin monotherapy.

Study design and eligibility criteria: The EXPECT study is a multicenter, open-label, single-arm phase 2 translational study. Eribulin will be administered at 1.4 mg/m² on Days (D) 1 and 8 for a 3-week cycle (C), and to obtain the cancer cells from the pleural effusion before and after eribulin administration, paired chest drainage will be performed on C1D1 and C1D8. MBC patients, regardless of their subtype, with pleural effusion are eligible for enrollment, and eribulin monotherapy in the study will be administered based on clinical practice. Therefore, there are no special inclusion/exclusion criteria except for the requirement that all patients be naïve to eribulin.

Methods: Spun-down cancer cells in the plural effusion will be processed via the cell block method and embedded in paraffin. An immunohistochemical analysis will be performed using candidate antibodies for EMT/MET markers, such as E-cadherin, cytokeratin (CK) 19, and 34betaE12 (CK1, CK5, CK10, CK14) as epithelial markers and N-cadherin, vimentin, Snail, Slug, Twist-1, ZEB1, ZEB2, ALDH1, and HIF-1alpha as mesenchymal markers, which are all concurrently being assessed in another confirmatory study. The changes in EMT/MET marker expression between pre- and post-treatment will be measured, and the relationship between these changes and the clinical outcome, such as the clinical benefit rate (CBR), progression-free survival, and overall survival, will be assessed.

Present and target accrual: The study was just approved by the institutional review board in March 2016 and is open for enrollment. The target accrual is 48 patients total, or 4 patients per month. The sample size calculation was not based on statistical consideration, such as power or type I error. As an illustration for the analysis, the relationship between the changes in the EMT/MET markers and the clinical outcome may be investigated by comparing the CBRs in the two groups with substantial and small changes in the marker expression. If we demonstrate CBRs of 38% and 13% in each group, respectively, then statistical significance will be demonstrated with a 0.10 significance level (2-sided).
Title: A phase II trial of neoadjuvant docetaxel/cyclophosphamide followed by epirubicin/cyclophosphamide for triple-negative breast cancer

Tanaka N, Hirano A, Inoue H, Ogura K, Hattori A, Jibiki N, Yukawa H, Matsuoka A, Kodera A, Kamimura M, Naritaka Y and Shimizu T. Tokyo Women's Medical University Medical Center East, Tokyo, Japan; Tokyo Women's Medical University Yachyo Medical Center, Yachiyo, Japan and Tokyo Women's Medical University Medical Center East, Tokyo, Japan.

Body: Background
Currently, an anthracycline followed by a taxane as adjuvant or neoadjuvant chemotherapy is considered the most effective treatment for patients with triple-negative breast cancer. However, docetaxel followed by an anthracycline as neoadjuvant chemotherapy results in a higher rate of pathological complete response (pCR) than the regimen including an anthracycline followed by docetaxel (Iwata et al. Jpn J Clin Oncol 2011). Adjuvant docetaxel/cyclophosphamide (DC) treatment resulted in prolonged survival compared to adjuvant doxorubicin/cyclophosphamide. Therefore, we planned a phase II trial of DC followed by epirubicin/cyclophosphamide (EC) (Trial registration: UMIN000011031).

Trial design
This is a phase II trial to evaluate the efficacy and toxicity of DC followed by EC as neoadjuvant therapy for triple-negative breast cancer. Patients will receive four cycles of docetaxel (75 mg/m$^2$) and cyclophosphamide (600 mg/m$^2$) every 21 days, followed by four cycles of epirubicin (90 mg/m$^2$) and cyclophosphamide (600 mg/m$^2$) every 21 days.

Eligibility criteria
Patients with histologically diagnosed triple-negative breast cancer, T1–4, N1–3, or T2–T4, N0 based on a core needle biopsy, will be included in this trial. Eligible patients must be between 20 and 70 years of age with a performance status of 0–2 and adequate organ function. They must not have undergone any prior operation, radiation therapy, chemotherapy, endocrine therapy, or immunotherapy.

Specific aims
The primary endpoint is the pCR rate in the breast and axilla, and the secondary endpoints are the breast-conserving rate, toxicities, feasibility, and 5-year overall survival and relapse-free survival. pCR is defined as disappearance of invasive cancer cells, including those in the axilla, although the presence of residual intraductal cancer is acceptable.

Statistical methods
The sample size was calculated using the Simon method, with a type I error of 10% and a study power of 80%. The expected pCR rate is 25%, with a threshold pCR rate of 10%, and the required number of patients has been estimated to be 33.

Present and target accrual
Patient accrual within two medical centers was started in September 2013. We plan to enroll a total of 34 patients in the trial.
A phase II trial of neoadjuvant epirubicin/cyclophosphamide followed by weekly nanoparticle albumin-bound paclitaxel with trastuzumab for HER2-positive breast cancer

Kodera A, Hirano A, Inoue H, Ogura K, Hattori A, Sakaguchi S, Yukawa H, Matsuoka A, Tanaka N, Kamimura M, Jibiki N, Fujibayasi M, Naritaka Y and Shimizu T. Tokyo Women's Medical University Medical Center East, Tokyo, Japan; Tokyo Women's Medical University Yachyo, Medical Center, Yachiyo, Japan; Tokyo Women's Medical University Medical Center East, Tokyo, Japan and Tokyo Women's Medical University Medical Center East, Tokyo, Japan.

Body: Background

Paclitaxel (PTX) is a standard treatment for metastatic breast cancer (MBC) and it is often used as adjuvant and neoadjuvant chemotherapy for patients with early-stage disease. Nanoparticle albumin-bound (Nab)-PTX was also effective in patients with metastatic and early-stage. A comparison of weekly and triweekly nab-PTX regimens suggested that weekly nab-PTX resulted in superior progression-free survival. However, the optimal dose and schedule of weekly nab-PTX have not been determined. The efficacy and tolerability of epirubicin/cyclophosphamide (EC) followed by weekly nab-PTX (125 mg/m²) ± trastuzumab in node-positive breast cancer was determined in our previous trial. A high pathologic complete response (pCR) rate was obtained in HER2-positive patients. However, because nab-PTX administration was frequently postponed and discontinued, the optimal dose needs to be determined. In the previous trial, the median relative dose intensity of nab-PTX was 80% among patients with pCR. Therefore the dose of nab-PTX was reduced by 20% in this newly designed trial.

Trial design

This phase II trial aimed to evaluate the efficacy and toxicity of neoadjuvant EC followed by weekly nab-PTX with trastuzumab in patients with HER2-positive breast cancer. Patients will receive 4 cycles of epirubicin (90 mg/m²) and cyclophosphamide (600 mg/m²) every 3 weeks, followed by 4 cycles of nab-PTX (100 mg/m²) on days 1, 8, and 15, over a 28-day cycle. Fifteen cycles of trastuzumab (2 mg/kg, loading dose: 4 mg/kg) will be added to the nab-PTX regimen.

Eligibility criteria

Surgery and chemotherapy-naïve patients with pathologically confirmed T2-4 N0-3 invasive breast cancer, as diagnosed by core needle biopsy, are included. Eligibility criteria include age 20–70 years, a performance status of 0–2, and adequate organ function.

Specific aims

The primary endpoint is the pCR rate in the breast and axilla. Secondary endpoints include the breast conservation rate, toxicities, relative dose intensities, feasibility, and overall survival. A pCR is defined as the disappearance of invasive cancer cells, including in the axilla; residual intraductal cancer is acceptable.

Statistical methods

The sample size was calculated using the Simon method, with a type I error of 5% and a study power of 80%. The expected rate of pCR is 72% with a threshold pCR rate of 45%. The required number of patients was estimated to be 25.

Present and target accrual

Patient accrual within two medical centers began in May 2014. A final study population of 30 patients is expected (Trial registration: UMIN000013886).
VENTANA (SOLTI-1501): Oral metronomic vinorelbine combined with endocrine therapy in luminal/HER2-negative early breast cancer: A window of opportunity trial

Adamo B, Vidal M, Gomez Pardo P, Zaragoza K, Ciruelos E, Virizuela JA Antonio, Blanch Tormo S, Pérez-Fidalgo JA, Murillo L, Lopez-Gonzalez A, Amillano Parraga K, Martinez Jañez N, González Farré X and Prat A. Hospital Clínic de Barcelona, Barcelona, Spain; SOLTI Breast Cancer Research Group, Barcelona, Spain; Hospital Universitari Vall d'Hebron, Barcelona, Spain; Hospital Universitario 12 de Octubre, Madrid, Spain; Clínica Quirón Sagrado Corazón, Sevilla, Spain; Fundación Instituto Valenciano de Oncología, Valencia, Spain; Hospital Universitario 12 de Octubre, Madrid, Spain; Hospital Clínico Universitario de Valencia, Valencia, Spain; Hospital Clínico Universitario Lozano Blesa, Zaragoza, Spain; Hospital de León, León, Spain; Hospital Universitari Sant Joan de Reus, Reus, Tarragona, Spain; Hospital Universitario Ramón y Cajal, Madrid, Spain; Hospital Universitari General de Catalunya, Sant Cugat del Vallés, Barcelona, Spain and Translational Genomics and Targeted Therapeutics in Solid Tumors, IDIBAPS, Barcelona, Spain.

BACKGROUND

The CDK4/6 inhibitor palbociclib, in combination with endocrine therapy (ET), has been approved for patients (pts) with HR+/HER2- metastatic breast cancer (BC), suggesting that inhibition of the cell cycle in combination with ET is a strategy to keep exploring. In this context, vinorelbine (VNB) inhibits chromosome segregation during mitosis and blocks cells at G2/M. Interestingly, several metronomic schedules of VNB are being used in the clinical setting, a strategy that might not only affect cell-cycle but also aims to target tumor angiogenesis.

VENTANA is a “window-of-opportunity” trial designed to explore whether, similarly to CDK4/6 and mTOR inhibitors, oral metronomic VNB in combination with endocrine therapy induces a superior anti-proliferative effect than ET alone, as suggested by preclinical and clinical studies. We believe that a biological synergy of the combined treatment could open the door to include this treatment strategy in pts with BC as an alternative to CDK4/6 inhibitors.

METHODS

VENTANA is a phase 0 multicenter, three-arm, randomized clinical trial of oral metronomic VNB and letrozole (LET) versus either treatment alone in postmenopausal women with newly diagnosed, untreated HR+ and HER2-, stage I-III operable BC. Other eligibility criteria include primary tumor size \( \geq \) 1 cm (cT1-3) and N0-1, ECOG PS 0-1 and evaluable diagnostic tumor sample. Pts are randomized (1:1:1) to receive LET 2.5mg daily, oral VNB 50mg 3 days a week, or LET 2.5mg daily and oral VNB 50mg 3 times a week. After 3 weeks of treatment, pts will undergo surgery, and both pre-treatment and post-treatment surgical samples will be analyzed for gene expression. Primary objective is to test if oral metronomic VNB and LET induce a superior anti-proliferative effect than either drug alone in pts with early BC defined as Luminal by PAM50. This will be evaluated by the expression of 11 proliferative genes contained in the PAM50 subtype predictor (BIRC5, CCNB1, CDC20, CDCA1, CEP55, KNTC2, MKI67, PTTG1, RRM2, TYMS and UBE2C) as surrogate signature biomarker of its anticancer activity.

VENTANA is a proof-of-concept study to describe the change in the expression of a proliferation-related gene signature in all 3 treatment arms. Changes in the proliferation signature will be determined by following formula: Mean suppression of proliferation signature score = 100 \( \cdot \) [geometric mean (post treatment proliferation score / pre-treatment proliferation score \( \cdot \) 100)]. By evaluating other BC-related gene signatures (560 genes), the antiangiogenic and immunogenic potential of the treatment arms will also be compared and genes regulated in a treatment-specific manner identified. All analyses will be performed within the different PAM50-defined subtypes (Luminal, Luminal A or Luminal B).

As the primary endpoint is continuous and there are no previous data to make assumptions about the degree of suppression of these genes, the sample size has not been determined by statistical calculations. A sample size of 20 pts per arm is considered appropriate to support our hypothesis. The targeted accrual of 60 pts will be enrolled in 10 sites across Spain (EudraCT Number 2015-004714-24).
Title: PAINTER: Evaluation of eribulin tolerability and correlation between a set of polymorphisms and neuropathy in patients with metastatic breast cancer

Body: BACKGROUND Eribulin is a synthetic analogue of halichondrin B which inhibits microtubule dynamics. It has been approved in Europe for the treatment of locally advanced or metastatic breast cancer (mBC) progressed after at least two chemotherapy regimens for advanced disease. The most common adverse events (AEs) were fatigue, neutropenia and peripheral neuropathy, which occurs with an incidence ranging from 13.9% to 35%. It was severe only in a small proportion of patients, suggesting an individual susceptibility. The neurotoxicity mechanisms associated with microtubulin interfering agents have not been fully defined. Few studies reported an association between some SNPs (Single Nucleotide Polymorphisms) and microtubulin interfering agents-induced neuropathy, mainly taxanes. As the use of Eribulin becomes more widespread, a better knowledge of its safety profile, outside of clinical trials, is warranted. Given that Eribulin toxicity can result in treatment discontinuation, the ability to anticipate which patients will experience severe toxicity could allow for either early intervention or even possibly for prophylactic therapy, or for a better selection of patients eligible for treatment.

METHODS This is a multicenter, interventional, single-arm, phase IV study. The primary objective is the evaluation of the safety and tolerability profile of Eribulin in an unselected population of patients with mBC. Secondary objectives are the description of compliance to treatment and efficacy.

ENDPOINTS
• Incidence, time of onset, severity and duration of all AEs experienced during treatment with Eribulin, especially the most common reported in previous studies but also other possible unexpected toxicities.
• Association between a set of selected SNPs and the onset of any grade peripheral neuropathy. Specifically, 15 SNPs located in genes involved in microtubule dynamics or resulted from genome wide association studies, will be analyzed.
• Evaluation of quality of life during treatment using validated questionnaires.
• Assessment of dose intensity and dose schedule maintenance.
• DOT (Duration Of Treatment) and OS (Overall Survival).

STATISTICAL METHODS Summary statistics will be used in order to describe patient characteristics. Safety endpoints will be estimated by means of absolute and relative frequencies and associated 95%CI. The relationship between baseline variables and the risk of severe toxicity, as well as the relationship between SNPs and risk of neuropathy will be described by means of contingency tables and their association with outcome will be assessed by $\chi^2$ test of Mantel-Haenzel and a logistic regression model. DOT and OS will be described using Kaplan-Meier curves. A sample size of 200 patients will also allow us to get a good fitting for statistical analysis of the relationship between primary endpoint and not more than 10 factors. Regarding the relationship between SNPs and risk of neuropathy it will be feasible to screen for association about 10-15 SNPs, with known prevalence >15%.

PRESENT ACCRUAL AND TARGET ACCRUAL 98 of 200 patients were enrolled until 18/05/2016. Target accrual is open for 200 patients.

CONTACT INFORMATION Nicla La Verde: nicla.laverde@asst-fbf-sacco.it.
Body: BACKGROUND:
The PI3K/AKT/mTOR (PAT) pathway alteration has been strongly implicated in breast cancer and may contribute to resistance to available therapy. PQR309 is an oral pan-PI3K and mTOR inhibitor that penetrates the blood-brain barrier. Experiments of eribulin in combination with PI3K inhibitors in luminal and TNBC pre-clinical models enhanced antitumor activity.

TRIAL OBJECTIVES:
The primary objectives of the study are: to identify the maximum tolerated dose (MTD), evaluate the efficacy, safety and tolerability as well as the pharmacokinetics (PK) of PQR309 in combination with eribulin. In addition, exploratory objectives include assessments of: PAT pathway alterations prior to treatment, pharmacodynamics (PD) activity of PQR309 in combination with eribulin and correlation of PAT pathway alterations and PD activity with PQR309 and eribulin PK.

TRIAL DESIGN:
This is an open label, non-randomized, multicenter phase 1/2b clinical trial (dose escalation followed by expansion part) of PQR309 p.o. in combination with the standard dose of eribulin mesylate (1.4 mg/m2) in patients with LAMBC until progression or unacceptable adverse events (AE).

The dose escalation part of the study will first investigate PQR309 administered in a continuous daily (q.d.) and two intermittent treatment schedules in combination with standard administration of eribulin mesylate in patients with HER2 negative LAMBC following the “modified” 3 by 3 design. MTD is defined as the highest dose level at which ≤1 of 6 pts experiences dose-limiting toxicity (DLT) during the 1st cycle. After the MTD of PQR309 in combination with eribulin has been defined in all the three treatment schedules, one schedule will be selected, based on the overall evaluation of clinical data from the dose escalation part of the study, for further evaluation of efficacy in the expansion part of the study.

The expansion part of the trial applies Simon's MiniMax two-stage design. At the first stage, > 3 pts with TNBC with clinical benefit (CB) among 14 pts will be necessary to continue to the second stage. At the study end, > 9 pts with CB out of 28 pts are required to reject the null hypothesis. With this design, there is an 80% probability of a positive finding if the true clinical benefit rate (CBR) is ≥ 43% and a 5% probability of a positive finding if the true CBR is ≤ 21%.

ELIGIBILITY:
Women with HER2- LAMBC with two to 5 prior chemotherapy regimens in advanced disease. Adequate organ function and performance status. Phase II specific selection criteria are: triple negative LAMBC and RECIST v1.1 evaluable disease.

ACCRUAL:
Approximately 60 patients will be enrolled in approximately 10 sites
Recruitment opened in March 2016.

2016 San Antonio Breast Cancer Symposium

Publication Number: OT1-01-07

Title: A phase 2 study of eribulin followed by doxorubicin and cyclophosphamide as preoperative therapy for HER2-negative inflammatory breast cancer

Overmoyer B, Goel S, Regan M, Hirshfield-Bartek J, Schlosnagel E, Yeh E, Qin L, Bellon J, Nakhlis F, Jacene H and Winer E. Dana Farber Cancer Institute, Boston, MA and Brigham and Women's Hospital, Boston, MA.

Body: Background: HER2 negative(neg) inflammatory breast cancer(IBC) exhibits relative resistance to chemotherapy evidenced by pCR(pathologic complete response rate) rates of 12-25% with preoperative taxane/anthracycline regimens. Eribulin(Eisai®) inhibits microtubular function via sequestration of tubulin into nonfunctional aggregates, thus being effective against taxane-resistant cancer. Preclinical data shows 2 mechanisms of action: reversion of EMT(epithelial to mesenchymal transition) and normalization of tumor vascularity. Treatment of triple negative breast cancer(TNBC) cell-lines with eribulin results in downregulation of mesenchymal markers with concomitant increase in expression of classical epithelial markers(Yoshida BJC 2014). In PDX models, eribulin improved blood perfusion in central region of tumors, increased vessel density, reduced vessel diameter, and reduced hypoxia. IBC is highly angiogenic, with increased microvessel density, higher fraction of proliferating endothelial cells and greater expression of pro-angiogenic genes compared with non-IBC(McCarthy CCR 2002). This preoperative study(EAC) exploits the angiogenic properties of IBC with the treatment scheme of eribulin(E) followed by doxorubicin/cyclophosphamide(AC) in newly diagnosed HER2neg IBC.

Methods: Pts with HER2neg Stage III (cT4d,any N,M0) IBC are eligible if they have not received prior therapy for BC, have adequate organ function, cardiac ejection fraction ≥ 50%, and willing to undergo 2 research biopsies (rbx) of the affected breast. Following baseline rbx, pts receive cycle 1, day(d)1 eribulin 1.4 mg/m2. A 2nd rbx occurs on d8, prior to dosing of E. Following 3 more cycles of E(1.4mg/m2 d1,d8,every 21d), pts receive 4 cycles of dose-dense AC(A-60 mg/m2,C-600mg/m2 every 14d). Pts with adequate disease response undergo mastectomy/axillary lymph node dissection followed by chest wall/regional lymph node radiation. Adjuvant endocrine therapy is used if hormone receptor positive. An imaging sub-study evaluates tumor perfusion via DCE-MRI pre and post 1st dose E.

Correlatives: To investigate whether E induces reversion of EMT in IBC, expression of 10 EMT-related genes are determined in each rbx, and normalization of tumor vessel phenotype are assessed by expression of 15 angiogenesis-related genes in rbx by RT-qPCR. Gene expression will be repeated on residual tumor at mastectomy. An imaging sub-study of DCE-MRI (10 pts) will assess vascular remodeling via changes in K\text{trans}, v_e and v_p determination of IBC region of interest, core and rim and changes in the iAUC computed pre and post 1st dose E.

Statistics: The primary endpoint is pCR. A Simon two-stage design is used. If the proportion of pts having pCR is ≤ 0.10 then EAC is considered minimally effective, versus alternative hypothesis that EAC is worthy of further study if proportion pCR ≥ 0.30. In the 1st stage, if ≤ 2/16 pts have pCR, the study is stopped; if ≥ 3 pts have pCR, the study proceeds. In the 2nd stage, EAC is rejected if ≤ 4 of 25 pts have a pCR(α=0.10;β=0.10). Up to 25 pts will be enrolled. Secondary endpoints are residual cancer burden, disease-free survival, time to treatment failure and overall survival. Clinical trial information: NCT02623972.
Title: Intensified alkylating chemotherapy in patients with oligo-metastatic breast cancer harboring homologous recombination deficiency: The OLIGO study

Body: Background
Approximately 5% of patients with metastatic breast cancer survive more than 10 years. Long-term survival is mostly seen in patients with limited metastatic disease, often referred to as 'oligo'-metastatic disease. Oligo-metastatic breast cancer is variably defined as a maximum of 3-5 metastases beyond the regional lymph nodes. Some believe that oligo-metastatic cancer can be treated with curative intent using a multidisciplinary approach that targets the detected metastases, circulating micro-metastases, and any locoregional disease if present. Optimal patient selection is of vital importance.

Intensified alkylating chemotherapy in the treatment of breast cancer patients is controversial, as older studies have not shown a survival benefit in unselected groups of patients. More recent retrospective analyses, however, have suggested that patients with homologous recombination deficiency (HRD) derive significant benefit from intensified chemotherapy in comparison to conventional chemotherapy.

Trial design
In this phase 3 trial patients with oligo-metastatic breast cancer and HRD start with 3 cycles of induction chemotherapy. Chemotherapy schedule includes anthracyclines and taxanes in treatment naïve patients and is personalized according to previously received (neo-)adjuvant chemotherapy in others. Patients with at least stable disease after 3 cycles are 1:1 randomized to receive another 3 cycles of conventional chemotherapy or progenitor cell mobilization with cyclophosphamide followed by 2 cycles of intensified chemotherapy (carboplatin 400 mg/m2 (day 1&2), thiotepa 250 mg/m2 (day 2), and cyclophosphamide 3000 mg/m2 (day 1)) and peripheral blood progenitor cell reinfusion. Following systemic treatment, all patients receive maximal local therapy of locoregional and distant disease with surgery and/or radiotherapy.

Eligibility criteria
Eligible patients have histologically proven, HER2 negative, oligo-metastatic breast cancer (1-3 distant metastatic lesions), with or without locoregional disease, either as de novo disease or recurrence. All lesions must be amenable to surgery or radiotherapy with curative intent. The tumor has to be deficient in homologous recombination by array comparative genomic hybridization and no prior chemotherapy for metastatic disease is allowed.

Specific aim
To study the difference in event-free survival (EFS) between intensified alkylating chemotherapy compared to standard chemotherapy as part of a multimodality treatment approach in patients with oligo-metastatic breast cancer harboring HRD.

Statistical methods and patient accrual
Primary endpoint of the study is EFS at 3 years. Toxicity, time to recurrence, and overall survival will be evaluated as secondary endpoints. A total of 65 EFS events will provide 80% power to detect a hazard ratio of 2.0 between treatment arms at the 0.05 two-sided significance level. Assuming an accrual period of 48 months and a maximum follow-up time of 60 months, 86 patients are required. At the time of abstract submission, 33 patients were randomized.

Title: Feasibility and safety of avoiding granulocyte colony-stimulating factor prophylaxis during the paclitaxel portion of dose dense doxorubicin-cyclophosphamide and paclitaxel regimen

Body: Background: The need for granulocyte-colony stimulating factor (G-CSF) support during dose-dense (DD) paclitaxel (T) after doxorubicin and cyclophosphamide (AC) is unclear. Given that G-CSF is not devoid of adverse effects, and adds significant costs to treatment, we are examining the feasibility and safety of avoiding G-CSF during dose dense T. Methods: This is a single center, single-arm, phase II, two stage study. The primary aim is to evaluate the rate of T treatment completion within 7 weeks (from D1 of cycle 1 to D1 of cycle 4 of T) omitting Pegfilgrastim using pre-specified safety rules. Secondary aims include: characterization of the utilization of Pegfilgrastim using pre-specified safety rules in patients receiving dose dense T; evaluation of the safety of omitting routine Pegfilgrastim support in patients receiving dose dense T; evaluation of total cost ($ United States) of omitting routine Pegfilgrastim use during dose dense T. As a secondary aim we will evaluate the safety of simplifying the pre-medication regimen used for the T portion of the regimen (withholding corticosteroids in cycle 3 and 4 if no evidence of allergic reactions in cycle 1 and 2). A Simon Optimal design was selected with an overall one-side type I error of 10% and 90% power to detect the difference between unacceptable T completion rate (75%) and desirable completion rate (85%). In the first stage, 51 evaluable patients will be enrolled. If during the first stage, at any point, a total of 12 or more patients do not complete treatment within 7 weeks the trial will be closed permanently. Among the 51 patients enrolled after the first stage, if at least 40 patients complete treatment without dose delay, accrual will continue to the second stage where an additional 74 evaluable patients will be enrolled. If there are at least 100 among the 125 evaluable patients completing treatment without dose delay, the regimen will be considered worthy of further study. If during the second stage, at any point, a total of 26 patients do not complete treatment within 7 weeks the trial will be closed permanently and the study intervention will not be of clinical interest. If the true treatment completion rate is 75%, the chance the regimen is declared ineffective is 91% (exact alpha = 0.094) and if the true treatment completion rate is 85% the chance that the regimen is falsely declared ineffective is 10% (exact power = 0.899). The estimated accrual rate is 6-8 patients/month. Accrual started in April 2016. Clinical trial information: NCT02698891.
Title: Multi-center phase IB trial of ACY-1215 (Ricolinostat) combined with nab-paclitaxel in unresectable or metastatic breast cancer

Body: BACKGROUND:
HDAC6, a cytoplasmic histone deacetylase, targets non-chromatin substrates including tubulin, HSP90, and cortactin, playing an important role in cell-cell interactions, motility, chaperone function, and protein degradation. ACY-1215 (Ricolinostat) is an orally active, selective HDAC6 inhibitor. Preclinical studies have demonstrated ACY-1215 to have activity in breast cancer, synergistic cytotoxicity with taxanes, possibly due to combined effects on microtubule stabilization, and protective effects against neurodegeneration and potentially peripheral neuropathy. Analysis of human primary breast cancer gene expression data has identified a set of 162 genes corresponding to a HDAC6 master regulator (MR) score that correlates with IC50 or sensitivity to ACY-1215, and may serve as a potential biomarker.

TRIAL DESIGN:
This is an open-label, multicenter Phase 1b trial (NCT01323751) of ACY-1215 combined with nab-paclitaxel in unresectable or metastatic breast cancer. Patients will receive ACY-1215 daily for 21 days of each 28-day cycle in combination with nab-paclitaxel 100 mg/m2 on days 1, 8, and 15 until progression of disease or unacceptable toxicity.

KEY ELIGIBILITY CRITERIA:
Patients aged ≥ 18 years with unresectable or metastatic breast adenocarcinoma, measurable or non-measurable disease, an ECOG performance status of 0 to 1, baseline toxicities and symptoms grade ≤1, and at least 2 weeks since prior treatment.

STATISTICAL METHODS:
Dose escalations will be performed according to the time to event continual reassessment method (TITE-CRM), starting at 120 mg to a maximum dose of 240 mg. The maximum tolerated dose (MTD) will be identified as the dose level associated with a target probability of dose limiting toxicity (DLT) of 0.25. The TITE-CRM will use an empirical dose-toxicity model, with a sample size of 24. The dose-toxicity model is calibrated to select a dose that yields between 17 and 33% DLT, which will be the recommended phase II dose (RP2D).

OBJECTIVES:
The primary objective of this trial is to determine the MTD of ACY-1215 in combination with weekly nab-paclitaxel. Secondary objectives include the evaluation of safety and tolerability, progression free survival, overall response rate (measured by RECIST 1.1), and clinical benefit rate. Exploratory analyses will assess pharmacokinetics and pharmacodynamics, correlation of biomarkers including the HDAC6 score with response, and the effect of ACY-1215 on taxane-induced peripheral neuropathy.

ACCRUAL: Target Accrual is 24 patients.

Title: Randomized phase 3 study of a novel, long-acting G-CSF (eflapegrastim) versus pegfilgrastim in the management of chemotherapy-induced neutropenia in early-stage breast cancer patients receiving docetaxel and cyclophosphamide (TC) (ADVANCE study)

Schwartzberg LS S, Bharadwaj J, Peguero JA A, Vacirca JL L, Ibrahim EN N, Bhat G, Choi MR, McGregor K and Agajanian R. West Cancer Center, Memphis, TN; Oncology Consultants, Houston, TX; North Shore Hematology/Oncology Associates, East Setauket, NY; Beaver Medical Group, Highland, CA; Spectrum Pharmaceuticals, Irvine, CA; Samaritan Hematology and Oncology Associates, Corvallis, OR; The Oncology Institute of Hope and Innovation, Downey, CA and Pacific Cancer Medical Center, Anaheim, CA.

Body: Background: Eflapegrastim is a distinct biologic that uses an innovative, proprietary long-acting protein/peptide discovery technology (LAPSCOVERY™). Eflapegrastim consists of a novel, modified recombinant human G-CSF conjugated to the Fc fragment of IgG4 via a polyethylene glycol linker to produce a new, longer-acting G-CSF with a potentially unique distribution to areas rich in Fc receptors including its site of action in the bone marrow. A successful dose-finding Phase 2 trial including a pegfilgrastim control arm established the dose for a Phase 3 non-inferiority trial.

Trial Design: This is a randomized, open-label, active-controlled, multinational, multicenter, Phase 3 study comparing the efficacy and safety of eflapegrastim to pegfilgrastim. Patients (n=580) will be randomized in a 1:1 ratio to receive either eflapegrastim (equivalent to 3.6 mg G-CSF) or pegfilgrastim (equivalent to 6.0 mg G-CSF) once per chemotherapy cycle (up to 4 cycles), approximately 24 hours after chemotherapy. The primary endpoint is to compare the efficacy of a single dose of eflapegrastim with pegfilgrastim in patients with ESBC receiving TC, as measured by the Duration of Severe Neutropenia (DSN) in Cycle 1. Key secondary objectives include Time to Absolute Neutrophil Count (ANC) Recovery in Cycle 1; Depth of ANC Nadir in Cycle 1; incidence of Febrile Neutropenia. Safety and pharmacokinetics will also be assessed.

Eligibility Criteria: This study is enrolling histologically confirmed ESBC patients who are: eligible to receive adjuvant or neoadjuvant TC chemotherapy; at least 18 years of age, with adequate hematologic, renal and hepatic function. Patients will be excluded if they have: active concurrent malignancy or life-threatening disease; a known sensitivity or previous reaction to E. coli derived products or any of the products to be administered during study participation; concurrent adjuvant cancer therapy; locally recurrent/metastatic or contralateral breast cancer; previous exposure to filgrastim, pegfilgrastim, or other G-CSF products in clinical development prior to the administration of study drug; bone marrow or hematopoietic stem cell transplant or radiation therapy prior to enrollment, or are pregnant or breast-feeding.

Statistical Methods: The goal of this study is to demonstrate non-inferiority. For the Primary Efficacy Analysis, the mean DSN in Cycle 1 will be compared between the eflapegrastim and pegfilgrastim treatment arms. A 2-sided 95% confidence interval (CI) of the difference between the mean DSN of the eflapegrastim arm and the mean DSN of the pegfilgrastim arm will be calculated using bootstrap resampling with treatment as the only stratification factor. For the Secondary Efficacy Analyses, the results will each be summarized by treatment arm and cycle. The two-sided 95% CI for the difference between the treatment arms will be calculated.

Title: A phase II, multicenter, randomized trial of eribulin plus gemcitabine (EG) vs. paclitaxel plus gemcitabine (PG) in patients with HER2-negative metastatic breast cancer as first-line chemotherapy

Park YH, Im S-A, Sohn JH, Lee KS, Chae YS, Lee KH, Kim J-H, Im Y-H, Ahn JS, Kim T-Y, Lee K-H, Kim S-B, Ahn J-H, Kim GM, Park IH, Lee SJ, Han HS, Kim SH and Jung KH. Samsung Medical Center; Seoul National University Hospital; Yonsei Cancer Center; National Cancer Center; Kyungpook National University Medical Center; Chungbuk National University Hospital; Seoul National University Bundang Hospital and Asan Medical Center.

Body: Background: Metastatic breast cancer (MBC) is an incurable disease and is needed to improve effective chemotherapy. Paclitaxel plus Gemcitabine (PG) combination chemotherapy is one of the preferred chemotherapeutic regimens for patients with MBC, and was found to be proper as a maintenance chemotherapy regimen with survival benefit and feasible toxicity profile. Eribulin mesylate is a non-taxane inhibitor of microtubule dynamics of the halichondrin class of antineoplastic drugs. A recent pooled analysis of two phase II studies with eribulin showed improved overall survival in in various patient subgroups with advanced/metastatic breast cancer who had previously received an anthracycline and a taxane. Furthermore, eribulin may have rational benefit compared with paclitaxel in terms of neurotoxicity. Therefore, Eribulin plus Gemcitabine (EG) combination chemotherapy may have less neurotoxicity comparing to PG.

Trial Design: Prospective randomized phase 2, open-label, two-arm, multi-center study comparing EG chemotherapy with PG chemotherapy for patients with HER-2 negative MBC as first-line chemotherapy.

Eligibility Criteria: Histologically confirmed breast cancer patients, at least 19 years of age, with no prior history of chemotherapy for metastatic, recurrent breast cancer with evaluable lesions (as per RECIST, 1.1) who have adequate hematologic, renal, and hepatic function. Patients either may or may not have a prior anthracycline containing regimen. Prior hormonal therapy as a treatment of metastatic disease is allowed.

Specific Aims:
The primary efficacy endpoint of the trial is Progression-Free Survival (PFS). The secondary efficacy endpoints are: Time to Treatment Failure (TTF); Overall Survival (OS); neuropathic scale (FACT for Taxane QOL assessment); toxicity; duration of response; Objective Response Rate (ORR); Clinical Benefit Rate. The exploratory endpoint of the study includes pharmacogenetic profile.

Statistical Methods:
The initial sample size of the present study was determined based on the data derived from a previous trial on PG maintenance chemotherapy design; 6-month PFS is 70% for PG chemotherapy. This design was hypothesized that EG chemotherapy would not be inferior to PG chemotherapy. Thus, estimated PFS for each arm is 70%. Based on this estimate, we would plan to recruit a total of 100 patients (50 per arm). Considering drop-out rate of 10%, total 112 MBC patients planned to be enrolled.

Present Accrual and Target Accrual: Enrollment has been completed as of March, 2016 with a target enrollment of 112 patients.

Title: Phase II neoadjuvant trial of nanoparticle albumin-bound paclitaxel and trastuzumab in patients with node-negative, Her-2 positive breast cancer (OMC-BC04)

Body: Background: Neoadjuvant chemotherapy plus trastuzumab results in a 30% to 50% pathologic complete response (pCR) rate in HER-2 positive breast cancer and has been associated with improved therapeutic outcomes. Thus, the pCR rate can be useful in evaluating novel agents in this patient population. Albumin-bound (nab)-paclitaxel can reduce the toxicity of Paclitaxel while maintaining its efficacy. We reported that neoadjuvant therapy using Anthracycline based regimens (EC,AC,FEC) followed by a combination with nab-Paclitaxel and Trastuzumab was effective and safe by OMC-BC01 Study (Tanaka et al. Clin Breast Cancer 15:191-196). The pCR rate was 36% and 71% in the patients with estrogen receptor-positive and negative cancer, respectively. In addition, Tolaney et al. showed that adjuvant Paclitaxel and Trastuzumab for node-negative, HER-2 positive tumors measuring up to 3 cm in greatest dimension was associated with patients outcomes that were better than expected on the basis of historical data (Tolaney et al. N Engl J MED.2015 Jan 8:372(2):134-141). We conducted a clinical Phase II, multicenter, neoadjuvant trial of combination with nanoparticle albumin-bound Paclitaxel and Trastuzumab in patients with node-negative, Her-2 positive, estrogen receptor-negative breast cancer measuring up to 3 cm in greatest dimension.

Patients and Methods: nab-Paclitaxel and Trastuzumab as neoadjuvant therapy in patients with Her-2 positive, node-negative, estrogen receptor-negative breast cancer measuring up to 3 cm in greatest dimension. Patients are treated with neoadjuvant nab-Paclitaxel (260mg/m2) and Trastuzumab q21d x 4, and undergo surgery 4-6 weeks later from completing chemotherapy. The primary endpoint, pCR is defined as no evidence of invasive tumors in the final surgical sample both in the breast and axillary lymph nodes. Secondary endpoints include objective clinical response rate, histological response rate, disease-free interval, rate of breast conserving surgery, and the safety of the treatment.

Accrual: Presently, a total number of 1 patient have been included since start of the study. The expected end of accrual of 30 patients will be the last quarter 2018.
Title: Prospective evaluation of the predictive value of biomarkers with complete pathologic response using neoadjuvant chemotherapy plus trastuzumab + pertuzumab in Her2 (+) breast cancer patients with invasive tumors

Diaz-Cantón E, Jankilevich G, Denninghoff V, Elizalde P, Galanternik F, Bianconi MI, Recondo G and Storino C. Instituto Universitario CEMIC (IUC), Buenos Aires, Buenos Aires (Ciudad), Argentina; Hospital Carlos G Durand, Buenos Aires, Buenos Aires (Ciudad), Argentina and Instituto de Biología y Medicina Experimental (IBYME), Buenos Aires, Buenos Aires (Ciudad), Argentina.

Body: Preoperative treatment with anthracycline/taxane containing chemotherapy plus trastuzumab and pertuzumab (CT/T/P) is a standard treatment in patients with Her 2 (+) invasive breast cancer requiring systemic therapy. Patologic complete response (pCR) is strongly associated with disease free survival (DFS) in Her2 (+) tumors. We want to correlate immune, inflammatory, and genetic characteristics before and after neoadjuvant CT/T/P in the cohort of patients depicted above.

We plan to include 40 patients in 2 years in this pilot, prospective, observational and multicentric study. After signature of an informed consent a core biopsy is going to be undertaken. Before given any treatment, we are going to evaluate: stromal tumor infiltrating lymphocytes (sTILs), CD8, PD1, PDL1, the mutational status of PI3K and the status of the STAT 3 pathway. CT/T/P x 6 cycles is going to be administered followed by the corresponding surgery. Afterwards, the same biomarkers are planned to be measured in the surgical specimen. Correlation of each one of the biomarkers with pCR will be evaluated. Discrete variables will be evaluated by logistic regression, Categoric variables are planned to be studied with uni and multivariate analysis.

Upon completion of the enrrollement of the patients the analysis of DFS and overall survival will be pursued.

Title: Phase I multicenter clinical trial evaluating the combination of trastuzumab emtansine (T-DM1) and non-pegylated liposomal doxorubicin (NPLD) in HER2-positive metastatic breast cancer (MBC) (MEDOPP038 study)

López-Miranda E, Brain E, Saura C, Gilgorov J, Dubot C, Dieras V, Suter TM M, Aguirre E, Perez-García JM, Llombart A and Cortés J. Ramón y Cajal University Hospital, Madrid, Spain; Institut Curie / Hôpital René Huguenin, St Cloud, France; Vall d’Hebrón University Hospital, Vall d’Hebrón Institute of Oncology (VHIO), Barcelona, Spain; APHP Tenon, IUC-UPMC, Sorbonne University, Paris, France; Institut Curie, Paris, France; Bern University Hospital, Cardiology, Bern, Switzerland; Medica Scientia Innovation Research – MedSIR ARO, Barcelona, Spain; Baselga Institute of Oncology, Quiron University Hospital, Barcelona, Spain and Hospital Arnau i Vilanova, Valencia, Spain.

Body: BACKGROUND:
Clinical efficacy and safety of T-DM1 for the treatment of HER2-positive MBC has been assessed in several phase II and III trials and is now considered the standard of care in taxane-and trastuzumab-progressing patients. However, although T-DM1 has shown encouraging antitumor activity in the advanced setting, several strategies to improve T-DM1 efficacy are currently evaluated, including the combination with non-pegylated liposomal doxorubicin (NPLD), considering that: i) doxorubicin is one of the most active chemotherapeutic agents against HER2-positive breast cancer; ii) the combination of doxorubicin and trastuzumab induces synergistic antitumor activity in HER2-overexpressing preclinical models; and iii) liposomal formulations of doxorubicin have a reduced risk of developing cardiac toxicity.

OBJECTIVES:
The primary objective of this trial is to determine the maximum tolerated dose (MTD) of the combination of T-DM1 and NPLD in patients with HER2-positive MBC naïve of anthracyclines and previously treated with trastuzumab and a taxane. The secondary objectives include 1) safety, with special emphasis on cardiac safety evaluated by left ventricular ejection fraction, high-sensitivity troponin I and B-type natriuretic peptide (BNP) levels, 2) pharmacokinetics, 3) antitumor activity, and the 4) role of single nucleotide polymorphisms of HER2 gene for developing cardiotoxicity.

TRIAL DESIGN:
This is a dose-finding, open-label, non-randomized and multicenter phase I clinical trial of T-DM1 at a fixed dose of 3.6 mg/kg IV in combination with three different dose levels (DL) of NPLD (45, 50, and 60 mg/m²) IV administered on Day 1 every three weeks. The trial follows a modified dose escalation scheme with a 3+3 design. A total of three patients will be included in the first cohort and observed for dose-limiting toxicities (DLTs) during the first two cycles of treatment. If none of these patients experiences a DLT, three other patients will be treated at the next DL. However, in case of at least one patient experiences a DLT, three more patients will be treated at the same DL. The MTD will be defined as the highest DL at which ≤1 of six patients experiences a DLT during the first two cycles of treatment. An expansion cohort of six additional patients at the MTD will be included.

ELIGIBILITY:
Anthracycline-naïve patients with HER2-positive MBC and up to two prior chemotherapy regimens in the advanced setting who previously were treated with trastuzumab and a taxane. ECOG performance status of 0-1. Adequate organ and cardiovascular function with LVEF ≥ 55%. RECIST v1.1 evaluable disease.

ACCRUAL:
A total of 12-24 patients will be enrolled at four sites in Spain and France. Recruitment was opened on September 2015. To date, four patients (three at DL1 and one at DL2) have been recruited.
Title: The DETECT V-study – Comparison of dual HER2-targeted therapy with trastuzumab plus pertuzumab in combination with chemo- or endocrine therapy in patients with HER2-positive and hormone-receptor positive metastatic breast cancer

Polasik A, Schramm A, Friedl TWP WP, Rack B, Trapp E, Tzschaschel M, Fasching PA A, Taran F-A, Hartkopf A, Schneeweiss A, Müller V, Aktas B, Meier-Stiegen F, Wimberger P, Janni W and Fehm T. Gynecology and Obstetrics, University Hospital Ulm, Ulm, Germany; Gynecology and Obstetrics, Klinikum der Ludwig-Maximilians-Universität, Munich, Germany; Gynecology and Obstetrics, University Hospital Ulm, Ulm, Germany; Gynecology and Obstetrics, University Hospital Erlangen, Erlangen, Germany; Gynecology and Obstetrics, University Hospital Tübingen, Tübingen, Germany; University Hospital Heidelberg, Germany; Gynecology and Obstetrics, University Hospital Hamburg-Eppendorf, Hamburg, Germany; Gynecology and Obstetrics, University Hospital Essen; University Hospital Hamburg-Eppendorf, Hamburg, Germany; Gynecology and Obstetrics, Heinrich-Heine-Universität; Duesseldorf, Germany and Gynecology and Obstetrics, University Hospital Dresden, Technische Universität Dresden, Germany.

Body: Background: Maintenance of quality of life (QoL) is one of the main aims of treatment of incurable diseases such as metastatic breast cancer (MBC). In patients with HER2-positive MBC, taxan-based chemotherapy in combination with dual HER2 targeted therapy with trastuzumab and pertuzumab has shown promising efficacy results in terms of prolonged survival. However, cytostatic treatment is often accompanied by adverse events of grade 3 or higher, seriously impacting the patients’ QoL. In patients with HER2-positive and hormone-receptor positive MBC, the combination of trastuzumab with aromatase inhibitors was shown to be a safe and effective treatment option. The synergistic combination of dual HER2-targeted therapy with trastuzumab and pertuzumab plus endocrine therapy might offer an even better treatment option for these patients. DETECT V is the first prospective randomized phase III clinical trial comparing the safety and efficacy of the dual HER2-targeted therapy in combination with either endocrine therapy or chemotherapy.

Trial design and eligibility criteria: Women with HER2-positive and hormone-receptor positive MBC with first to third line therapy are 1:1 randomized either to a dual HER2-targeted therapy with Pertuzumab and Trastuzumab plus endocrine therapy or to the dual HER2-targeted therapy plus chemotherapy.

Specific aims: The primary objective of this study is to compare the safety and QoL in both arms, as assessed by the occurrence of AEs during the treatment period. We developed a modified adverse event score - including all adverse events grade 3 or higher, except neutropenia, which is included only if rated grade 4, and alopecia, rash, hand-foot-syndrome and peripheral neuropathy which are included if rated grade 2 or higher – in order to better reflect the clinical, physiological and psychological impact of AEs on patients’ QoL. Key secondary endpoint, besides the efficacy endpoints progression free survival (PFS) and overall survival, is to compare quality-adjusted survival (QAS), as measured using the quality-adjusted time without symptoms and toxicity (Q-TWiST) method, between both treatment arms. QAS as measured using the Q-TWiST method provides a single metric value that is a composite measure of quantity of survival time and quality of survival as assessed by the patients themselves. Q-TWiST analyses account for possible trade-offs between quantity and quality of life (e.g. prolonged time to progression at the cost of higher toxicity, which adversely affects QoL), and provide an excellent tool to evaluate whether two treatment options differ with regard to the overall perceived value to the patients.

Translational research projects focus on Circulating Tumor Cell (CTC)-enumeration (the presence of CTCs is not obligatory in DETECT V), prognostic role of CTC dynamics, and the assessment of marker expression on CTCs in order to calculate an endocrine responsiveness score which will be evaluated regarding its suitability to predict treatment success.

Contact: For further information on the DETECT V study please contact www.detect-studien.de or studienzentrale.ufk@uniklinik-ulm.de.

Publication Number: OT1-02-05

Title: Phase II clinical trial of neratinib in patients 60 and older with HER2 over-expressed or mutated breast cancer: Trial design considerations for older adults

Body: Background: This study addresses a key knowledge gap identified by the Institute of Medicine report on quality cancer care. Although there has been a growth in the number of targeted agents approved for the treatment of breast cancer, there are limited data regarding the efficacy, toxicity, and management of side effects in older adults. Neratinib is a potent oral small molecule tyrosine kinase inhibitor. Early clinical data have demonstrated the activity of neratinib in patients who have already progressed through HER2 targeted therapies. This study is designed to evaluate the tolerability and toxicity profile of neratinib in older adults with metastatic breast cancer (MBC) incorporating geriatric oncology design considerations.

Trial Design: This is an open label, single arm, phase II study of single agent neratinib in patients with HER2 positive MBC. Neratinib is given at 240mg orally in 28 day cycles. Unique factors of this geriatric oncology trial design include: 1) pre-treatment and on-treatment geriatric assessment; 2) additional nurse toxicity visits; 3) an algorithm for aggressive management of diarrhea; 4) measurements of the pharmacokinetics (PK) of neratinib; 5) inclusion of biomarkers of aging; 6) measurement of patient adherence; and 7) evaluation of quality of life.

Eligibility Criteria: Patients must be age ≥60 with histologically-proven HER2 positive MBC or MBC with HER2 receptor activating mutations. There is no limitation on the number of previous lines of therapy, but patients must have adequate organ and bone marrow functions, and a baseline LVEF ≥ 50%. Exclusion Criteria include: prior treatment with neratinib; major surgery within 28 days; uncontrolled cardiac disease; concurrent use of digoxin; or chronic diarrhea.

Specific Aims: The primary objective of this study is to identify the rate of grade 2 or higher toxicities attributed to neratinib in adult age ≥60 with HER2 over-expressing breast cancer. The secondary objectives are to describe the full toxicity profile (including all grades of gastrointestinal toxicities); to estimate the rate of dose reduction, holds and hospitalizations; to describe the PK parameters; to estimate the adherence rate to neratinib; and to estimate the overall response, clinical benefit rate, progression-free and overall survival. Furthermore, we will explore the role of a cancer-specific geriatric assessment and serum biomarkers of aging (IL-6, CRP, and D-dimer) in predicting treatment toxicities and PK parameters.

Statistical Design: We plan to enroll 40 patients age ≥60 (at least 5 patients age 75 years or older, and no more than 15 patients 60-70) in order to assure that our sample is representative of the entire age range of older adults. Given a sample size of 40 subjects, the widest half-width of the 95% confidence limits for the rate of grade 2 or higher toxicities will be less than or equal to 0.16. An interim analysis will be performed after 20 subjects have been on study for at least one cycle.

Accrual goal: 40

Title: HERMIONE: A phase 2, randomized, open label trial comparing MM-302 plus trastuzumab with chemotherapy of physician's choice plus trastuzumab, in anthracycline naive HER2-positive, locally advanced/metastatic breast cancer patients previously treated with pertuzumab and ado-trastuzumab emtansine (T-DM1)

Miller K, Cortes J, Hurvitz SA A, Krop IE E, Tripathy D, Verma S, Dionne M, Reynolds JG G, Wickham T, Molnar I and Yardley DA A. Indiana University Melvin and Bren Simon Cancer Center, Indianapolis, IN; Vall d’Hebron Institute of Oncology (VHIO) and Ramon y Cajal University Hospital, Barcelona and Madrid, Spain; University of California Los Angeles, Los Angeles, CA; Dana-Farber Cancer Institute, Boston, MA; MD Anderson Cancer Center; Sunnybrook Odette Cancer Centre, Toronto, Canada; Merrimack Pharmaceuticals, Inc., Cambridge, MA and Sarah Cannon Research Institute, and Tenesseee Oncology, PLLC, Nashville, TN.

Body: Background: Although HER2-targeted therapies such as pertuzumab and T-DM1 have improved patient outcomes for HER2-positive metastatic breast cancer (MBC), treatment resistance typically occurs. MM-302 is a HER2-targeted liposomal doxorubicin in development by Merrimack Pharmaceuticals. In a Phase 1 study, patients with HER2-positive MBC were treated with MM-302 alone and in combination with trastuzumab with or without cyclophosphamide. MM-302 had an acceptable safety profile, and promising efficacy was observed in patients not previously exposed to an anthracycline.

Trial design: HERMIONE (NCT02213744) is a randomized Phase 2, two-arm, open-label trial designed to evaluate if MM-302 can address an unmet medical need in patients with anthracycline naïve, trastuzumab-, pertuzumab- and T-DM1-pretreated HER2-positive locally advanced breast cancer (LABC)/MBC. Patients are randomized 1:1 to receive MM-302 (30mg/m^2, Q3W) plus trastuzumab (6mg/kg, Q3W) or chemotherapy of physician's choice (vinorelbine, capecitabine, or gemcitabine) plus trastuzumab (6mg/kg, Q3W).

Eligibility criteria: Centrally confirmed HER2-positive LABC/MBC, no prior anthracycline exposure, prior trastuzumab in any setting, prior T-DM1 in the LABC/MBC setting, prior pertuzumab in LABC/MBC setting or disease recurrence within 12 months of neoadjuvant/adjuvant treatment, unlimited prior lines of therapy, ECOG 0-1 and LVEF ≥50%. CNS metastases are permitted if stable and without symptoms or steroids for 4 weeks.

Specific aims: The primary endpoint is progression free survival (PFS) as assessed by an independent blinded review of tumor assessments. Secondary endpoints include investigator assessed PFS, overall survival, response rate, safety and patient related outcomes.

Statistics: 250 patients will be enrolled to observe 191 PFS events for 90% power to detect a Hazard Ratio of 0.625. The MM-302 arm will be compared to the control arm on the primary endpoint of PFS using a stratified log-rank test at one-sided 0.025 level.

Accrual status: First patient treated was in December 2014 and enrollment is expected to be complete in 2017. Sites are open in the US, Canada and Western Europe and are currently enrolling patients.

**Title:** SOPHIA: A phase 3, randomized study of margetuximab plus chemotherapy vs trastuzumab plus chemotherapy in the treatment of patients with HER2+ metastatic breast cancer

Rugo HS S, Pegram MD D, Gradishar WJ J, Cortes J, Curigliano G, Hong S, Wigginton JM M, Lechleider RJ J and Cardoso F. University of California, San Francisco, San Francisco, CA; Stanford School of Medicine, Stanford, CA; Robert H. Lurie Comprehensive Cancer Center of Northwestern University, Chicago, IL; Vall d'Hebron Institute of Oncology, Barcelona, Spain; Istituto Europeo di Oncologia, Milano, Italy; MacroGenics, Inc., Rockville, MD and Champalimaud Cancer Centre, Lisbon, Portugal.

**Body:** Background: Despite significant advances in targeted therapy, HER2+ metastatic breast cancer (MBC) remains incurable. Ideal treatment includes pertuzumab and trastuzumab in combination with a taxane in the first line setting, followed by ado-trastuzumab emtansine on progression. Optimal treatment regimens in the third and greater line of therapy are not defined, but continued anti-HER2 therapy is recommended. Margetuximab is a Fc-modified monoclonal antibody to HER2 that recognizes the same epitope on HER2 as does trastuzumab, with similar affinity. Margetuximab demonstrates increased affinity to the activating CD16A Fc-receptor found on NK cells and macrophages and decreased affinity to the inhibitory CD32B receptor compared to trastuzumab. In vitro studies showed enhanced antibody dependent cell-mediated cytotoxicity compared to trastuzumab. In a Phase 1 dose escalation and expansion trial, margetuximab showed single agent clinical activity against HER2+ tumors in patients previously treated with trastuzumab and other anti-HER2 agents. Methods: SOPHIA is a randomized, prospective study testing the hypothesis that margetuximab plus chemotherapy (CTX) is more effective than trastuzumab plus CTX in patients previously treated for HER2+ MBC. Sequential primary endpoints are centrally assessed progression free survival (PFS) and overall survival (OS). The study size of 530 patients is determined to have 80% power to detect a hazard ratio for OS of 0.75. Secondary endpoints are investigator assessed PFS and centrally assessed overall response rate. Eligibility includes prior treatment with trastuzumab, pertuzumab, and ado-trastuzumab emtansine; no more than 3 prior lines of therapy in the metastatic setting; prior demonstration of HER2+ status at a local reference laboratory; and absence of active brain metastases. Eligible patients are randomized 1:1 to receive CTX (physician's choice: capecitabine, eribulin, gemcitabine or vinorelbine) plus either margetuximab or trastuzumab until disease progression or toxicity. Antibody may be continued after stopping CTX in patients with responding or stable disease. **Progress to date:** The trial was initiated July 2015 and is ongoing in the US and Europe with planned expansion to Korea and Israel. ClinicalTrials.gov Identifier NCT02492711; EudraCT 2015-000380-13.
Title: A phase II single arm trial to assess the efficacy of ASLAN001 plus capecitabine in previously irradiated, progressing central nervous system (CNS) metastases for HER2+ breast cancer patients

Lee GE. National Cancer Centre Singapore, Singapore.

Body: Brain metastasis in breast cancer (BMBC) has always been associated with very poor prognosis with no current standard of treatment. Treatment options generally involve local control. Subsequent to local treatment, systemic control can be re-initiated via systemic therapies or trial participation. ASLAN001 has been shown to be active in pre-clinical tumor models. It is a potent, specific, adenosine triphosphate competitive inhibitor of the tyrosine kinases of the cell surface receptors (HER)-1, HER-2, and HER-4. It also has a pre-clinical safety profile consistent with its known pharmacology. A Phase 1 study using ASLAN001 in combination with capecitabine showed a response rate of 38% in 20 HER2+ breast cancer patients.

This is a single arm phase II study. 29 patients with previously irradiated, progressing brain metastases in Her2 positive breast cancer will be enrolled to receive ASLAN001 (400mg bd daily) and capecitabine (1000mg/m2 bd per day for day 1-14 of 21 day cycle). Treatment will continue until disease progression or unacceptable toxicity. Baseline brain imaging using either Magnetic resonance imaging (MRI) will be performed, with follow-up scans repeated every 2 cycles until progression. Non-brain imaging will also be performed at the same settings.

Specific Aims:
Evaluate the efficacy of ASLAN001 in combination with capecitabine in terms of CNS response
Evaluate the activity (clinical benefit) of ASLAN001 in combination with capecitabine in systemic disease (outside CNS)
Evaluate the tolerability of ASLAN001 in combination with capecitabine

Eligibility:
HER2 positive breast cancer patients with previously irradiated, progressing brain metastases.
Previously irradiated CNS metastases (WBRT or SRS or both).
Adequate end organ function.
No prior exposure to either lapatinib or capecitabine

Statistical Design:
In order to minimize the expected number of patients treated in the event that the regimen proves to be very disappointing or very successful; a two-stage design will be used for patient accrual (Simon 1989).

Stage 1 of accrual: 10 response evaluable patients will be entered in the first stage. Using response hypothesis of H0<5% and Ha>20%, we would reject the drug combination at the end of the first stage of accrual if less than 1 response was observed.

Stage 2 of accrual: Additional 19 patients will be accrued. We would accept the drug combination as active if 4 or more objective responses are observed from a total of 29 patients accrued.

Significance level and power: To test the null hypothesis that the response rate is <5% and rejects this in favour of the alternative hypothesis of response rate is >20%. The significance level (i.e., the probability of rejecting H₀ when it is true) is α=5% (1-tailed) and the power (i.e., 1-beta, the probability of deciding the regimen is active) is 80%. The expected sample size with this design is 29 using the optimal design criterion of Simon's two-stage method. At stage 1 (10 patients), at least 1 response needs to be seen in order to initiate stage two with the remainder of 19 patients. The trial will be positive if at the end 4 responses will be seen in the 29 patients.
Title: A phase 2 randomized, double-blinded, controlled study of ONT-380 vs. placebo in combination with capecitabine (C) and trastuzumab (T) in patients with pretreated HER2+ unresectable locally advanced or metastatic breast carcinoma (MBC) (HER2CLIMB)

Hamilton E, Borges V, Murthy R, Anders C, Cameron D, Carey L, Müller V, Curigliano G, Gelmon K, Hortobagy G, Krop I, Loibl S, Pivot X, Pegram M, Slamon D, Hurvitz S, Tsai M and Winer E. Sarah Cannon Research Institute, Nashville, TN; Tennessee Oncology, PLLC, Nashville, TN; University of Colorado Cancer Center, Aurora, CO; The University of Texas MD Anderson Cancer Center, Houston, TX; University of North Carolina at Chapel Hill, Chapel Hill, NC; Oncology, Edinburgh Cancer Centre Western General Hospital, Edinburgh, United Kingdom; University Medical Center Hamburg-Eppendorf, Hamburg, Germany; Drug Development, Istituto Europeo di Oncologia, Milano, Italy; British Columbia Cancer Agency, Vancouver Cancer Centre, Vancouver, BC, Canada; Dana-Farber Cancer Institute, Boston, MA; Medicine and Research, German Breast Group, Neu-Ilsenburg, Germany; Service Oncologie Medicale, CHU Besançon, Hôpital Jean Minjoz, Besançon, France; The University of California Los Angeles, Los Angeles, CA; U.C.L.A. School of Medicine, Los Angeles, CA; University of California, Los Angeles (UCLA), Los Angeles, CA and Virginia Piper Cancer Institute, Minneapolis, MN.

Body: Background: ONT-380 is a highly selective small molecule inhibitor of HER2 kinase with nanomolar potency. Unlike dual HER2/EGFR agents, it does not inhibit EGFR at clinically relevant concentrations, decreasing the potential for EGFR-related toxicities (severe skin rash and diarrhea). In preclinical studies, ONT-380 demonstrated synergistic activity with T, and was active in HER2+ models of brain metastases (mets). In a Phase 1b study, ONT-380 was combined with C and T in pts with HER2+ MBC previously treated with trastuzumab emtansine (T-DM1) and T. Objective responses were seen, including in pts with brain mets. The combination was well tolerated, with low rates of Gr 3 diarrhea at the recommended dose (300 mg PO BID, equivalent to the single agent MTD). Based on these data, ONT-380 is now being evaluated in a Phase 2 study in combination with C and T (HER2CLIMB).

Trial Design: The primary study objective is to assess the effect of ONT-380 vs. placebo given with C + T on progression-free survival (PFS) based on independent central review. Additional objectives include ORR, duration of response, clinical benefit rate, and safety. The study population includes adult pts with progressive HER2+ locally advanced or MBC who have had prior treatment with a taxane, T, pertuzumab and T-DM1 but not C or lapatinib. Pts with brain mets, including untreated or progressive mets, may be enrolled. 180 pts will be enrolled in North America and Europe. Pts are receiving C (1000 mg/m2 PO BID for 14 days of a 21-day cycle) and T (8 mg/kg IV loading dose; 6 mg/kg IV once every 21 days), and are being randomized in a 2:1 ratio to ONT-380 300 mg PO BID or placebo. Pts with isolated CNS progression may continue on study treatment after undergoing local CNS therapy. An independent Data Monitoring Committee is monitoring pt safety.
Title: A phase 2 study of poziotinib in patients with HER2-positive metastatic breast cancer (MBC) who have received prior HER2 regimens for MBC

Lathrop K, Lucas J, Vacirca JL L, Bhat G, Choi MR and Naughton M. The University of Texas Health Science Center at San Antonio, San Antonio, TX; Marin Cancer Care, Greenbrae, CA; North Shore Hematology/Oncology, East Satauket, NY; Spectrum Pharmaceuticals, Irvine, CA and Washington University, St Louis, MO.

Body: Background: Poziotinib is a novel, oral, quinazoline-based pan-HER inhibitor that irreversibly blocks signaling through the epidermal growth factor receptor (EGFR) family of tyrosine-kinase receptors, including EGFR (HER1/ErbB1/EGFR), HER2 (ErbB2), and HER4 (ErbB4), as well as HER receptor mutations. This, in turn, leads to inhibition of the proliferation of tumor cells that overexpress these receptors. It is well established that breast cancers are associated with a mutation in, or overexpression of, members of the EGFR receptor family. The primary objective of this Phase 2 study is to evaluate the Objective Response Rate (ORR) of poziotinib in patients with human epidermal growth factor receptor 2 (HER2)-positive MBC. The secondary efficacy variables are Progression-Free Survival (PFS), Disease Control Rate (DCR), Overall Survival (OS), and Time to Progression (TTP).

Trial Design: This is a Phase 2, open-label, multicenter study to evaluate the efficacy, safety and tolerability of poziotinib in patients with HER2-positive MBC who have received at least 2 prior HER2- directed treatment regimens. Each treatment cycle is 21 days in duration. During each cycle, eligible patients receive 24 mg of poziotinib orally (as three 8-mg tablets) once daily for 14 days, followed by a 7 day treatment-free period.

Eligibility Criteria: Eligible patients are at least 18 years of age, have confirmed HER2 overexpression, adequate hematologic, renal and hepatic function, and have received at least 2 prior HER2-directed therapy regimens, including trastuzumab and trastuzumab emtansine (TDM-1). Patients are excluded if they have prior exposure to poziotinib, a history of congestive heart failure, left ventricular ejection fraction <50%, unable to take oral medications, or have conditions that cause malabsorption. A 30 day wash out period from previous chemotherapeutic or radiation therapies is required.

Statistical Methods: The purpose of this study is to evaluate the efficacy of poziotinib compared to the efficacy of other standard HER2-positive breast cancer treatments as reported in the literature. The ORR will be analyzed descriptively along with the 95% CI. The secondary efficacy variables will be analyzed descriptively.

Contact Information: For more information or to refer a patient, email: spi-poz-201@sppirx.com or fax: 1-949-398-9711.
**Title:** The UK LORIS trial: Randomizing patients with low or low intermediate grade ductal carcinoma in situ (DCIS) to surgery or active monitoring

Francis A, Bartlett J, Billingham L, Bowden S, Brookes C, Dodwell D, Evans A, Fairbrother P, Fallowfield L, Gaunt C, Hanby A, Jenkins V, Matthews L, Pinder S, Pirrie S, Rea D, Reed M, Roberts T, Thomas J, Wallis M, Wilcox M and Young J. University Hospital Birmingham, Birmingham, United Kingdom; Ontario Institute for Cancer Research, Toronto, Canada; Cancer Research UK Clinical Trials Unit (CRCTU), Birmingham, United Kingdom; University of Leicester, Leicester, United Kingdom; St James's Hospital, Leeds, United Kingdom; University of Dundee, Dundee, United Kingdom; Independent Cancer Patients' Voice, England, United Kingdom; SHORE-C, Brighton and Sussex Medical School, Brighton, United Kingdom; University of Leeds, Leeds, United Kingdom; King's College London, London, United Kingdom; Brighton and Sussex Medical School, Brighton, United Kingdom; Western General Hospital, Edinburgh, United Kingdom and Addenbrooke's Hospital, Cambridge, United Kingdom.

**Body:**

**Background:** The independent review of the UK National Health Service Breast Screening Programme reported (The Lancet, Volume 380, Issue 9855, Page 1778, 17 Nov 2012) on the benefits and harms of breast screening. It concluded that breast screening saves lives and acknowledged the existence of overtreatment. It encouraged randomized trials to elucidate the appropriate treatment of screen-detected DCIS to gain a better understanding of its natural history. The LORIS trial addresses the possible overtreatment of low and low/intermediate grade screen-detected (low risk) DCIS by randomizing patients to standard surgical treatment or active monitoring, each with long term follow up.

**Trial Design:** LORIS is a phase III, multicentre, 2 arm study, with a built in 2 year Feasibility Phase, in patients confirmed to have low risk DCIS defined by strict criteria and determined by central pathology review. Patients will be randomized between standard surgery and active monitoring, with annual mammography. Patients will be followed up for a minimum of 10 years.

**Eligibility Criteria:**
1) Female, age ≥ 46 years
2) Screen-detected or incidental microcalcification (with no mass lesion clinically or on imaging)
3) Low risk DCIS on large volume vacuum-assisted biopsy, confirmed by central pathology review
4) Patient fit to undergo surgery
5) No previous breast cancer or ipsilateral DCIS diagnosis
6) Written informed consent

**Specific Aims:** The LORIS Trial aims to establish whether patients with newly diagnosed low risk DCIS can safely avoid surgery without detriment to their wellbeing (psychological and physical) and whether those patients that do require surgery can be identified by pathological and radiological means.

**Primary endpoint:** Ipsilateral invasive breast cancer free survival time

**Secondary endpoints:** Overall survival; mastectomy rate; time to mastectomy; time to surgery; patient reported outcomes; health resource utilisation and assessment of predictive biomarkers.

A digital image data repository and tissue bank will provide a prospective resource for both translational and imaging studies.

**Statistical Methods:** A total of 932 patients will be randomized to a non-inferiority design to test the null hypothesis that active monitoring of women diagnosed with low risk DCIS is not non-inferior in terms of ipsilateral invasive breast cancer free survival (iiBCFS) time compared to treatment with surgery. The iiBCFS time will be compared across the two arms on a per protocol and intent-to-treat basis, using a 1-sided ($\alpha=0.05$) log-rank test for non-inferiority. The iiBCFS rate is assumed to be 97.5% in the surgery arm at 5 years, utilizing 80% power to exclude a difference of more than 2.5% in the active monitoring arm.

**Present Accrual and Target Accrual:** 32 UK centres are open for the Feasibility Phase of the trial which is nearing completion. The web-based central pathology review process is functioning efficiently, with a one week maximum turn around. Registrations and sites randomizing patients are on or above target. Randomizations are currently approximately 70% of target. A total of 60 centres will open in the main trial.

**Contact Information:** For further information, please email the LORIS Trial Office LORIS@trials.bham.ac.uk.
Title: Cambridge brain mets trial 1 (CamBMT1): A proof-of-principle phase 1b / randomised phase 2 study of afatinib penetration into brain metastases for patients undergoing neurosurgical resection, both with and without prior low-dose, targeted radiotherapy

Baird RD D, Ramenatte N, Watts C, Jonson A, Jones L, Biggs H, Harrison E, Oberg I, Bullen G, Williams M, Qian W, Gilbert F, Jodrell D, Caldas C, Karabatsou K, Dunn L, Jena R, Whitfield G, Chalmers A, Jefferies S and Price S. Cambridge Cancer Centre - Breast Cancer Research Unit, Cambridge, Cambridgeshire, United Kingdom; Cambridge Clinical Trials Unit – Cancer Theme, Cambridge, Cambridgeshire, United Kingdom; Cambridge Cancer Centre - Early Phase Clinical Trials Team, Cambridge, Cambridgeshire, United Kingdom; University of Cambridge, Cambridge, Cambridgeshire, United Kingdom; Neuro-Oncology, Addenbrooke's Hospital, Cambridge, Cambridgeshire, United Kingdom; Cancer Research UK Cambridge Institute - PK-PD Core Facility, Cambridge, Cambridgeshire, United Kingdom; University of Glasgow - Neuro-Oncology, Glasgow, United Kingdom; University of Manchester, Manchester Academic Health Science Centre, Christie NHS Foundation Trust, Manchester, United Kingdom and University of Cambridge - Cambridge Cancer Centre, United Kingdom.

Body: Background

Failure of drugs to cross the blood brain barrier (BBB) can be a major reason for treatment failure for patients with brain tumors. For most patients who don't respond to treatment, it is not known whether this is due to inadequate drug concentrations in the tumor, or due to drug resistance. Preliminary data suggest that low-dose radiotherapy may disrupt the BBB, and could facilitate increased drug delivery into brain tumors. Afatinib is a potent, irreversible inhibitor of EGFR / HER2 / HER4 and takes approximately 8 days to achieve steady-state concentrations in cancer patients.

Aims

CamBMT1 has been designed to investigate the delivery of afatinib into brain metastases and whether this might be enhanced by low dose-radiotherapy.

Patient Population

Key eligibility criteria

Patients with operable brain metastases from breast or lung primaries for whom neurosurgical resection would be standard of care, as determined by the local multi-disciplinary team. ECOG PS 0, 1 or 2.

Trial design

After a phase 1b safety run- in, the phase 2 part of the trial randomises patients (n=60) into 3 pre-operative arms:

<table>
<thead>
<tr>
<th>Arm 1</th>
<th>afatinib alone for 11 days, then neurosurgery on day 12</th>
</tr>
</thead>
<tbody>
<tr>
<td>Arm 2</td>
<td>afatinib for 11 days plus a single 2 Gy fraction on day 10, then neurosurgery on day 12</td>
</tr>
<tr>
<td>Arm 3</td>
<td>afatinib for 11 days plus a single 4 Gy fraction on day 10, then neurosurgery on day 12</td>
</tr>
</tbody>
</table>

Primary endpoint: to compare steady-state afatinib concentration in resected brain metastases, following afatinib administered alone, or in combination with radiotherapy (2 Gy or 4 Gy). Afatinib concentrations are measured in the resected brain metastases and in plasma.

Secondary endpoints: safety of afatinib administration in combination with radiotherapy; and multi-sequence MRI (optional) to detect changes in perfusion, vascular density, blood-brain-barrier permeability and interstitial pressure.

Exploratory endpoints: molecular profiling of resected brain metastases, for comparison with paired primary lung and breast cancers; the establishment and study of patient-derived xenografts.

Statistical methods

With 20 patients randomised in each of 3 arms in the phase 2 part of CamBMT1, the trial has a power of 84% at a significance level of 20% (one-sided) to detect an increase in afatinib concentrations with targeted radiotherapy, measured as a Cohen's D
(standardised mean difference) $\geq 0.5$.

**Accrual**

By the end of q2 2016, phase 1b had nearly completed enrolment. The randomised phase 2 part of CamBMT1 is due to open by q4 2016 at additional Experimental Cancer Medicine Centres.

**Acknowledgments**

CamBMT1 is funded by Cancer Research UK, the Brain Tumour Charity and Boehringer-Ingelheim.

**Body:** Background: The addition of trastuzumab to cytotoxic chemotherapy has improved outcomes for patients (pts) with HER2+ breast cancer. Increased survival coupled with limited blood-brain barrier (BBB) penetration of trastuzumab may contribute to the increased incidence of brain metastases (mets) in these pts. Half of these pts die of intracranial disease progression rather than extracranial systemic disease. Therefore, strategies to improve survival must include increased CNS disease control. Lapatinib crosses the BBB & demonstrates modest activity against intracranial mets. Based upon preclinical data & phase I study results, it’s hypothesized that lapatinib plus whole brain radiotherapy (WBRT) can improve the intracranial disease control compared to WBRT alone.

**Trial design:** A randomized phase II trial that will evaluate if there is a sufficient enough signal in improved 12-week complete response (CR) rate following WBRT with the addition of lapatinib vs. WBRT alone in pts with mets from HER2+ breast cancer to warrant a future phase III trial. An amendment to allow protocol RT to be delivered as WBRT or stereotactic radiosurgery (SRS) is in process.

**Eligibility Criteria:** Eligibility includes HER2+ breast cancer with at least one measurable, unirradiated parenchymal brain met (≥10 mm if solitary, & > 5 mm if multiple on enhanced MRI). The two populations targeted for accrual include pts with 1) newly diagnosed, multiple brain mets or 2) progressive brain mets after SRS or surgical resection of 1-3 mets. Pts are stratified by breast-specific graded prognostic assessment; use of non-CNS penetrating HER2 targeted therapy; & prior SRS or surgical resection. Non-CNS penetrating HER2 targeted therapy is permitted throughout the study, but pts not on trastuzumab, pertuzumab or any other breast cancer therapy at study entry are not permitted to begin this therapy while on protocol treatment, but may begin it 24 hours after its completion. Prior lapatinib is allowed, last dose > 21 days prior to study entry.

**Specific aims:** Primary objective is to determine if there is an increase in CR rate in the brain at 12 weeks post WBRT as determined by MRI scan of the brain, with the addition of lapatinib to WBRT vs. WBRT alone. Secondary objectives includes: CR rate at 4 weeks on MRI post WBRT, objective response rate on MRI at 4 & 12 weeks, evaluation of lesion specific MRI response rates; CNS progression-free survival rate, overall survival rate, & adverse event rates.

**Statistical methods:** The randomization of experimental & control arms is set as 1:1. With 114 eligible pts there will be 86% power to detect a 15% absolute increase in CR rate at a significance level of 0.10, using a 1-sided Z-test for 2 proportions. Targeted accrual is 143 accounting for up to a 5% ineligibility rate, 15% pts not evaluable for the primary endpoint due to death, pt withdrawal, or other reasons.

**Contact Information:**

Body: **Background** For breast cancer (BC) patients with brain metastases (BM) who are not suitable for surgery/radiosurgery, whole brain radiotherapy (WBRT) remained the only standard treatment. Recently, we have demonstrated that bevacizumab preconditioning followed by etoposide and cisplatin (BEEP) is a highly effective treatment for BM of BC progressing from WBRT (Clin Cancer Res. 2015;21(8):1851). The CNS objective response rate is 77.1% according to volumetric criteria, and 60% according to RECIST 1.1. It has been demonstrated that enlarged brain tumor size is a predictor of WBRT failure. We hypothesized that, for BC with BM, induction BEEP treatment could decrease the size of brain metastases and thereby enhance effectiveness of WBRT. **Methods** This is a Phase II, randomized, open-labelled study (NCT02185352). Key inclusion criteria: BC with measurable brain metastatic tumor who had not received WBRT and not suitable for surgery or radiosurgery; KPS ≥ 30%. Key exclusion criteria: patients who had leptomeningeal metastases; history of disease progression during prior cisplatin treatment. In the experimental arm, patients will be treated by induction BEEP for three cycles followed by WBRT. In the control arm, patients will receive upfront WBRT for brain metastases. The BEEP regimen consist of bevacizumab (15 mg/kg) on Day 1 and, with a 1 day window period, followed by etoposide (70 mg/m²/day, Day 2 to Day 4) and cisplatin (70 mg/m², Day 2), in a 21-day cycle. Stratification is based on the Graded Prognostic Assessment (GPA) score. Primary endpoint: brain-specific progression free survival (PFS) according to RECIST 1.1; key secondary endpoint: the 2-month brain-specific objective response rate (BS-ORR) of BEEP alone and WBRT alone. Other secondary endpoints include overall survival, extra-CNS tumor PFS, safety, time-to-improvement of neurological function, brain-specific PFS according to volumetric criteria, and BS-ORR. Approximately 126 patients will be 2:1 randomized. Multi-center recruitment is ongoing. To our knowledge this is the first randomized trial investigating a targeted therapy plus chemotherapy as induction regimen followed by WBRT as first line treatment for BC with BM.
Title: A phase 2 randomized, double-blind, placebo-controlled trial of endocrine therapy ± radium-223 dichloride in HER2-negative, hormone receptor–positive breast cancer patients with bone metastases

Coleman RE E, Fried G, Petrenciuc O, Sawhney A, Li R and Rugo HS S. University of Sheffield, Weston Park Hospital, Sheffield, United Kingdom; Rambam Medical Center, Haifa, Israel; Bayer HealthCare Pharmaceuticals, Whippany, NJ and UCSF Helen Diller Family Comprehensive Cancer Center, San Francisco, CA.

Body: Background: Bone-metastatic breast cancer (MBC) treatment is limited. In a phase 2a study of bone-dominant MBC patients, radium-223, a first-in-class \( \alpha \) emitter with targeted cytotoxic effect on bone metastases (mets), reduced bone biomarker levels with favorable safety (Coleman et al. Breast Cancer Res Treat. 2014).

Trial design: This study evaluates efficacy and safety of radium-223 versus placebo (pbo), each + endocrine treatment (ET), in patients with HER2\(^{-}\) estrogen receptor\(^{+}\) (ER\(^{+}\))bone-dominant MBC (NCT02258464). Patients receive (1:1) radium-223 50 kBq/kg IV or pbo q 4 wk (6 cycles) + ET + denosumab or bisphosphonates + best supportive care. Stratification is by geographic region (EU/N America vs Asia), number of prior ET lines (1 vs \( \geq 2 \)) for MBC, and number of prior skeletal-related events (SREs) (1 vs 2).

Eligibility criteria: Eligible patients are pre- or postmenopausal with HER2\(^{-}\) ER\(^{+}\) bone-dominant MBC and \( \geq 2 \) bone mets or with soft tissue and/or visceral mets, and 1-2 prior SREs (external beam radiotherapy, pathologic bone fracture, spinal cord compression, orthopedic surgery); they have received \( \geq 1 \) line of ET for MBC and are considered appropriate for further ET. Patients must have evaluable disease (RECIST 1.1), be taking bisphosphonates or denosumab for \( \geq 1 \) month before study treatment, have an ECOG score 0-1, and have adequate hematologic, renal, and liver function. Patients must not have had visceral or brain mets or leptomeningeal disease, or need chemotherapy for MBC, and must not be suitable for everolimus for MBC. Patients are not eligible if they had prior radium-223 treatment or have untreated spinal cord compression.

Specific aims: The primary end point is SSE-free survival (SSE-FS). Secondary end points are radiologic progression-free survival; overall survival; times to opioid use, pain progression, and cytotoxic chemotherapy; pain improvement rate; and safety. Patients are assessed for efficacy and safety and are followed to SSE, radiologic progression, death, or withdrawal.

Statistical methods: Assuming 1-sided \( \alpha 0.1 \), power 90\%, ~ 119 SSE-FS events are needed for analysis. Time-to-event analysis will use a log-rank test, accounting for stratification. Kaplan-Meier estimates and survival curves will be given for each treatment group. Safety analyses will be descriptive.

Present and target accrual: Target accrual is \( \sim 227 \). Currently, 40 patients are randomized.

2016 San Antonio Breast Cancer Symposium

Publication Number: OT1-04-05

Title: A phase 2 randomized, double-blind, placebo-controlled trial of radium-223 dichloride with exemestane and everolimus in patients with HER2-negative, hormone receptor–positive breast cancer and bone metastases

Rugo HS S, Drumea KC C, Campone M, Barnadas A, Petrenciuc O, Zhang A, Li R and Coleman RE E. UCSF Helen Diller Family Comprehensive Cancer Center, San Francisco, CA; Rambam Medical Center, Haifa, Israel; Institut de Cancerologie de l'Ouest, Saint Herblain, France; Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; Bayer HealthCare Pharmaceuticals, Whippany, NJ and University of Sheffield, Weston Park Hospital, Sheffield, United Kingdom.

Body: Background: Treatment options for bone-dominant metastatic breast cancer (MBC) are limited. Radium-223, a first-in-class α emitter with a targeted antitumor effect on bone metastases (mets), was well tolerated and reduced bone biomarker levels in a phase 2 study in patients with bone-dominant MBC (Coleman et al. Breast Cancer Res Treat. 2014). In patients with HER2-estrogen receptor+ (ER+) bone-dominant MBC, everolimus + exemestane (EVE+EXE) improved progression-free survival (PFS) versus EXE alone. Radium-223 combined with EVE+EXE may improve outcomes in patients with HER2-ER+ bone-dominant MBC; this trial will evaluate efficacy and safety of radium-223 versus placebo in these patients (NCT02258451).

Trial design: Patients are randomized to receive (1:1) radium-223 (50 kBq/kg [55 kBq/kg after National Institute of Standards and Technology update] IV) or placebo x 6 cycles q 4 wk + EXE (25 mg PO q d) + EVE (10 mg PO q d) plus best supportive care. EXE+EVE continues until disease progression or unacceptable toxicity. Stratification is by geographic region (EU/N America vs Asia), prior hormone therapy (1 vs ≥2), and presence of visceral disease (yes vs no).

Eligibility criteria: Eligible patients are pre- or postmenopausal with HER2-ER+ MBC and have ≥2 bone mets or have soft tissue and/or visceral mets. Patients must have measurable disease per RECIST v1.1, ≥1 prior line of hormone therapy for MBC, and 1-2 prior skeletal-related events; be on bisphosphonates or denosumab; and have an ECOG score of 0-1. Patients must have had no past or current need for chemotherapy for MBC, no unresolved spinal cord compression, and no prior EVE treatment.

Specific aims: The primary end point is symptomatic skeletal event–free survival (SSE-FS). Secondary end points are overall survival; times to opiate use, pain progression, and cytotoxic chemotherapy; radiologic PFS; and safety. Safety and efficacy are assessed every 4 weeks. Long-term safety is assessed until study termination.

Statistical methods: Assuming a 1-sided α of 0.1, 90% power, ~160 SSE-ES events will be required for the analysis. Efficacy will be analyzed by a stratified log-rank test. Safety analysis will be descriptive.

Present and target accrual: Estimated enrollment is ~311 patients. Currently, 74 patients are randomized. Contact Oana Petrenciuc, Bayer HealthCare Pharmaceuticals, oana.petrenciuc@bayer.com, for more information.
Title: NRG-BR002: A phase II/III trial of standard of care therapy with or without stereotactic body radiotherapy (SBRT) &/or surgical ablation for newly oligometastatic breast cancer

Chmura SJ, Winter KA, Salama JK, Woodward WW, Borges VF, Al-Hallaq H, Martuszak M, Jaskowiak NT, Milano MT, Bandos H, and White JR. University of Chicago, Chicago, IL; NRG Oncology Statistics and Data Management Center, Philadelphia, PA; Duke University Medical Center, Durham, NC; MD Anderson, Houston, TX; University of Colorado, Denver, CO; University of Michigan, Ann Arbor, MI; University of Rochester, Rochester, NY; and University of Ohio, Columbus, OH.

Body: Background:
The current standard of care for metastatic breast cancer patients (pts) is to deliver palliative chemotherapy, biologic &/or hormonal therapy when appropriate, with radiation &/or surgery reserved for the management of symptomatic or non-responsive (mets). For selected pts with limited metastatic (met) disease, mets-directed ablative therapy, with either surgical resection or high dose conformal radiotherapy (in addition to standard systemic therapies) to lung, liver, CNS adrenal, & multiple organs has been shown to result in long-term disease control numerically superior to systemic therapy alone. NRG-BR002 is a randomized Phase II trial to evaluate stereotactic body radiotherapy (SBRT) &/or surgical resection (SR) of all met sites in newly oligometastatic breast cancer in addition to standard systemic therapy.

Trial Design & Eligibility
For the Ph IIR, eligible breast cancer pts with biopsy confirmed metastatic disease to <\= 2 sites will be randomized to receive either standard systemic therapy with mets directed therapy as needed (control arm) versus ablative therapy of all met sites with either body SBRT &/or surgical resection (SR) (per the treating physician discretion) to determine if there is an improvement median progression free survival (PFS). If this aim is met the trial continues as a Ph III to evaluate if SBRT/SR improves 5 year overall survival. Secondary aims include local control in the met site, new distant mets rate, & technical quality. The primary translational endpoint tests whether < 5 CTCs (per 7.5ml of blood) is an independent prognostic (outcome) marker for improved PFS & OS in oligometastatic breast cancer.

Women are within 1 year of metastatic diagnosis, on first line systemic therapy without progression & the primary site disease is controlled. CNS mets are ineligible. ER/PR & HER-2 neu are required on either the primary or met site. Site radiation credentialing & a facility questionnaire are required. Randomization is to standard systemic therapy with local radiotherapy/surgery for palliation when necessary vs ablative therapy of all mets with SBRT &/or SR.

Statistics:
For the Ph IIR portion to detect a signal for improved median PFS from 10.5 months to 19 months with 95% power & accounting for ineligible/lost pts, 146 pts will be required. For the Ph III, an additional 246, for a total of 402 pts will be required to definitively determine if ablative therapy improves 5-year overall survival from 28% to 42.5% (HR=0.67), with 85% power & a 1-sided type I error of 0.025. For the translational research, the number of pts accrued in the Ph IIR & Ph III portions will provide sufficient power \( \geq 91\% \) to detect whether < 5 CTC’s is a prognostic marker for improved PFS & OS.

Present Accrual & Target Accrual
NRG BR002 activated 12/24/2014 with a target accrual of 146 pts for the Ph II component & 256 additional for the Ph III.

2016 San Antonio Breast Cancer Symposium

Publication Number: OT1-04-07

Title: VICTORIANE: A randomized phase 3 study assessing the addition of oral vinorelbine to aromatase inhibitors for the treatment of patients with metastatic breast cancer

Villanueva CB B, Barthelemy P, Ferrero JM, Jacquin JP, Bonnetain F, Mansi L and Pivot X. University Hospital of Besançon, Besançon, France; University Hospital of Strasbourg, Strasbourg, France; Centre Lacassagne de Nice, Nice, France; Institut de Cancérologie Lucien Neuwich, Saint Priest en Jarez, France and Université de Franche Comté, Besançon, France.

Body: Background: The addition of anti-proliferative agents such new inhibitors of CDK4/6 to hormonotherapy have significantly improved the efficacy in patients with metastatic breast cancer (MBC). Oral vinorelbine provided the opportunity to give new schedules of chemotherapy with favourable tolerability and prolonged exposure. The present trial was designed to evaluate the clinical effects of the addition of oral vinorelbine to aromatase inhibitors in first line treatment for MBC.

Methods: In this phase III, randomized, prospective, open trial named VICTORIANE (NCT02730091), postmenopausal women with HR+/HER2– with MBC are randomized (1:1) between letrozole or anastrozole once a day (Arm A) versus oral vinorelbine 50 mg three times a every week with letrozole or anastrozole (Arm B). Continuous daily schedule (days 1-28 of each 28 days cycle) is planned until disease progression or discontinuation for other reasons. A minimisation algorithm was used stratifying treatment allocation according to the existence of visceral metastases, prior adjuvant hormonal treatment and centers. The study is conducted in compliance with the principles of good clinical practice and the declaration of Helsinki.

Key inclusion criteria include, histologically proven HER2-negative and Estrogen Receptor-positive breast cancer, metastatic setting, no prior systemic anti-cancer therapy for MBC, recurrence after prior hormonal therapy in the adjuvant setting is allowed if disease free interval is greater than 24 months from the completion of treatment, normal liver, bone marrow and renal functions, Performance status greater than 2. Non inclusion criteria include symptomatic visceral disease, or disease burden precluding endocrine therapy, and prior therapy with vinorelbine.

The primary endpoints is progression-free survival (PFS; local assessment, RECIST v1.1) and secondaries endpoints are overall survival, health-related quality of life, overall response rate and safety. Analysis of the primary endpoint will be performed with a stratified log-rank test (95% confidence interval). A 30 percent reduction in the risk of events (Hazard Ratio (HR) = 0.70) was assumed under H1 in the arm B. This reduction was estimated based on an absolute gain of 3.857 months in terms of median PFS, from 9 months (arm A) to 12.857 months (arm B). Global recruitment of the planned 340 pts is ongoing and should be completed in March 2018. Final results will be expected in 2019.
**Title:** Phase 3 study of etirinotecan pegol versus treatment of physician's choice in patients with metastatic breast cancer who have stable brain metastases previously treated with an anthracycline, a taxane, and capecitabine

Tripathy D, Tolaney S, Seidman AD D, Anders CK K, Ibrahim N, Rugo HS S, Twelves CJ J and Cortes J. University of Texas MD Anderson Cancer Center, Houston, TX; Dana-Farber Cancer Institute, Boston, MA; Memorial Sloan-Kettering Cancer Center, New York, NY; University of North Carolina School of Medicine, Chapel Hill, NC; University of California San Francisco, San Francisco, CA; St James’ University Hospital, Leeds, United Kingdom and Ramon y Cajal University Hospital, Madrid, Spain.

**Body:** Background: Etirinotecan pegol (EP) is a next-generation topoisomerase I inhibitor-polymer conjugate that provides continuous exposure to SN-38. A mouse model of brain metastases demonstrated high penetration and retention of SN-38 in CNS lesions, resulting in decreased size of CNS lesions and improved survival at concentrations clinically achieved at the recommended dose of EP in patients (pts) (Adkins et al, BMC Cancer 2015). A previous phase 3 trial comparing single-agent EP to treatment of physician's choice (TPC) was conducted in 852 pts with advanced breast cancer (BC) (Perez et al, Lancet Oncol 2015). Although the primary efficacy endpoint of improved survival was not met (HR 0.087; p value = 0.08), a subset of 67 pts who entered the study with stable brain metastases demonstrated improved overall survival (HR 0.51 [95% CI 0.304 – 0.858]; p < 0.01). A phase 3 trial has therefore been designed for this population of high unmet medical need. **Trial Design:** Pts with MBC with stable brain metastases will be randomized 1:1 to receive either single-agent EP or TPC in an open-label, randomized, multicenter Phase 3 study. **Key Entry Criteria:** Adults, with ECOG PS 0 or 1 with adequate liver, kidney and marrow function. All pts must have received prior therapy with an anthracycline, a taxane, and capecitabine (ATC) (these drugs may have been administered in the neo/adjuvant or locally advanced/metastatic setting); pts must have had 1 prior cytotoxic regimen for MBC (triplet negative BC); 2 prior cytotoxic regimens and 1 prior hormone therapy (hormone-receptor+ BC); or 2 prior cytotoxic regimens and 1 prior HER2-targeted therapy (HER2+ BC). Pts are required to have undergone definitive local therapy of brain metastases (either whole brain radiation; stereotactic radiation or surgical resection); signs and symptoms of brain metastases must be stable with steroids either unchanged or decreasing for ≥ 7 days prior to randomization. Prior toxicities must have resolved to ≤ Grade 1 (except sensory neuropathy ≤ Grade 2 and complete resolution of prior diarrhea). **Methods:** Primary efficacy endpoint is OS. Key secondary endpoints: ORR by RECIST v1.1, clinical benefit rate (ORR+SD ≥ 6 months), PFS by RANO-BM and QoL. EP is given IV at 145 mg/m² over 90-min every 21 days without premedications. Pts randomized to TPC must receive 1 of the following: eribulin, ixabepilone, vinorelbine, gemcitabine, paclitaxel, docetaxel or nab-paclitaxel (the agent must be available at the treating institution). Pts are stratified by region, ECOG PS and receptor status (TNBC, HER2+ or HR+/HER2-). **Target Accrual:** ~350 pts will be randomized to obtain the number of deaths required at 90% power to detect a statistically significant improvement in OS; 1 interim analysis will occur when 50% of the deaths are reported (130 events). PK sampling is performed in a subset of pts; UGT1A1 testing will occur in pts randomized to EP. Plasma ctDNA will be assessed at baseline for potential predictive markers of efficacy. Enrollment is expected to open in 2016.
Title: Circulating tumor cell number and CTC-endocrine therapy index predict clinical outcomes in ER positive metastatic breast cancer patients: Results of the COMETI Phase 2 trial

Paoletti C, Regan MM M, Liu MC C, Marcom PK Kelly, Hart LL L, Smith II JW W, Tedesco KL L, Amir E, Krop IE E, DeMichele AM M, Goodwin PJ J, Block M, Aung K, Cannell EM M, Darga EP P, Baratta PJ J, Brown ME E, McCormack RT T and Hayes DF F. University of Michigan Comprehensive Cancer Center, Ann Arbor, MI; Dana-Farber Cancer Institute, Boston, MA; Mayo Clinic, Rochester, MN; Duke University, Duke Cancer Center, Durham, NC; Florida Cancer Specialist (South Division), Fort Myers, FL; Northwest Cancer Specialists, Portland, OR; New York Oncology Hematology, US Oncology Research, Albany, NY; Princess Margaret Hospital, Toronto, ON, Canada; Dana-Farber Cancer Institute, Boston, MA; University of Pennsylvania, Philadelphia, PA; Mt. Sinai Hospital-Toronto, Toronto, ON, Canada; Nebraska Cancer Specialists, Omaha, NE and Janssen Pharmaceuticals, Inc., Raritan, NJ.

Body: Introduction: Only half of hormone receptor positive (HR+) metastatic breast cancer (MBC) patients (pts) benefit from endocrine therapy (ET). Circulating tumor cells (CTC) are prognostic in pts with MBC using CellSearch® technology. The CTC-endocrine therapy index (CTC-ETI) provides semi-quantitative analyses of CTC-ER (estrogen receptor), BCL2, HER2, and Ki67 expression. We hypothesized that CTC-ETI high (elevated CTC number and/or low expression of ER and BCL2, and high expression of HER2 and Ki-67) might predict resistance to ET in a prospective, multi-institutional clinical trial: COMETI-P2-2012.0 (NCT01701050).

Methods: 121 pts with ER+, HER2 negative (-), and progressive MBC after one or more lines of ET or within 12 months (mos) of completing adjuvant ET, who were initiating a new ET, were enrolled after informed consent. CTC and CTC-ETI were determined as previously reported (Paoletti C et al, CCR 2015) at baseline (BL), 1, 2, 3, and 12 mos, and/or at the time of progression. Imaging was performed every 3 mos. Association of CTC levels and CTC-ETI with patient outcomes (progression free survival (PFS); rapid progression (RP) defined as progression within 3 mos) was assessed using logrank and Fisher's exact tests. Trial design estimated 85 PFS and 51 RP events, providing >90% power (2-sided a=0.05); pts with unsuccessful BL CTC-ETI or ineligible were unevaluable. Only baseline (BL) data are reported in this abstract.

Results: 32% of enrolled pts had progression within 12 mos of completing adjuvant ET, whereas 40%, 20%, and 8% had 1, 2, ≥3 lines of ET for MBC. CTC-ETI was successfully determined in 93% of pts (90% CI, 88% to 97%). CTC were ≥5 CTC/7.5 ml whole blood in 37/108 (34%) pts evaluable for clinical validity. Elevated CTC was associated with worse PFS (median (m) PFS: 3.3 vs. 5.9 mos; P<0.01). Low, intermediate, and high CTC-ETI were observed in 75 (69%), 6 (6%), and 27 (25%) pts, respectively. CTC-ETI was associated with PFS (logrank P<0.01): pts with low, intermediate, and high CTC-ETI had mPFS of 5.7, 8.5, and 2.8 mos, respectively. In the 96 pts eligible for determination, elevated CTC was associated with RP, (65.6% vs. 42.2%; P=0.05) as was CTC-ETI (P=0.003): 79.2% (95% CI, 57.8% to 92.9%) of pts with high CTC-ETI had RP versus 41.2% (95% CI, 29.4% to 53.8%) with low CTC-ETI; in the small group with intermediate CTC-ETI 1 of 4 pts (25%) had RP.

Conclusions: In this multi-institutional, prospective study, CTC-ETI was accurately determined, confirming the previously established analytical validity of the assay, meeting the primary objective of the trial. Elevated CTC and CTC-ETI high compared to low were associated with poor outcomes to ET. CTC-ETI distribution resulted in a small number of patients assigned to the intermediate group, restricting our ability to associate this group with outcomes. These results suggest that CTC-biomarker phenotype and enumeration have clinical validity. CTC-ETI may identify ER+ HER2– MBC pts who are unlikely to benefit from ET and might be better treated with ET in combination with other therapies or proceed to chemotherapy. Further analyses including CTC-ETI at serial time points during ET are planned.
Circulating tumor cells (CTC) and endothelial cells (CEC) prognostic value in HER2 negative metastatic breast cancer patients treated with first line weekly paclitaxel and bevacizumab: First results of a prospective cohort from the French Breast Cancer InterGroup Unicancer (UCBG): COMET study

Pierga J-Y, Tredant O, Chevrier M, Dubot C, Lorgis V, Romieu G, Goncalves A, Debled M, Levy C, Ferrero J-M, Jouanaua C, Luporsi E, Mouret-Reynier M-A, Dalenc F, Berger F, Lemonnier J, Proudhon C and Bidard F-C. Institut Curie, Paris, France; Institut Curie, Saint Cloud, France; Centre Leon Berard, Lyon, France; Centre Georges-François Leclerc, Dijon, France; Institut du Cancer de Montpellier, Montpellier, France; Institut Paoli Calmettes, Marseille, France; Institut Bergonié, Bordeaux, France; Centre François Baclesse, Caen, France; Centre Antoine Lacassagne, Nice, France; Institut Jean Godinot, Reims, France; ICL Alexis Vautrin, Vandoeuvre les Nancy, France; Centre Jean Perrin, Clermont-Ferrand, France; Institut Claudius Regaud, Toulouse, France and R&D Unicancer, Paris, France.

Body: Background: increased levels of circulating tumor cells (CTC) are associated with worse progression-free survival (PFS) and overall survival (OS) in patients (pts) with metastatic breast cancer (MBC). It has been hypothesized that bevacizumab could modify CTC prognostic value. CEC variations to predict benefit of anti-angiogenic treatment is still controversial. Predictive markers for response to bevacizumab combined to chemotherapy in MBC remains a clinical unmet need.

Patients & methods: The French cohort COMET is a prospective study including first line HER2 negative patients (pts) receiving weekly paclitaxel and bevacizumab according to EMA approved combination. The aim of this cohort is to evaluate clinical, biological and radiological parameters associated with pts outcome (CTC, CEC, serum markers, ctDNA, pharmacogenomic polymorphisms, metabolomic parameters, visceral fat assessed by initial CTscan, serum estradiol level, and quality of life). We present here the first planned analysis on 203 pts evaluated for CTC and CEC using the FDA cleared CellSearch method.

Results: For CTC substudy, 211 patients were included from 09/2012 to 5/2014. Median follow-up is 24 months. Median PFS was 10 months (CI95 9-12) and response rate was 57%. Median OS was not reached. 203 patients were evaluable for both CTC and CEC at baseline and first day of second cycle of CT (D1C2). At baseline, 97/203 (48%) pts had ≥ 5 CTC (median 4 (range 0-30,000). Median number CEC was 21 (0-2231) at baseline and 22 (1-881) at D1C2. LDH, CEA, CA15.3 and CYFRA 21 were above normal at baseline in 44%, 46%, 73% and 71% of the cases respectively. CTC level was not correlated with any patients' characteristics except a number of metastatic site >3. After one cycle of chemotherapy (D1C2) 37 pts (22%) had still ≥ 5 CTC: 36 pts with initial high level and only one patient with low CTC at baseline had increased CTC above 5. Prognostic factors for PFS at univariate analysis were visceral disease, number of metastatic sites (> 3), triple negative status, LDH, CTC level at baseline and CEC level after one cycle of chemotherapy (D1C2). None of serum marker nor CEC level at baseline or any variations had prognostic value. In multivariate analysis for PFS, CTC level after one cycle of chemotherapy predicts poor outcome.

**Conclusion:** We confirm in a large prospective series the lack of clinical validity of CEC to predict response to an antiangiogenic based treatment in MBC. A persistent elevated level of CTC after just one cycle of chemotherapy is a very strong and independent marker of poor outcome in a homogeneously bevacizumab-treated cohort of MBC patients. This marker could be used to stopped earlier an inefficient and costly treatment.
Title: Dynamics of circulating tumor cells during the course of chemotherapy and prognostic relevance across molecular subtypes in high-risk early breast cancer patients – Results from the adjuvant SUCCESS A trial

Tzschaschel MLJ L J, Rack B, Andergassen U, Friedl TWP W P, Schneeweiss A, Mueller V, Tanja F, Pantel K, Gade J, Lorenz R, Rezl M, Tesch H, Soelung U, Polasik A, Alunni-Fabbroni M, Trapp EK K, Mahner S, Schindlbeck C, Lichtmenerger W, Beckmann MW W, Fasching PA A and Janni W. Ludwig Maximilians Universitaet Muenchen Klinik und Poliklinik fuer Frauenheilkunde und Geburtshilfe, Munich, Germany; University Hospital Ulm, Ulm, Germany; National Center for Tumor Diseases, University Hospital Heidelberg, Heidelberg, Germany; Universitaetsklinikum Hamburg-Eppendorf, Hamburg, Germany; Heinrich-Heine-University Duesseldorf, Duesseldorf, Germany; University Medical Center Hamburg-Eppendorf, Hamburg, Germany; Diakoniekrankenhaus Friederikenstift, Hannover, Germany; Gemeinschaftspraxis Dr. Lorenz, Hecker, Wesche, Braunschweig, Germany; Luisenkrankenhaus Duesseldorf, Duesseldorf, Germany; Onkologische Gemeinschaftspraxis am Betahenien-Krankenhaus, Frankfurt, Germany; Gemeinschaftspraxis Siehl und Soelung, Cassel, Germany; Clinical Center Traunstein, Traunstein, Germany; Charité University Hospital Campus Virchow, Berlin, Germany and University Hospital Erlangen, Friedrich-Alexander, Erlangen, Germany.

Body: Background: The presence of circulating tumor cells (CTCs) before chemotherapy is known to be associated with reduced disease free survival (DFS) and overall survival (OS) in early breast cancer (EBC). In addition, recent findings suggest that CTCs persisting after adjuvant chemotherapy indicate poor prognosis. In an explorative analysis of the SUCCESS A trial, we evaluated the prognostic relevance of changes in CTC counts during the course of adjuvant chemotherapy across molecular subtypes to assess whether the prognostic role of persisting CTCs varies according to tumor biology.

Methods: The SUCCESS A trial is a phase III study, where patients with high-risk EBC (stage pN1-3 or pT2-4 or grade 3 or age ≤ 35 or hormone-receptor negative) were randomized to adjuvant chemotherapy with 3 cycles of epirubicin-fluorouracil-cyclophosphamide followed by either 3 cycles of docetaxel or 3 cycles of gemcitabine-docetaxel. CTC enumeration was performed before and after chemotherapy using the FDA-approved CellSearch® System (Janssen Diagnostics, LLC), and CTC positivity was defined as ≥ 1 CTC in 23 ml blood. Molecular subtypes were defined as luminal A like (hormone-receptor positive, grading 1 or 2), luminal B like (hormone-receptor positive, grading 3), triple-negative or HER2-positive. Patient outcome in terms of DFS and OS was analyzed using univariate log-rank tests and Cox regression models (median follow-up time 65.2 months).

Results: Data on both molecular subtypes and CTC status before and after chemotherapy were available for 1485 (39.6%) of 3754 patients randomized. This cohort contained 577 (38.9%) luminal A like, 236 (15.9%) luminal B like, 379 (25.5%) HER2-positive and 293 (19.7%) triple negative tumors. Overall, 917 (61.8%) patients were CTC negative before and after chemotherapy (neg/neg), 260 (17.5%) patients had a negative CTC status before and a positive CTC status after chemotherapy (neg/pos), 229 (15.4%) patients converted from positive to negative CTC status (pos/neg), and 79 (5.3%) patients were positive for CTCs at both time points (pos/pos). There were significant differences in DFS and OS among these four groups in patients with luminal A like tumors (log rank test, both p < 0.003) and patients with luminal B like tumors (log rank test, both p < 0.001). In both patients with luminal A like or luminal B like tumors, persistently CTC positive patients had the worst outcome (relative to persistently CTC-negative patients) in terms of DFS and OS. In contrast to luminal-like tumors, no significant differences with regard to DFS or OS were found among the four groups (neg/neg, neg/pos, pos/neg, pos/pos) in patients with HER2-positive or triple-negative tumors (log rank test, all p > 0.13).

Conclusion: The presence of CTCs both before and after adjuvant chemotherapy was associated with poor survival in luminal A like and luminal B like tumors, but not in HER2-positive or triple-negative tumors. Further research is needed to evaluate the effect of chemotherapy on CTC prevalence in different molecular subtypes of EBC.
Comprehensive genomic characterization of circulating tumor cells (CTCs) in metastatic breast cancer (MBC) sheds light on the biology of blood-borne metastasis

Body: Background: CTCs offer a relatively non-invasive source of metastatic tissue for molecular analysis. To elucidate the underlying biology of blood-borne metastasis, we profiled CTCs from MBC patients (pts).

Methods: CTCs were isolated by IE/FACS (immunomagnetic enrichment/fluorescence-activated cell sorting). Expression of 64 cancer-related genes in CTCs was analyzed via microfluidic-based multiplex QPCR. Genome-wide copy number (CN) analysis by array comparative genomic hybridization (ACGH) was performed on CTCs isolated from the same tumor-enriched blood samples. The Illumina platform was utilized for next generation sequencing and data was analyzed using NantOmics analysis pipeline and Nexus 8.0 software. Mutations were confirmed by Sanger sequencing or by digital droplet PCR.

Results: Expression profiles of CTCs from 105 MBC pts clustered away from those of blood, indicating high-purity isolation of CTCs by IE/FACS. In addition to EPCAM, tumor-related genes, e.g., CCND1, MUC1, and TTF3 were upregulated in CTCs. Approximately 70% of the CTC samples were considered ER-positive, of which 47% were ER+HER2+, and 22% ER+HER2-. Among the ER+HER2- samples, about two-thirds (68%) had low proliferative (MKI67) status. HER2-positive and triple-negative CTCs accounted for 27% and 30% of the samples, respectively. Furthermore, 30% of the samples were assigned to luminal A, 6% to luminal B, 13% to Her2-enriched, 33% to basal-like, and 12% to normal-like subtypes. Expression profiling of CTCs in 74 serial blood samples from 28 pts showed fluctuations in expression at the gene-level, while subtype calls were mostly consistent across time points.

CTCs from 49 of the 105 pts analyzed by ACGH revealed numerous genomic aberrations such as 1q/8q gains and 8p/16q losses, consistent with breast cancer origin. CN profiles grouped into three major clusters: CTCs exhibiting low genomic instability, 8q gain, and 1q gain/11q loss. ERBB2 and CCND1 were upregulated in CTCs showing increased genomic alterations.

Changes in ER (n=102) and HER2 (n=130) status between CTCs and matched primary tumors (PT) were observed in 27% and 23% of the pts, respectively, indicating that biomarker status may change during disease progression.

Comparative analysis of CN data from low-pass whole genome sequencing (WGS) of CTCs vs. matched PTs (n=7 pairs) demonstrated clonal-relatedness as well as genetic divergence. WGS (38x) and whole exome sequencing (140x) analysis of CTCs from an index pt diagnosed with invasive lobular carcinoma detected numerous genomic aberrations, including a copy loss and a frameshift mutation in E-cadherin (CDH1). Interestingly, analysis of CN and mutation data revealed that CTCs were more closely related to the lymph node metastases than to the PT. Single-cell sequencing of CTCs revealed uniformity in genome-wide CN alterations, while cell-to-cell heterogeneity was observed only when single-cell expression profiles were analyzed.

Conclusions: Comprehensive molecular characterization provided novel insights into the biology of breast CTCs. Further CTC profiling may open avenues for discovery and development of novel biomarkers for personalized medicine and strategies to prevent metastasis.
Title: Prognostic values of circulating tumor cells (CTC) and cancer associated macrophage-like cells (CAML) enumerations in metastatic breast cancer: The role for innate immunity in the metastatic process

Mu Z, Wang C, Ye Z, Rossi G, Austin L, Yang H and Cristofanilli M. Robert H Lurie Comprehensive Cancer Center, Feinberg School of Medicine, Northwestern University, Chicago, IL; Sidney Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA and U.O.C. Oncologia Medica 1 - Istituto Oncologico Veneto - IRCCS IOV, Padova, PD, Italy.

Body: Background: The enumeration of circulating tumor cells (CTCs) using the CellSearch assay is a well-established prognostic and predictive marker for metastatic breast cancer (MBC). However, additional prognostic markers are lacking in patients with \( \geq 5 \) CTCs in 7.5 ml of blood. Tumor-associated macrophages (TAMs) are derived from circulating monocytes or tissue-resident macrophages. TAMs have a controversial role in metastasis and anti-tumor processes. Recent studies showed that circulating cancer associated macrophage-like cells (CAMLs) are specialized phagocytic myeloid cells and found in the peripheral blood of patients with solid tumors including breast cancer, but not in healthy individuals. The presence of CAMLs may indicate the activation of innate immunity in cancer patients. The function and prognostic value of CAMLs in MBC is unknown. In the current study, we measured CTCs and CAMLs on the CellSearch™ platform and investigated their prognostic values in MBC.

Methods: Peripheral blood samples from 127 stages IV breast cancer patients were collected at baseline before starting first-line therapy. The detection and enumeration of CTCs and CAMLs in 7.5 ml blood sample were performed on the CellSearch™ system. CTCs were identified by cytokeratins (CK-8, 18, and 19) positive and CD45 negative staining. CAMLs were defined by positive staining for cytokeratins and CD45 (Adams et al, PNAS, 111(9):3514-9, 2014). CTCs and CAMLs enumeration in associations with the progression-free survival (PFS) and overall survival (OS) of patients were evaluated using Kaplan Meier curves and Cox proportional hazards modeling.

Results: The image review of CAMLs by using CellSearch analysis showed heterogeneous morphological phenotypes. CAMLs are large cells presenting enlarged nuclei or multiple individual nuclei, and both cytokeratin and CD45 positive with diffused cytoplasmic staining. Among the 127 MBC patients, 38 (29.9%) had elevated CTCs (\( \geq 5 \) CTCs), and 21 (16.5%) had at least one CAML detected. Patients with CAMLs had a significantly increased PFS (\( p=0.0374 \)) and OS (\( p=0.0042 \)), compared to patients without CAMLs at baseline. Patients with elevated baseline CTCs and CAMLs had worse PFS with a hazard ratio (HR) of 4.04 (95% CI 2.16 -7.56, \( P<0.0001 \)), compared to patients with < 5 CTCs and without CAMLs. The combined analysis of baseline CTCs enumeration and CAMLs showed similar effect on patient OS. Compared to patients with < 5 CTCs and without CAMLs, patients with < 5 CTCs and with CAMLs, patients with \( \geq 5 \) CTCs and without CAMLs, and patients with \( \geq 5 \) CTCs and with CAMLs, had an increasing trend of death risk, with an HR of 2.66 (95% CI 0.53-13.21), 6.14 (2.10-17.92), and 9.13 (3.05-27.37), respectively (\( p \) for trend<0.0001).

Conclusion: Baseline enumerations of both individual CTCs and CAMLs are feasible and increase our ability to accurately predict outcome in MBC patients. Evaluation of CAMLs in peripheral blood may be a marker of innate immunity and provide additional prognostic values for MBC.
Ki67-positive CTCs are associated with early disease relapse in patients with early breast cancer undergoing adjuvant chemotherapy

Agelaki S, Spiliotaki M, Politaki E, Spanaki A, Kassiou L, Koinis F, Georgoulias V and Mavroudis D. Laboratory of Translational Oncology, School of Medicine, University of Crete, Heraklion, Greece and University General Hospital of Heraklion, Heraklion, Greece.

Background: The determination of Ki67 in the primary tumor has prognostic value in early breast cancer (BC). We evaluated Ki67 expression in circulating tumor cells (CTCs) from patients with early BC undergoing adjuvant chemotherapy and correlated Ki67 positivity with patient outcome. Methods: Ki67 expression in CTCs was evaluated by immunofluorescent analysis in paired blood samples of patients with early BC (n=166) obtained before and after adjuvant chemotherapy. Ki67 expression was also evaluated in CTC-positive patients at 6 - 24 months after the end of chemotherapy (n=31). Cytospins of peripheral blood mononuclear cells were double stained with A45-B/B3 cytokeratin and Ki67 antibodies. The proliferation index (PI) of CTCs was defined as the ratio of Ki67-positive CTCs/total CTCs. Results: CTCs were detected in 53 (32%) patients before and/or after chemotherapy. Ki67-positive [Ki67(+) CTCs were identified in 79% of CTC-positive patients, 25% presenting exclusively Ki67(+) CTCs and 21%, exclusively Ki67(-) CTCs. The mean value of Ki67(+) CTCs/patient remained unchanged pre- and post-chemotherapy [(mean±SE): pre- vs post-chemotherapy 2.5±0.7 vs 4.2±2, respectively; p= 0.900]. Similarly, the PI among the total CTCs detected pre- and post-chemotherapy was 59% and 60%, respectively. Ten (19%) of 53 CTC-positive and 9 (8%) of 113 CTC-negative patients relapsed (p = 0.039). In addition, all CTC-positive patients who relapsed harbored Ki67(+) CTCs before and/or after chemotherapy. Interestingly, 70% of them experienced early disease recurrence, ranging from 6-29 months after the initiation of adjuvant chemotherapy. Furthermore, 38.5% of patients with exclusively Ki67(+) CTCs relapsed compared to none among patients with exclusively Ki67(-) CTCs (p = 0.041). Of the 31 CTC-positive patients evaluated during follow-up, 39% remained CTC-positive. However, only 33.3% of them harbored Ki67(+) CTCs, 8.3% had exclusively Ki67(+) CTCs and 66.7% exclusively Ki67(-) CTCs. The mean value of Ki67(+) CTCs/patient was significantly reduced on the follow-up samples [(mean±SE): follow-up vs pre-chemotherapy, 1.35±1.3 vs 2.5±0.7, respectively; p=0.014 and follow-up vs post-chemotherapy, 1.35±1.3 vs 4.2±2, respectively; p= 0.026]. Conclusions: Ki67 expression on CTCs is predictive of early relapse in patients with early BC. Ki67 expression is not decreased by adjuvant chemotherapy, whereas it is reduced early during follow-up, possibly due to adjuvant hormone therapy and/or anti-HER2 therapy. The above results suggest that additional therapy is needed for patients with early BC and Ki67(+) CTCs to prevent early disease recurrence.
Title: Maintenance of genomic integrity in dormant circulating tumor cells

Boral D, Vishnoi M, Liu HN N, Yin W, Marchetti D, Hong DS S and Scamardo A. Houston Methodist Research Institute, Houston, TX and University of Texas M D Anderson Cancer Center, Houston, TX.

Body: More than 67% of deaths in breast cancer patients occur after the initial 5-year survival period while residual disease can be dormant for periods longer than 20 years. Patients are asymptomatic because circulating tumor cells (CTCs) remain dormant and are undetectable by current clinical tools. Dormant CTCs may retain their long-term tumor-initiating (LTI) potential by adhering to their original genome, unlike rapidly cycling cancer cells that are known to have increased genomic instability. We hypothesized that hyperactive mechanisms of DNA repair preserve the genomic make-up of dormant CTCs allowing them to retain their LTI potential, ultimately causing disease relapse.

We isolated and characterized breast cancer CTCs by mutiparametric flow cytometry and DEPArray™. Individually isolated breast cancer CTCs had a large proportion (>40%) of dormant (Ki67-/PCNA-) cells. Dormant CTCs had a lower incidence of double-strand DNA breaks (DSB) than proliferating cells as assessed by the phosphorylation status of Serine139 on gamma H2AX. This observation was further validated in a panel of eight genetically distinct breast cancer cell lines. Second, to understand whether dormant cells are inherently more resistant to DSB, we induced DSB in breast cancer cells by UV radiation and bleomycin treatment, and measured residual DSB at regular intervals. Results showed that besides being more resistant to DSB de novo, dormant breast cancer cells were also more efficient repairing their DNA. There are two distinct phases of DSB repair - early [within 2 hours of DSB using Non-Homologous End Joining (NHEJ) methods] and late [evident after 24 hours using Homologous Recombination (HR)]. Unlike proliferating (S-G2-M) cells, dormant (G0) cells lack the sister chromatid and repair their DNA exclusively by NHEJ methods. Therefore, and third, we investigated key players of the NHEJ pathway and examined their roles in maintaining genomic integrity. We found that the human telomere-associated protein RIF1, a mediator of alternative NHEJ, was significantly up-regulated in a dormant CTC subset. Dormant sub-populations of breast cancer cells confirmed RIF1 foci formation in areas of DNA damage. Fourth, mis-sense mutation of RIF1 in CAMA-1 cells (∆RIF1 E1598K) as well as shRNA mediated RIF1 knockdown in HCC1954 and ZR-75-1 cell lines attenuated resistance of the dormant subset to UV and bleomycin treatment. Finally, RIF1 knockdown activated both p38 and pERK pathways albeit to varying degrees in multiple cell lines resulting in metastatic inefficiency in xenograft and syngeneic mouse models. Collectively, these findings suggest that RIF1 may play functional roles in maintaining the genomic integrity of dormant CTCs and be a potential biomarker of breast cancer CTC survival while in circulation.
2016 San Antonio Breast Cancer Symposium

Publication Number: P1-01-08

Title: The evolution of breast cancer circulating tumor cells mediating brain metastasis

Boral D, Vishnoi M, Liu HN N, Yin W, Hong DS S, Scamardo AT T and Marchetti D. Houston Methodist Research Institute, Houston, TX and University of Texas M D Anderson Cancer Center, Houston, TX.

Body: Multiple studies concur that CTCs - the “seeds” of fatal metastasis - intravasate into the bloodstream throughout the early stages of cancer promoting generation of micro-metastatic reservoirs, some of which ultimately evolve to metastatic tumors. However, while it may take decades for CTCs to progress from cells in circulation to clinically detectable metastases, once detected, the tumor usually grows at an exponential rate. This difference in growth dynamics at two ends of the metastatic spectrum should also be reflected in the behavior of CTCs shed from these organ sites. Having a focus towards breast cancer brain-colonizing CTCs and their properties, we hypothesized that a gradual evolution of dormant CTCs into mitotically active CTCs with brain-metastatic potency is central to the progression of primary breast cancer to brain metastasis.

We isolated CD44+/CD24- (stem-like) and Pan-Cytokeratin+ (epithelial) breast cancer CTCs from peripheral blood of two groups of breast cancer patients – five with brain metastases (BCBM) (MRI-detectable) and five without brain metastases (No BCBM). CTCs were isolated by multi-parametric flow cytometry and the expression of CTC-specific antigen was confirmed by immuno-cytochemistry and DEPArray™ platform. Intra-cellular flow cytometry showed that No BCBM patients had 3-fold higher mitotically dormant (Ki67-) CTCs compared to BCBM patients. Whole genome expression arrays demonstrated low generalized transcriptional activity in CTCs suggestive of mitotic/metabolic dormancy. Comparison of CTC transcriptomes with ER+/PR+, HER2+ and triple negative breast cancers identified a unique CTC gene signature valid not only across the three molecular subtypes but also independent of the molecular subtype patients were initially diagnosed as. Pathway analyses predicted increased activation of pluripotency-related pathways along with decreased protein translational machinery and proliferative pathways in CTCs. Further, to dissect mechanisms of metastatic reactivation in the brain microenvironment, we compared the CTC transcriptome in BCBM vs No BCBM patients and identified a 126 gene signature potentiated in BCBM CTCs. Subsequent pathway analyses revealed upregulation of known CTC pathways like Notch along with novel hematopoietic and immune evasion networks. Cellular and functional annotations of cell migration and chemotaxis were significantly activated in BCBM along with pro-inflammatory (TNF, IL1β, NF-kB), immunomodulatory chemokines (CXCL8, CXCR4, CD86) and mitogenic growth factors (PDGF-BB). Lastly, lack of cell surface expression of Urokinase Plasminogen Activator Receptor (uPAR) and integrin beta-1 (int-β1) were used to identify CTCs in a state of metastatic dormancy. Whole genome sequencing showed significantly higher incidence of genomic mutations in proliferating CTCs compared to their dormant counterparts.

We provide first time evidence of signaling pathways keenly implicated in breast cancer CTC biology based on comprehensive analyses of CTC transcriptomes. We discovered the existence of CTCs in a state of metabolic/mitotic dormancy and identified genomic instability as a switch for CTCs to revert to their proliferative phenotype.
Title: Comparison of HER2, estrogen and progesterone receptor expression profiles of primary tumor, synchronous axillary lymph node metastases and circulating tumor cells in early breast cancer patients

Aktas B, Westerwick D, Mairinger F, Kasimir-Bauer S, Kimmig R, Schmid K and Bankfalvi A. University Hospital Essen, Essen, NRW, Germany and University Hospital Essen, Essen, NRW, Germany.

Body: Background: Targeted systemic therapy in early breast cancer with synchronous lymph node metastasis is currently based on the expression of the hormone receptors (ER/PR ≥1%) and overexpression of HER2 in the primary tumor. However, the expression of these predictive markers on lymph node metastases as well as on circulating tumor cells (CTCs), the precursors of metastatic disease, has not yet been taken into account. The aim of the present study was to compare the HER2/ER/PR expression profiles of primary tumors, synchronous lymph node metastases and circulating tumor cells in early breast cancer patients and relate the results to 5-year overall (OS) and disease-free survival (DFS).

Patients and Methods: 76 patients with early breast cancer diagnosed between 2006 and 2010 were enrolled in this study. Blood was obtained at the time of first diagnosis of disease and analyzed for CTCs using the AdnaTest BreastCancer (Qiagen Hannover GmbH) for the expression of EpCAM, MUC-1, HER2, ER and PR respectively. Formalin-fixed and paraffin-embedded archival tissues of the primary tumors and the lymph node metastases were analyzed by two pathologists. ER, PR and HER2 expression was assessed by fully-automated immunohistochemistry (Ventana medical Systems, Tucson, AZ, USA) and HER2/CEN17 dual chromogenic in situ hybridization (Zytomed Systems, Berlin, Germany) according to modified ASCO/CAP guidelines (2010 and 2013, respectively).

Results: The detection rate for CTCs was 22% (17/76 patients). In the primary tumors, the expression rate of HER2 was 16% (13/76 patients), 78% for ER (61/76 patients) and 75% for PR (57/76 patients) respectively. Changes in biomarker profiles between primary tumors, metastases and CTCs, as a whole, were observed in 89% of the cases (68/76). The discordance rates between primary tumors and lymph node metastases were 10% for HER2 (p<0.001), 5% for ER (p= p<0.001) and 11% for PR (p<0.001). The intrinsic subtypes between primary tumors and lymph node metastases changed in 16% of all cases (12/76 patients; gain of HER2 in four, activation of HRs in three cases, loss of HER2 in three and loss of HRs in one case becoming triple negative). Of note, both OS and DFS of patients with subtype discordance were reduced to a median of 41 months (mean: 39) vs 56 months (mean: 51).

CTCs were either triple negative or HER2 positive. Discordance rates for HER2, ER and PR status compared to the primary tumors were 16% (12/76 patients), 83% (63/76 patients) and 72% (55/76 patients), respectively. Discordant rates between lymph node metastases and CTCs were 25% for HER2 (19/76 patients), 82% for ER (62/76 patients) and 72% for PR (55/76 patients).

Conclusion: Our preliminarily results demonstrate, that changes in molecular profiles are the rule rather than the exception throughout tumour progression in breast cancer. In cases with discordant biomarker profiles, prognosis seems to follow the subtype of lymph node metastasis. Biomarker or subtype shift may be of essential therapeutic significance for individual patients.
**Title:** Exome sequencing of circulating tumor cells in metastatic breast cancer

Ignatiadis M, Rothé F, Peeters D, Rouas G, Smeets D, Haan J, Lambrechts D, Campbell P, Piccart M, Voet T, Dirix L, Venet D and Sotiriou C. Jules Bordet Institute, Brussels, Belgium; Antwerp University Hospital, Anwerp, Belgium; KU Leuven, Leuven, Belgium and Sanger Institute, United Kingdom.

**Body:**

**Aim:** We interrogated whether Circulating Tumor Cells (CTCs) can complement metastatic biopsies for genomic analyses.

**Patients and Methods:** We compared single nucleotide variants (SNVs) and copy number aberrations (CNAs) identified using whole exome sequencing (WES) of DNA from frozen tumor tissue (primary/metastasis), amplified DNA from CTCs and normal DNA from 3 metastatic breast cancer (BC) patients (pts). All samples of the same patient were collected at the same timepoint. CTC isolation was performed using CellSearch and DEPArray systems followed by whole genome amplification (Ampli1 kit). WES was performed using the Illumina HiSeq2000 with 200X targeted coverage. Reads were aligned using bwa. SNVs had to be called by both Haplotype Caller (vs. reference genome) and Strelka (vs. paired normal). CNAs were determined by counting reads in 1MB windows and by comparing tumor/CTC samples with normal DNA. Pairwise concordance of CNAs profiles of different samples from the same patient was assessed using Spearman correlation (ρ). Significance of ρ differences between pts was obtained by Kruskal-Wallis test. Orthogonal validation for selected SNVs was performed.

**Results:** We studied 3 patients from the 3 major BC subtypes, patient (pt)1 with ER-/HER2+ BC (samples collected at diagnosis, initially metastatic disease), pt2 with triple-negative BC (samples collected 2 years from diagnosis) and pt3 with ER+/HER2- BC (samples collected 8 years from diagnosis).

We first compared tumor tissue and CTCs for SNVs. For pt1, of the 77 SNVs identified in the tumor, 51 were found on at least one of 12 CTCs samples. For pt2, of the 62 SNVs identified in the tumor, 19 were found on at least 1 of 11 CTCs samples. For pt3, of the 225 SNVs identified in the tumor, 48 were found on at least 1 of 3 CTCs samples. Interestingly, by increasing the number of CTCs analyzed, we increased the % of identified SNVs from synchronous tumor tissue. SNVs with high variant allele fraction (VAF) in tumor tissue were detected significantly more often in CTCs: 22% of the SNVs with VAFs <20% were found at least once, compared to 53% and 74% of SNVs with VAFs >20% and >40%, respectively (p=10^{-12}, Fisher exact test). Then, we compared tumor tissue and CTCs for CNAs. As time from diagnosis of metastatic disease to samples collection increased, we observed significantly higher heterogeneity within CTCs from the same patient (median ρ between CTCs was 86% for pt1, 84% for pt2 and 28% for pt3, p<0.01) and between CTCs and tumor tissue from the same patient (median ρ was 78% for pt1, 67% for pt2 and 21% for pt3, p<10^{-4}). Interestingly, in pt3 one CTC was more similar to the metastasis than the other 2 (p of 53%, 21% and 21%). When a phylogenetic tree was constructed for pt3 by combining SNVs and CNAs data, three clones were identified: one clone with an AKT1 (E17K) and a TP53 (R248W) mutation and a 8p deletion, a second clone with the above profile plus an 8q amplification and a third clone with an AKT1 and an ESR1 (Y537N) mutation and 1p deletion. The metastasis was similar with the first clone.

**Conclusions:** These data suggest that tumor tissue and single CTC exome sequencing analyses provide complementary information to map tumor heterogeneity. Further validation for potential clinical applications is needed.

**Title:** Something from nothing? The case for quality control in liquid biopsy studies

Porras TB B, Bains PK K, Ring A, Carrasco S, Forte V, Punj V and Lang JE E. University of Southern California Norris Cancer Center, Los Angeles, CA.

**Body:** Background: Circulating tumor cells (CTCs) as a liquid biopsy strategy are currently being studied as a surrogate biomarker that may reflect metastatic tumor biology. Given the rarity of CTCs, target enrichment is commonly used to profile the gene signatures of valuable clinical samples to evaluate for multiplexed gene panels of interest. The aim of our study was to evaluate if the NanoString PAM50 could be used for accurate gene expression profiling of CTCs and controls using the research-use-only probeset.

Methods: We collected two 7.5mL EDTA tubes of blood from 12 healthy female volunteers. CTC assays were performed using the ANGLE Parsortix system as a microfluidics filter that separates cells based on size and deformability. The cell lines Hs578T (basal-like) and SK-BR-3 (HER2 amplified) were used to spike 20 cells into n=6 blood tubes per cell line (termed spiked samples). N=12 7.5mL tubes of blood (termed unspiked samples) and n=12 spiked samples were processed using Parsortix for CTC harvesting and lysis using a 10 micron cassette. From each lysate, 5uL was taken for cDNA amplification, multiple target enrichment for 14 cycles, followed by NanoString PAM50 assays. From each of the 12 peripheral blood (PB) samples, we extracted RNA and used 100ng for NanoString PAM50 assays. For cell line controls, 100ng of Hs578T or SK-BR-3 were subjected to NanoString Assays.

Results: Low PAM50 gene expression was observed in all 12 PB samples. Unspiked PB harvested from the CTC assay showed a higher level of PAM50 gene expression compared to PB, suggesting that the target enrichment amplification produces false positive detection of expected breast cancer related transcripts. On ANOVA testing, 10/12 (83%) of unspiked, sorted, target enriched samples had significant differential expression (p<0.0001) of the mean log normalized counts for the PAM50 genes compared to PB.

In spiked experiments using n=20 cells in 7.5mL of PB, sorted Hs578T were found to be triple negative in only 3/6 (50%) while sorted SK-BR-3 were found to be HER2 positive in only 3/6 (50%). On ANOVA testing, the spiked/sorted and bulk were found to have a difference among the mean log normalized counts for the PAM50 genes across all samples for both cell lines (p<0.0001). However, 3/6 (50%) samples had a difference in mean PAM50 gene expression when compared to bulk Hs578t on multiple comparison testing while 2/6 (33%) were statistically significantly different when comparing spiked, sorted SK-BR-3 versus bulk cell line.

Conclusions: Unspiked blood processed via a CTC assay and subjected to target enrichment showed high expression of genes in the NanoString PAM50 assay, likely due to amplification bias. When working with enriched but not ultra-pure CTC samples, amplified gene expression of background leukocytes may influence read counts. This is important to consider in assays that enrich for CTCs but retain a leukocyte background. Further studies will address the effect of the CTC assay procedure and number of leukocytes on accuracy of gene expression of rare CTC mimics. This study emphasizes the importance of selecting genes that are not expressed in PB or performing background subtraction or normalization as strategies for accurate gene expression profiling of CTCs.
Prevalence of insulin-like growth factor-1 receptor (IGF1R) expression in circulating tumor cells (CTCs) of patients with early breast cancer and its association with E-cadherin expression and patient survival

Agelaki S, Spiliotaki M, Kokotsaki M, Matikas A, Vetsika E-K, Georgoulias V and Mavroudis D. Laboratory of Translational Oncology, School of Medicine, University of Crete, Heraklion, Greece and University General Hospital of Heraklion, Heraklion, Greece.

**Body: Background:** Components of the IGF system are deregulated and IGF1R overexpression is common in breast cancer (BC). E-cadherin (E-CAD) has a prominent role in epithelial differentiation. We investigated the expression of IGF1R in CTCs from patients (pts) with BC and evaluated its correlation with E-CAD expression and survival.

**Methods:** Cytospins of peripheral blood mononuclear cells (PBMCs), obtained from early (n=62) and metastatic (n=100) pts before adjuvant and 1st-line chemotherapy, respectively, were analysed. Cytospins were double or triple stained with anti-cytokeratin (CK) (A45-B/B3) and anti-IGF1R or with anti-CK, -IGF1R and -E-CAD antibodies, respectively, and evaluated by immunofluorescent microscopy (Ariol system).

**Results:** CTCs were detected in 20 (32%) and 45 (45%) pts with early and metastatic BC, respectively. IGF1R(+) CTCs were more prominent in early (84% vs 64% of total CTCs, p=0.0007) and IGF1R(-) CTCs in metastatic disease (36% vs 16%, p=0.0001). Among early pts, 80% had exclusively IGF1R(+) CTCs, 20% had both IGF1R(+) and IGF1R(-) and none had exclusively IGF1R(-) CTCs. The respective values in metastatic pts were 42%, 33% and 25% (p=0.005). Early BC pts with exclusively IGF1R(+) CTCs had significantly higher DFS (p=0.0283) and OS (p=0.0016) compared to those with both subpopulations. Triple IF staining revealed that IGF1R(-)/E-CAD(-) CTCs prevailed in metastatic disease (54% vs 6% of total CTCs, p=0.0167). Among early pts, 67% had exclusively IGF1R(+)E-CAD(+) CTCs, 33% also had IGF1R(-)/E-CAD(-) and none had exclusively IGF1R(-)/E-CAD(-) CTCs. The respective values in metastatic pts were 15%, 77% and 8% (p=0.03). Among CTC(+) early BC pts with detectable CTCs on relapse, the median % of IGF1R(+)E-CAD(+) CTCs/pt was reduced (59% vs 89%) whereas the median % of IGF1R(-)/E-CAD(-) CTCs/pt increased (41% vs 11%) on disease progression.

**Conclusions:** IGF1R(+) CTCs are detected more frequently in early compared to metastatic BC. IGF1R and E-CAD are co-expressed at the single CTC-level and the progression from early to metastatic disease is accompanied by a loss of both proteins. These results suggest that IGF1R expression on CTCs contributes to a more differentiated and less invasive phenotype possibly through E-CAD. Accordingly, IGF1R expression in CTCs is associated with improved survival in early BC.
Title: A new workflow comprising size based CTC enrichment followed by in situ labeling and micromanipulation with CellCelector™ enables label-free enrichment, isolation and characterization of circulating tumor cells in breast cancer

Neubauer HJ J, Lampignano R, Neumann MHD HD, Behrens B, Franken A, Stoecklein N, Niederacher D and Fehm TN N. University Hospital and Medical Faculty of the Heinrich-Heine University, Duesseldorf, Germany and University Hospital and Medical Faculty of the Heinrich-Heine University, Duesseldorf, Germany.

Body: Circulating tumor cells (CTCs) are believed to be metastatic precursors of most solid epithelial tumors. Therefore, characterization of their genomic, transcriptomic, and proteomic features may improve cancer diagnosis and prognosis as well as treatment selection and monitoring. CTCs are mostly detected by systems utilizing expression of the epithelial cell adhesion molecule (EpCAM) on CTCs. However, CTCs which have acquired mesenchymal-like features are overlooked although they are believed to be the most malignant cells. Moreover, due to inter cellular heterogeneity single cell isolation by e.g. micromanipulation is required to achieve cellular resolution.

In this project we established a workflow combining the Parsortix™ system to enrich for EpCAM\textsuperscript{low/negative} CTCs by size and deformability and the CellCelector™ micromanipulator to singularize them for further molecular characterizations. First, our workflow was validated by cell-line spiking experiments into blood from healthy subjects (MCF7). Captured cells were stained \textit{in situ} for nuclei, cytokeratin and leukocyte markers, were harvested and then micromanipulated as single cells reaching a capturing rate of 62.66% (± 17.79) and a harvesting rate of 72% (± 29.61). Then this workflow was applied to a cohort of metastatic breast cancer blood samples which were previously depleted for EpCAM\textsuperscript{high} cells. In 18 out of 22 samples 541 EpCAM\textsuperscript{high} CTCs and in 16 samples 257 EpCAM\textsuperscript{low/negative} potential CTCs were found. Of these 156 EpCAM\textsuperscript{low/negative} and comparable numbers of EpCAM\textsuperscript{high} cells were successfully isolated and lysed for whole genome amplification (Ampli™). Successful genome-wide amplification was observed in 6.5% of EpCAM\textsuperscript{low/negative} cells vs. 30% of EpCAM\textsuperscript{high} cells indicating lower quality of genomic DNA in the first subpopulation. Sanger sequencing of PCR-amplified exons 9 and 20 of PIK3CA gene revealed heterogeneous mutation status in EpCAM\textsuperscript{low/negative} cells from the same patient. High quality WGA products were also processed for array-based comparative genomic hybridization (aCGH). Comparison of resulting profiles to 267 archived aCGH profiles from breast cancer single cells identified similar somatic copy number alterations: i.e. chromosome 1p loss and 1q gain confirming the tumor origin of captured EpCAM\textsuperscript{low/negative} cells. In addition we could also identify some different aberrations which need to be further investigated.

In summary, our workflow combining size based CTC enrichment followed by in situ labeling and micromanipulation is suitable for single tumor cell analysis.
**Title:** Nuclease-activated oligonucleotide probes for detection of breast cancer circulating tumor cells (CTCs): Early clinical results

Giangrande PH H, Kruspe S, Dickey DD D, Kamboj S, Clark KC C, Urak K, Burghardt E, Smith B, Thomas A and McNamara JO O. University of Iowa, Internal Medicine, Iowa City, IA; University of Iowa, Genetics Program, Iowa City, IA; University of Iowa, MCB Program, Iowa City, IA and University of Iowa, Biostatistics, Iowa City, IA.

**Body:**

**Introduction:**
A challenge for CTC-based diagnostic tests has been the development of methods with sufficient sensitivity to detect low levels of CTCs. Expense, accuracy and complexity have also limited clinical uptake of CTCs. To overcome these limitations we explored detecting CTCs by measuring their nuclease activity with *nuclease-activated probes*. We present the development of a rapid and highly-sensitive CTC detection assay based on probes that are selectively digested (activated) by target nucleases expressed in breast cancer cells.

**Methods:**
Nuclease activity in samples from women with Stage IV breast cancer and healthy donors was determined and correlated with clinical data. Patients seen at University of Iowa Clinics were eligible for this IRB-approved study. Blood samples were processed using microfilter (ScreenCell) units for CTC enrichment and converted into cell lysates that were examined by means of three different chemically-optimized oligonucleotide probes. CTC-derived nuclease activity was quantified using a fluorometer. The presence of CTCs was confirmed using established CTC detection methods (e.g. RT-PCR, immunohistostaining).

**Results:**
Sensitivity of the probe assay was 5 cancer cells in buffer solution and ~200 cancer cells in 1 mL of healthy donor blood. The final study cohort included 28 breast cancer patients and 10 healthy donors. The averaged signal intensities from patient samples were significantly higher compared to the healthy donor control group, presumably arising from CTCs in the blood. Statistical analysis further revealed short incubations in the assay (<20 min) to be optimal. From an ROC analysis we obtained AUC values of 0.8821, 0.8103 and 0.9356 for the three different probes. The oligonucleotide probe being the best predictor of disease yielded 100% sensitivity in the patient samples with a specificity of 70%. The *dsDNA 20 minute probe* was correlated negatively with tumors being ER+/PR+ (*p*=0.03). The *21'-RNA 0 minute probe* correlated significantly with HER2- tumors (*p*=0.04). In this smaller series other trends were also suggested.

**Conclusion:**
We describe a novel diagnostic for the detection of CTCs that could overcome limitations of CTC detection assays and could provide a robust diagnostic tool for breast cancer. Future clinical assays derived from this technology could require minimal training and infrastructure and might be developed into a point-of-care testing format.
Title: DETECT V - Detection of the expression of estrogen receptor and human epidermal growth factor receptor 2 on circulating tumor cells from metastatic breast cancer patients

Fehm T, Meier-Stiegen F, Riethdorf S, Schramm A, Polasik A, Niederacher D, Rack B, Taran F-A, Müller V, Janni W and Huober J. Gynecology and Obstetrics, Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany; University Hospital Hamburg-Eppendorf, Hamburg, Germany; Gynecology and Obstetrics, University Hospital Ulm, Ulm, Germany; Gynecology and Obstetrics, Klinikum der Ludwig-Maximilians-Universität, Munich, Germany; Gynecology and Obstetrics, University Hospital Tübingen, Tübingen, Germany and Gynecology and Obstetrics, University Hospital Hamburg-Eppendorf, Hamburg, Germany.

Body: Background: The prognostic relevance of circulating tumor cells (CTCs) in metastatic breast cancer (MBC) has constantly been shown in several clinical studies. Nevertheless, the predictive value of CTCs still remains unclear. The DETECT study concept evaluates the impact of CTCs on therapeutic decisions. Patients with hormone-receptor positive, HER2-positive MBC participating in DETECT V are randomized to a dual HER2 targeted therapy (Trastuzumab and Pertuzumab) combined with either endocrine therapy or chemotherapy. Based on the expression of Estrogen Receptor (ER) and Human Epidermal Growth Factor Receptor 2 (HER2) on detected CTCs, an „Endocrine Responsiveness Score (ERS)” is calculated for prediction of endocrine treatment response. Aim of this project was the optimization of staining procedures using immunofluorescence.

Methods: CTCs are enumerated and characterized using CELLSEARCH® CXC Kit which is based on the immunomagnetic enrichment of EPCAM-positive cells and immunofluorescent characterization of these cells. Comparison of staining intensities in different cell lines with known expression of ER and HER2 was used to validate the staining protocol. To validate ER-staining, staining intensities of the following cell lines were compared: SKBR-3 (negative control), MCF-7 (positive control) and T47D (intermediate expression). HER2-staining was validated comparing staining intensities of SKBR3 (positive control), MDA-MB 453 (intermediate expression) as well as MCF-7 (negative control).

Results: Staining intensities were divided into the following categories: negative, weak, moderate and strong. Signal intensities using CELLSEARCH® system correlated with the known expression of HER2 and ER in the different cell lines. No expression of ER could be shown in SKBR3 cells, T47D cells showed weak expression of ER. MCF-7 cells showed moderate to strong expression of ER but no expression of HER2. MDA-MB 453 and SKBR3 showed moderate to strong expression of HER2, respectively. Expression of HER2 and ER could be depicted accurately using CELLSEARCH® CXC Kit. Results were validated in a ring test in all participating laboratories. First patient samples are currently analyzed.

Conclusion: Establishment and validation of the ERS by characterizing CTCs within the framework of the DETECT V study pursues the objective of assessing the potential benefit of endocrine therapy. Validation results and first patient results will be shown.
Title: Circulating tumor cells (CTCs) biomarker evaluation from patients with metastatic breast cancer (MBC) utilizing the TargetSelector™ platform

Body: Background: Circulating blood biomarkers represent the promise of non-invasive, real-time surrogates for tumor tissue-based biomarkers as well as afford monitoring opportunities over the course of therapy as tumors evolve and acquire resistance to treatment. Circulating tumor cells (CTCs) are cells that disseminate from tumors and can be identified in peripheral blood. CellSearch® is an FDA approved methodology for detecting and enriching this rare CTC population. The prognostic value of CTCs has been established, however the potential to characterize biomarkers on CTCs to inform treatment decisions remains an active area of investigation. Among the emerging platforms for detection and characterization of CTCs is the TargetSelector™ system. While CellSearch® is limited to capture and detection of epithelial derived CTCs based on EpCAM and cytokeratin (CK) respectively, Biocept's TargetSelector™ platform utilizes a novel microfluidic system for CTC enrichment based on an antibody capture cocktail that allows for enumeration of CTCs with variable phenotypes (including CK- CTCs). The CTCs are captured in transparent microfluidic chambers and cells can be viewed in situ by fluorescence microscopy and analyzed via immunocytochemistry (ICC), fluorescence in situ hybridization (FISH) and PCR analyses.

Methods: Sixty-one patients with metastatic breast cancer consented and provided blood for utilization in the TargetSelector™ platform. Based on the molecular analysis of tissue biopsies, 92% of these patients had ER+ breast tumors. Biomarker expression on captured CTCs was determined by ICC for ER and by FISH for HER2. Concordance between these results and biomarker expression on archival tumor tissue from these patients was calculated.

Results: CTCs were detected in 60 of 61 patient blood samples (range 2–4471); 68% had both CK+ and CK- CTCs, and 32% had only CK- CTCs. None had only CK+ CTCs. Of those with CK+ CTCs, concordance for ER expression between the tissue and blood analyses was 85% (35/41). Concordance was much lower for patients with only CK- CTCs (32%, 6/19). Concordance for HER2 amplification in CK+ patients was 93% (38/41), and 68% (13/19) in CK- patients. For this study, the liquid biopsy was obtained over an extended period of time from when solid tumor ER and HER2 assessments were obtained; this latency period may have influenced concordance levels. For HER2, there was a significantly longer time interval between biopsies for non-concordant than for concordant pairs of samples (58.1 ± 19.7 vs. 30.9 ± 4.3 months) regardless of the CK status. No such difference was seen for the ER analysis.

Conclusions: In this exploratory analysis of 61 patients with MBC, we observed a high rate of detectable CTCs as well as CTC concordance for ER (85%) and HER2 amplification (93%) for patients who had CK+ CTCs. Concordance was less if patients only had CK- CTCs. This may be attributable to heterogeneity in the breast cancer phenotypes associated with these CK- CTCs in addition to inherent issues with testing cell surface markers in this population of cells. The variable latency between the collection of tissue and blood samples for these analyses may account for the discrepancies observed.
**Title:** Establishment and preliminary clinical application of breast cancer CTC detection kit based on immune magnetic lipid microsphere/human breast mammaglobin

Yang B, Wu J, Liang X, Mei S and Zhou B. Fudan University Shanghai Cancer Center, Shanghai, China; State Key Laboratory of Oncogenes and Related Genes, Shanghai Cancer Institute, Renji Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China and Shanghai Baihuikang Biotechnology Co., Ltd, Shanghai, China.

**Body:**

**Objective**
To explore the effect of breast cancer CTC detection kit based on immune magnetic lipid microsphere (IML) separation and human breast mammaglobin (hMAN) identification, we combined epithelial cell adhesion molecule (EpCAM) IML enrichment and immune fluorescence staining of CK/hMAN (IML/hM-BCD) method.

**Methods**

74 patients with metastatic breast cancer (MBC) were selected to validate the performance of our integrated CTC capture platform by carrying out side-by-side comparisons with the Cellsearch assay using the same sample. In each study, 15 mL blood was divided equally to identify CTC numbers by employing either Cellsearch and our platform.

**Results**

In MBC patients, the rates of diagnostic positive detection of Cellsearch and IML/hM-BCD method were 50% and 83.4%, respectively. The IML/hM-BCD method presented a greater ability to capture CTCs from MBC patients. A significant difference in the number (1~5) of CTCs captured by IMLM was observed in the images (2-fold more for IMLM vs Cellsearch\textsuperscript{TM}, \(P<0.001\)). Furthermore, the morphology and footprint sizes of the cells detected by IML/hM-BCD method offer another approach to validating these observations from the perspectives of cell pathology and cytology. The combined information was utilized to delineate CTCs (DAPI+/CK+/CD45-, cell size > 5 µm) from WBCs (DAPI+/CK-/CD45+, cell size < 15 µm) and cellular debris. Our immunomagnetic lipid microsphere captured significantly different CTC numbers that corresponded to the patients’ clinical data.

**Conclusions**

The panel of IML separation and combined CK/hMAN identification may serve as representative enrichment and biomarkers for CTCs, thus it presents potentially significant valve for monitoring early metastasis, therapeutic efficacy and prognosis for the patients with breast cancer.
A multiplexed immunofluorescence identifies phenotypic heterogeneity of circulating tumor cells in breast cancer

Kamal M, Zhang R, Walker M, Squires R, Talbert B, Dooley W, Razaq W and Tanaka T. University of Oklahoma Health Sciences Center, Stephenson Cancer Center, Oklahoma City, OK; University of Oklahoma Health Sciences Center, School of Medicine, Oklahoma City, OK; University of Oklahoma Health Sciences Center, Stephenson Cancer Center, Oklahoma City, OK and University of Oklahoma Health Sciences Center, School of Medicine, Oklahoma City, OK.

Body: **Introduction**: Circulating Tumor Cells (CTCs) have attracted significant attention as a new class of "liquid biopsy", enabling longitudinal and non-invasive disease monitoring to capture an overall snapshot of individual disease. Primary breast tumors are highly heterogeneous due to their genetic instability. Thus, the presence of heterogeneous populations of CTCs is expected. A number of attempts have been made to address CTC's phenotypic heterogeneity using different methods and approaches. For comprehensive understanding of distinct CTC phenotypes, transcriptomic and cell surface marker studies using single cell analysis separated CTCs into different subgroups with epithelial-, mesenchymal-, and stem-like signatures. These studies concluded that the prevalence of stem-like CTCs is associated with poor prognosis. Immunofluorescence is an ideal approach to understand the heterogeneity of 3 - 4 markers in a large number of distinct CTCs; however, such approach does not address the presence of overlapping phenotypic signatures. The collection method of CTCs adds another layer of complexity since the most commonly adopted CTC enumeration strategy relies on affinity-based selection using antibody against EpCAM, which, although abundantly expressed on epithelial cancer cells, automatically eliminates a large fraction of non-epithelial CTCs. To better understand the whole landscape of this heterogeneous disease, the use of marker-independent unbiased methods to collect CTCs is critical to obtain the overall landscape of phenotypic heterogeneity.

**Aim**: We aimed to investigate the heterogeneity of breast CTCs on a single cell level using size exclusion- based enrichment principal.

**Methods**: Whole blood was collected from metastatic breast cancer patients under IRB approved protocol. CTCs were isolated on porous membrane (8 µm) under negative pressure (ISET®) from 10 mL of blood. CTCs were fixed on the porous membrane and used for multiplexed immunofluorescence to investigate the expression of epithelial (CK and EPCAM), mesenchymal (Vimentin, Snail and TWIST), and stem-like markers (CD44, ALDH1, and CD133) on CTCs.

**Results**: CTCs were isolated on ISET filter from all subtypes, Stage IV patients. CTCs were identified based on their morphological and phenotypical characteristics with our CTC criteria of size of nucleus ≥16 µm, triple negative for α-smooth muscle actin, fibroblast associated protein, and CD45. The CTCs were further characterized based on their mesenchymal and stem-like signatures to understand their heterogeneity.

**Conclusions**: Multiplex immunofluorescence staining of CTCs collected using the size-based enrichment approach enabled us to identify the heterogeneity of CTCs. The phenotypic heterogeneity represents a corner stone for future studies to identify a subset of CTCs that may be associated with breast cancer patient prognosis.
Title: Circulating tumor cells in triple-negative breast cancer patients express prostate related genes and show different genetic profiles in US and German patient cohorts

Kasimir-Bauer S, Gao H, Bittner A-K, Plappert L, Feniuk N, Ueno NT T, Cohen L, Valero V, Woodward WA A, Alvarez RH H, Hoffmann O, Kimmig R and Reuben JM M. University Hospital Essen, Essen, Germany; Hematopathology, Houston, TX; Qiagen Hannover GmbH, Langenhagen, Germany; Breast Medical Oncology, Houston, TX; Integrative Medicine, Houston, TX and Radiation Oncology, Houston, TX.

Body: Background: Triple negative breast cancer (TNBC) is known for its aggressive behavior and poor prognosis since treatment options are limited. Specific biomarkers are urgently needed to treat patients (pts) accordingly. In this regard, circulating tumor cells (CTCs) are discussed to be an ideal surrogate marker for individualized treatment options. Using a multi-marker gene panel for the characterization of CTCs, we recently demonstrated that CTCs in TNBC pts and non-TNBC pts showed different genetic profiles including the expression of the androgen receptor (AR). We here compared CTCs of TNBC pts in two different national Institutions in the US (mainly Afro-American women) and Germany (Caucasian women) to identify potentially ethnical differences and to further explore AR expression related similarities of prostate cancer to TNBC.

Methods: 2x5 ml blood of TNBC pts before therapy (n=18 from the Dep. of Gynecol. and Obstetrics, Essen, GER; n=31 from the MDA Cancer Center Houston, US) were analyzed for CTCs applying positive immunomagnetic selection targeting EpCAM, EGFR and HER2 using the AdnaTest EMT-2/Stem Cell Select (QIAGEN Hannover GmbH, Germany). Subsequently, cDNA was pre-amplified for specific genes using TaqMan PreAmp Master Mix according to in house designed assays. Establishment of a 19 gene qPCR panel was performed for the markers PI3K, AKT2, ERCC1, AURKA, HER2, HER3, EGFR, ALK, AR, BRCA1, c-KIT, c-MET, KRT5, mTOR, NOTCH1, PARP1, SRC1, CD45 (leucocyte control) and GAPDH (housekeeping gene) as well as an internal reference. The cutoff was calculated, taking the false positive rate in healthy donors into account, and defined as Ct (cutoff) - Ct (sample) - [Ct (CD45cutoff) – Ct (CD45sample)]. Using the AdnaPanel Prostate Cancer (QIAGEN Hannover GmbH, Germany), cDNA obtained from a subset of 14 pts was further analyzed for the expression profile of AR, prostate specific antigen (PSA) as well as prostate specific membrane antigen (PSMA).

Results: The overall CTC-positivity rate (at least one of the markers expressed) was comparable between both sites (GER: 78%; US: 65%). Similar overexpression frequencies were found for AKT2, AR, AURKA, c-KIT, NOTCH1 and SRC at both sites. However, ALK, BRCA1, HER3 and KRT5 were predominantly found in CTCs of German pts while these genes were not or only weakly expressed in CTCs of the US group. In contrast, c-MET, ERCC1, HER2 and PARP were mainly expressed in CTCs of the US group and rarely in the German group. Interestingly, EGFR was not detected in both groups. Analyzing the overexpression of prostate related genes in a subgroup of 14 TNBC pts resulted in the expression of AR in 21%, PSA in 14%, and PSMA in 36% of cases, respectively.

Conclusion: Although we observed similar gene expression profiles in both patient cohorts, clear differences in some gene expression frequencies were detected at both sites. Whether these findings can be related to ethnic differences will be subject of further investigations. Furthermore, we were able to demonstrate that prostate related genes were frequently detectable which so far have not been discussed in the context of breast cancer.
Title: Inertial focusing circulating breast cancer cells based on the novel 3D-printed serpentine microfluidic chips

Yin P, Hu B, Zhu S and Tian J. School of Life Science and Technology, Xidian University, Xi’an, Shaanxi, China.

Background:
In the field of CTCs, single breast cancer cell information is fundamental for precision testing and prognosis. Traditional method to obtain CTCs information based on CellSearch system always get minimum biological information. Microfluidic chip is a promising tool for handling single cell especially metastatic breast cancer cells in the peripheral blood. Microfluidic fabrication based on polydimethylsiloxane (PDMS) by soft lithography is an expensive, involves substantial human labor, being hard to fully automate method. With the development of 3D printing, which provides extremely fast, cost-effective and less labor used tools, it has recently attracted attention as an approach to fabricate microfluidic chips. CTCs and leukocytes continuously focusing, ordering and positioning individually in microfluidic channel is very important for following single cell detection and analysis.

Methods:
Three type of 3D printers has been studied for printing microfluidic chips, including fused deposition modeling (FDM) (Cloud terminal 3D printer Realme 3D Ltd., China), stereolithography (SLA) (Form 1+, Formlabs, United States) and inkjet-based 3D printer (Projet 3500 HD, 3D system, United States).

In order to focusing breast CTCs and leukocytes into a single line, a serpentine microchannel was used with appropriate Reynolds Numbers, Dean Number, aspect ratio and channel length. Specific function and fabrication method of the chips dictate the design of the microfluidic device so that we design appropriate channels which consider below conditions. (1) Feature size of the microchannel should be printed by 3D printers; (2) Structure of the channel should focus CTCs and leukocytes into a single line one by one with a high throughput.

Results:
From our results, the inkjet 3D printing is suitable for fabricating microfluidic chips and the other two are not. The accuracy of FDM 3D printer, with a resolution of 1 mm channel feature size, is not satisfied with printing microfluidic chips and the material used by FDM was not transparency. Commercial SLA devices, with a resolution of 500 mm channel feature size, will be used to printing microfluidic chips one day with the improvement of photo spot controllable. At present, inkjet printing method, which has a resolution of 150 mm channel feature size, can be used as fabricating microfluidic chips with proper channel size.

Serpentine channels can be used to focus two different cells in a single line. According to calculation and simulation results, some proper conditions are present as follows. Rp should be less than 1 and can’t be far lower than 1; Dean Number approximate to 10; Rc should be between 1 ~100. should be approximate 0.1. The results also showed that aspect ratio of microchannel was 0.5 and the minimum channel length was 2.5cm calculated by lateral migration velocity.

Conclusions:
3D printing, which holds several significant advantages, can be utilized to fabricating inertial microfluidic chips. Commercial inkjet 3D printing can be used to printing useful inertial microfluidic chips. Serpentine microfluidic channel with sheath buffer flow can focusing breast cancer cells in a single line for detection such as Raman spectroscopy.

**Title:** Circulating tumor DNA analysis to predict relapse and overall survival in early breast cancer – Longer follow-up of a proof-of-principle study

**Body:**

**Background**

In a previous proof-of-principle study we demonstrated that detection of circulating tumour DNA (ctDNA) in the adjuvant setting, after completion of surgery and chemotherapy for early stage breast cancer, was associated with a high risk of early relapse. Here we present longer follow-up of the same series, to define the predictive power of ctDNA analysis for disease free survival, and assess the potential to predict overall survival.

**Methods**

We recruited a cohort of 55 women presenting with early stage, primary breast cancer, who were all scheduled to receive neo-adjuvant chemotherapy. The primary tumour was sequenced to identify somatic mutations, identifying at least one mutation in 43 patients. Mutations were tracked with digital PCR to identify ctDNA, in plasma samples taken either at a single post-surgical time point (2-6 weeks post-surgery) or with serial plasma samples taken every 6 months in the adjuvant setting.

**Results**

At a median 31.7 months follow-up, 42% (18/43) patients had relapsed. Detection of ctDNA at the single post-surgical time point was associated with poor disease free survival, HR=13.6 95%CI (4.5, 41.2) p<0.001, and overall survival HR=84.7 95%CI (9.8, 730.4) p<0.001. All patients with ctDNA detected in a single post-surgery time point relapsed and died in the follow-up period (7/7, 100% specificity), although the single post-surgery time point had modest 39% (7/18) sensitivity for relapse. Detection of ctDNA at any point in serial sampling was associated with poor disease free survival HR=25.7 95%CI (8.3, 79.8) p<0.001 and overall survival HR=47.1 95%CI (6.1, 366.1) p<0.001. All patients with ctDNA detected in a serial mutation tracking relapsed in the follow-up period (14/14, 100% specificity), with 78% (14/18) sensitivity for relapse. Sensitivity was limited by 3 cases of brain only relapse and one case of solitary ovarian relapse. Detection of ctDNA in serial sampling had a median lead-time of 8.1 months over clinical relapse.

**Conclusion**

Detection of ctDNA in the adjuvant setting has a high predictive power for future relapse and death from breast cancer. Therapeutic trials are required to determine whether mutation tracking identifies relapse sufficiently early to allow for further adjuvant therapy.

Title: ESR1 mutations in circulating tumor cell versus circulating cell-free DNA of metastatic breast cancer patients before first-line endocrine therapy and at progression

Sieuwerts AM M, Beije N, Kraan J, Van M, Onstenk W, Vitale SR R, van der Vlugt – Daane M, Hamberg P, Dirix LY Y, Brouwers A, de Jongh FE E, Jager A, Seynaeve CM M, Jansen MPHM PHM, Foekens JA A, Martens JWM WM and Sleijfer S. Erasmus MC Cancer Institute, Erasmus University Medical Center, Rotterdam, Netherlands; Cancer Genomics Netherlands, Rotterdam, Netherlands; University of Catania, Italy; Franciscus Gasthuis, Rotterdam, Netherlands; 5 Oncology Center GZA Hospital Sint Augustinus, Translational Cancer Research Unit, Antwerp, Belgium and Ikazia Hospital, Rotterdam, Netherlands.

Body: Background
Mutations in ESR1, the gene encoding the estrogen receptor, have been linked to endocrine resistance in metastatic breast cancer (MBC). It is thought that these mutations are selected during endocrine treatment (ET), but direct evidence that these ESR1 mutations (mESR1) emerge during treatment with endocrine agents is scant. We set out to evaluate mESR1 in circulating tumor cells (CTCs) and matched plasma cell-free DNA (cfDNA) of MBC patients before start of 1st line ET and at progression.

Materials & Methods
CellSearch-enriched CTCs (≥ 5 CTC/7.5 mL) of 37 MBC patients before start of 1st line ET (baseline cohort; BL) and 38 MBC patients who had progressed on any line of ET for metastatic disease (progressive disease cohort; PD) were evaluated. 52% of the PD patients received one line of ET and 48% more lines, of which 92% contained an aromatase inhibitor. In addition, 10 CellSearch-enriched fractions from healthy blood donors (HBDs) and 46 matched plasma samples (7xHBD, 15xBL, 24xPD) were included. DNA was isolated using the AllPrep kit and cfDNA with the QIAamp CNA kit (Qiagen). Hotspot mutations for ESR1 (D538G, Y537S, Y537C and Y537N) were evaluated with mutation-specific Taqman assays by chip-based digital PCR (QuantStudio 3D). mESR1 status was assessed after target-specific ESR1 amplification capturing all 4 mutations, with thresholds for positivity based on the highest variant allele frequencies in HBDs.

Results
Of all the CTC samples in the BL cohort, 1 patient had mutated Y537N copies, while this mutation was not detected in the matched cfDNA. This patient had received adjuvant treatment with tamoxifen. Also none of the other 14 BL cfDNA samples analyzed harbored mESR1. Three PD patients (8%) were positive for mESR1 in their CTCs (2x D538G and 1x Y537S). These D538G variants identified in CTCs were also detected in the corresponding cfDNA of these patients; for the Y537S mutation no matched cfDNA was available. Seven additional mESR1 carriers were identified in the other 22 matched cfDNA PD samples, resulting in 38% mESR1 positivity of the PD plasma samples (7x D538G, 1x Y537C and 1x Y537C).

Conclusion
Sensitivity for detecting mESR1 in CTC fractions (identified in 8% of the PD patients) was lower than for cfDNA samples. Using cfDNA for mESR1 detection, we found an higher prevalence of mESR1 variants in samples obtained at progression to ET (38%) compared to baseline (0%). These findings further substantiate the role of mESR1 in endocrine resistance.
Title: Circulating inflammatory markers, growth factors, and tumor associated antigens in women with early stage breast cancer receiving neoadjuvant metformin

Dowling RJ JO, Niraula S, Chang MC C, Ennis M, Stambolic V and Goodwin PJ J. Princess Margaret Cancer Centre, University Health Network, Toronto, ON, Canada; CancerCare Manitoba and University of Manitoba, Winnipeg, MB, Canada; Pathology and Laboratory Medicine, Toronto, ON, Canada; Mt. Sinai Hospital, University of Toronto, Toronto, ON, Canada; Lunenfeld-Tanenbaum Research Institute, Toronto, ON, Canada and Applied Statistician, Markham, ON, Canada.

Body: Background: Numerous clinical studies have reported that diabetic patients receiving metformin exhibit decreased cancer incidence and cancer related mortality. Metformin's mechanism of anti-tumor action has been attributed to both direct effects on cancer cells and systemic changes in insulin metabolism. Indeed, metformin reduces circulating insulin levels, which may be integral to its effectiveness in the breast cancer (BC) setting where hyperinsulinemia is associated with both recurrence and death. While the impact of metformin on blood glucose and insulin is well documented, its effects on other systemic physiologic and inflammatory factors are unknown. We completed a neoadjuvant “window of opportunity” study of metformin in non-diabetic women with BC and performed a series of analyses on plasma samples to assess the impact of metformin on circulating inflammatory markers, growth factors, and tumor associated antigens.

Methods: Non-diabetic women with early stage, untreated BC were given metformin 500 mg tid for ≥2 weeks post diagnostic core biopsy until surgery. Fasting blood was collected at diagnosis and surgery to assess circulating markers pre- and post-metformin administration. Plasma was isolated from blood samples and evaluated for CRP, TNF-alpha, IL-6, IL-8, VEGF, EGF, PIGF (placenta growth factor), CA15-3, and SBGP (serum bone Gla protein). Change scores (post-metformin minus pre-) were calculated and the degree of change characterized by the median change and the rank-biserial correlation. The Wilcoxon signed-rank test was used to test the null hypothesis that the change scores were symmetrically distributed around zero versus more positive or negative change.

Results: A total of 39 patients (mean age 51 years) completed the study and received metformin for a median of 18 days (range 13-40). Metformin was associated with changes in the levels of growth factors, with increases seen in EGF (median increase 1.1 pg/mL, r=0.42, p=0.027) and VEGF (1.7 pg/mL, r=0.31, p=0.09). A reduction in PIGF levels (-0.18 pg/mL, r=-0.6, p=0.0028) was also observed. The tumor associated antigen CA15-3 was significantly reduced after metformin treatment (-0.4 pg/mL, r=-0.56, p=0.0024) and a marker of bone turnover (SBGP) that has been linked to metastasis was increased (2 nM, r=0.30, p=0.1). For circulating inflammatory markers, a significant increase in the levels of IL-8 (0.8 pg/mL, r=0.36, p=0.048) was observed, but changes in TNF-alpha and IL-6 were minimal (TNF-alpha 0.2 pg/mL, r=0.20, p=0.29; IL-6 0.1 pg/mL, r=0.14, p=0.46) and no change was seen in CRP (0 mg/L, r=-0.05, p=0.93).

Conclusions: Short-term metformin administration was associated with alterations in systemic physiologic and inflammatory factors. Such increases in circulating cytokines and growth factors indicate possible alterations in the inflammatory state of the host and/or tumor. Of note, the reduction seen in the tumor antigen CA15-3 may reflect a disease-modifying effect of metformin in BC.

Title: Adipocyte fatty acid binding protein levels predict risk of obesity associated breast cancer

Sauter E, Hao J, Yan X, Kong M and Li B. Hartford Healthcare, Hartford, CT and University of Louisville, Louisville, KY.

Body: Background: Breast cancer risk has been linked to obesity, especially in postmenopausal women. Adipocyte fatty acid binding protein (A-FABP) is found in adipose tissue, and preliminary evidence suggests that its expression in serum is associated with obesity and breast cancer risk. Surgery for morbid obesity appears effective in decreasing morbidity and/or mortality from a variety of diseases of adulthood, including cancer. We evaluated the association of A-FABP expression with 1) body mass index (BMI), 2) breast cancer and 3) change in BMI after obesity surgery.

Hypothesis: Increased A-FABP expression is associated with 1) BMI level, 2) breast cancer, and 3) change in BMI after obesity surgery.

Methods: Serum was collected under an institutional review board approved protocol from two cohorts of obese women: 1) those with or without breast cancer, and 2) those undergoing surgery for morbid obesity. In the first cohort, samples were collected from 101 women prior to surgery to diagnose and treat a concerning breast lesion. In the second, samples were collected from 82 healthy obese women at baseline, and whenever possible, at 3, 6, and 12 months after obesity surgery. A-FABP levels in serum were measured using human A-FABP4 ELISA kits. The student's t-test was used to compare A-FABP levels in the two groups. Linear mixed effect models were used to examine the relationship between A-FABP and BMI or change of BMI over time, controlling for age, menopause status and history of breast cancer.

Results: A-FABP levels were significantly higher in women with cancer than healthy controls among obese women (p=0.039), but not among non-obese women (p > 0.05). A-FABP levels were higher in obese than non-obese women without (p=0.038) and with breast cancer (p<0.001). Among healthy obese controls, A-FABP was associated with BMI at baseline (p=0.016) and its change over time after surgery (p=0.005). The association of A-FABP with BMI was significant for women of normal breast cancer risk regardless of their menopause status (p=0.012 for pre-menopause and p<0.001 for post-menopause), but not for those with a family history of breast cancer (p>0.05). A-FABP was also more predictive of change in BMI in postmenopausal normal risk women (p<0.001) than in other groups (p>0.05).

Impact: Circulating levels of A-FABP are associated with cancer in obese women, with baseline BMI in healthy women and with change in BMI in normal risk women undergoing surgery for morbid obesity. These findings all point to a clinically important mechanistic role for A-FABP in obesity influenced breast cancer. They also suggest that downregulation of A-FABP may be involved in the decreased risk of cancer, including breast cancer, that has been observed in follow-up after obesity surgery.
Title: Prognostic role of PIK3CA mutational status in circulating tumor DNA (ctDNA) from HER2-positive metastatic breast cancer patients

Body: Phosphatidylinositol-4, 5-biphosphate 3-kinase, catalytic subunit alpha (PIK3CA) is one of the most commonly mutated genes in breast cancer. But the prognostic and predictive role of PIK3CA mutations remains a matter of debate. It has been suggested that PIK3CA mutations are related to resistance to trastuzumab-based therapies, but they were also related to relatively indolent disease with better progression-free survival. Recently, circulating tumor DNA has been proposed to be a sensitive biomarker for detecting the presence of specific genetic aberrations in various cancer types, providing prognostic and predictive information. In this study, we evaluated prognostic and predictive role of PIK3CA mutations in patients with HER2-positive metastatic breast cancer treated with 1st line trastuzumab and taxane combination chemotherapy.

Thirty-four patients with blood samples obtained before 1st line trastuzumab and taxane combination chemotherapy were included in the study. We analyzed two PIK3CA hotspot mutations (E545K, H1047R) in ctDNA by digital droplet PCR (Raindrop™). The samples were collected from April 2005 to December 2011, centrifuged and stored as plasma, and were analyzed in 2015, after 4-10 years of storage period.

Median age was 47 years (range: 31 to 75 years), and histologic type of cancer was ductal carcinoma in all cases. PIK3CA mutations were detected in 21 (61.8%) of 34 patients. Patients with mutated PIK3CA in ctDNA had longer progression-free survival (PIK3CA wild type vs mutant, 11.0 months vs 22.0 months; P = 0.013). In hormone receptor positive group, patients with mutated PIK3CA had longer progression-free survival (PIK3CA wild type vs mutant, 12 months vs 18 months, P=0.17). Patients with PIK3CA mutations had a lower objective response rate than patients with wild-type, but there was no statistical significance (CR+PR; PIK3CA wild type vs mutant, 84.6% vs 66.7%, P=0.43). There was no significant difference in response rate (P = 0.48) or PIK3CA mutational status (P = 0.44) according to hormonal receptor status (estrogen receptor and/or progesterone receptor).

In conclusion, PIK3CA mutations were frequently detected by digital PCR from ctDNA of patients with HER2-positive breast cancer and they were related to significantly better PFS. We plan to analyze the PIK3CA mutation status in matched tumor tissue.
**Title:** Serial monitoring of circulating tumor DNA in patients with metastatic breast cancer

Patel A, Mukherjee A, Hwang D, Ensor J, Patel TA A, Chang JC C and Rodriguez AA A. Houston Methodist Cancer Center, Houston, TX.

**Body:**

**Background:** For patients with MBC, there is currently no evidence that changing therapy on the basis of biomarker results improves outcome. Clinical benefit of treatment is defined as complete response, objective response, or stable disease as determined by RECIST criteria on radiological evaluation. Serial measurements of serum biomarkers such as CA2729 and CTCs have proven unsuccessful in predicting clinical benefit. Circulating tumor DNA (ctDNA) has emerged as a potential biomarker that may predict response to therapy or progression of disease. The present retrospective study was conducted to evaluate the relationship between change in ctDNA with clinical benefit determined by clinical and radiological evaluations of patients with MBC patients. **Methods:** We conducted a retrospective, single-institutional study to determine if serial monitoring of ctDNA allele frequency levels predict clinical benefit of a treatment. 55 patients with measurable MBC who had serial monitoring of ctDNA between August 2014 and May 2016 were included. The median age was 55.9 (27–94) years). Clinical outcomes were determined as per standard guidelines. The analysis was performed on all cases that had serial measurements of ctDNA with no change in therapy in between and the repeat blood draw was done within 30 days of repeat radiographic evaluation. The dataset contained 125 observations from 48 unique patients. The relationship between the change in ctDNA and clinical benefit was analyzed using a generalized linear model with a random subject effect to account for the intrapatient dependence occurring from obtaining multiple evaluations from the same patient. A logit link function was used akin to logistic regression and a compound symmetric correlation structure was assumed. **Results:** 68.8% of the cases were hormone receptor-positive, 18.8% HER2-positive, and 27.1% TNBC. The treatments received were 58.4% hormonal therapy, 31.2% chemotherapy, 26.4% included anti-HER2 therapy, 2 cases were on targeted therapy, and 1 case was not on any treatment. Three patients had stage 4 disease in complete remission. ctDNA analysis was repeated on average 4 days prior to radiological evaluation. The average time between repeat assessments was 108.5 days. 93% of the patients had a genomic alteration detected at some point during their course of disease. The most common mutations detected were TP53 41.7%, PIK3CA 35.4%, ESR1 18.8%, and ERBB2 amplifications 6.3%. A dichotomized change in ctDNA is a significant predictor of clinical benefit (p < 0.0001). The intrapatient correlation is estimated to be 0.273 for the transformed variable. The model yields a predicted probability of clinical benefit of 26.9% when the increase in ctDNA is greater than or equal to 0.5 and when the increase in ctDNA is less than 0.5, the a predicted probability of clinical benefit is 78.4%. The concordance of change in ctDNA and change in CA 27-29 was 76.2%. **Conclusions:** Serial evaluation of serum ctDNA may be useful to evaluate molecular response to treatment which may correlate with clinical benefit and potentially guide treatment decisions. Early indication that a chosen therapy is not effective may lead to avoidance of overtreatment and initiation of an alternative regimen. Further, prospective studies are needed.
Title: Delineation of breast cancer based on circulating protein biomarker profile using the OLINK proteomics multiplexed proximity extension assay

Jayachandran G, Cohen EN N, Gao H, Alvarez RH H, Valero V, Lim B, Woodward WA A, Ueno NT T and Reuben JM M. The University of Texas MD Anderson Cancer Center, Houston, TX; Cancer Treatment Centers of America, Newnan, GA; The University of Texas MD Anderson Cancer Center, Houston, TX and The University of Texas MD Anderson Cancer Center, Houston, TX.

Body: Background: Expression of cancer related genes and proteins in clinical specimens are the mainstay of personalized targeted therapy. In this study we investigated a blood-based non-invasive and sensitive technique to map biomarkers in breast cancer patients at the protein level instead of expression of cancer related genes. Other multi-platform assays require a large amount of clinical material, multi-step sample processing and complicated data analysis. Proximity Extension Assay performs a harmonious blending of immunoassay and PCR to amplify protein expression signal, thereby enabling multiplexing with small sample input (1 µl).

Material and methods: Plasma samples (n=25) from patients with inflammatory breast cancer (IBC) or non-IBC, metastatic and non-metastatic, collected prior to starting a new therapy (treatment naive) or a new line of therapy were analyzed using the Proseek Multiplex Oncology I v2 panel (Olink Proteomics, Uppsala, Sweden) for simultaneous detection of 92 human protein biomarkers. In the assay, each protein biomarker is detected by a matched pair of antibodies coupled to unique DNA-tags. Upon binding to the proteins, the correctly hybridized DNA-tags form an amplicon that is measured by a digital PCR. The data was subjected to a dynamic Principal Component Analysis (PCA) with a T-test filter using Multid GenEx software allowing the identification of a specific protein signature with the greatest inter-group differences. Plasma from seven healthy normal donors (HD) was also included in the analysis as comparison.

Results: A plasma protein signature consisting of MK, elf-4B, VIM biomarkers delineated all breast cancers from normal healthy donors. IL-8, CD40L, GDF-15, MCP-1, PARK7, CXCL11, FADD, CAIX, CD69, MIC-A, VEGF-D, EGFR, elf-4B, VIM, and PRSS8 distinguished patients with metastatic breast cancer from normal healthy donors. PCA also identified differences between IBC patients, non-IBC patients, and healthy donors. Clustered association of several protein biomarkers (MCP-1, VIM, HGF, PRSS8 and HER2) distinguished IBC from healthy donors. Plasma from IBC and non-IBC patients differed in their distribution of TNFSF14, CAIX, KN1A, CDHE4 and EGFR. All protein comparisons have p values < 0.05.

Conclusion: These preliminary data suggest that it is possible to distinguish between cancer patients and healthy normal donors, and IBC and non-IBC patients based on a plasma protein profile using the Proseek Multiplex Oncology I v2 panel from OLINK with just 1 µl of plasma. This pilot study will lead to the establishment of a training set for a protein signature to be applied in a subsequent validation in a larger cohort to assess treatment induced biomarker profile changes.
Title: Provista-002: A prospective, multi-center study to determine the effectiveness of a biomarker assay to distinguish benign from invasive breast cancer in women with BI-RADS 3, 4 and 5 imaging reports

Wolf J, Lourenco A, Alpers J, Rohatgi N, Constantini C, Hollingsworth A, Grobmyer S, Pederson H, Haythem A, Polen W, Northfelt D, Morris M, Baker K, Ghosh K, Kass F, Arterbery E, Yang R, Tran Q, Letsios E, Mulpuri R and Reese DE E. Rhode Island Hospital; Avera Cancer Institute; Sutter Institute; Scripps; Provista Diagnostics; Mercy Women's Hospital; Cleveland Clinic; Henry Ford Health System; Summit Medical Group New Jersey; Mayo Clinic; Banner Research Institute; St. Joseph's Hospital; Sansum Clinic; St. Mary's of Michigan and Lahey Clinic.

Body: Introduction:
The ability to detect Breast Cancer (BC), including ductal carcinoma in situ (DCIS) and invasive breast cancer (IBC), in a precise manner remains a challenge. Combinatorial biomarker panels, in conjunction with imaging, were developed to accurately detect BC independently using a serum-based approach. Prior studies demonstrated effectiveness in women under the age of 50; this study tests performance in women ages 25-75. This report presents data on the demographics of enrollment and comprehensive performance characteristics of the biomarker panel models.

Methods:
To rigorously test model performance in women with suspicious breast imaging, we enrolled 1,005 women across 2 cohorts in a national, multi-center, blinded and randomized manner. Serum was collected after a BI-RADS 3, 4 or 5 assessment (as assessed by any imaging modality including mammography, Ultrasound, 3-D Tomosynthesis or MRI) and blood was drawn prior to biopsy and serum frozen for later analysis. Participants who were not diagnosed with BC were followed for 6-12 months. Serum was evaluated for 11 Serum Protein Biomarkers (SPBs) and 33 Tumor Associated Autoantibodies (TAAbs). These measurements were modeled together with patient specific data to determine sensitivity, specificity, PPV and NPV in determining the presence or absence of BC (Grades I through III) in this population.

Results:
As observed in prior studies, the combinatorial use of multiple types of protein biomarkers (SPBs and TAAbs) and patient specific data result in superior performance characteristics than each class of biomarker alone. Both cohorts performed similarly where cohort 1 (n= 492) served as a model development set for cohort 2 (n= 502) which served as a validation set. Similar performance characteristics were observed in the validation set which represents the largest rigorously controlled proteomic clinical trial to date.

Conclusions:
These assays were developed to accurately detect BC and reduce false positives in clinically suspicious population. The majority of image-based false positives and false negatives occur in this group. Used properly, this test could ultimately reduce the number of unnecessary biopsies and possibly detect BC at an earlier, more easily treated stage.

Trial Registration:
ClinicalTrials.gov, NCT01839045 and NCT02078570.
Title: Clinical significance of sequential measurements of ESR1 mutations in plasma cell-free DNA in estrogen receptor positive recurrent metastatic breast cancer patients

Takeshita T, Yamamoto Y, Yamamoto-Ibusuki M, Sueta A, Tomiguchi M and Iwase H. Kumamoto University, Graduate School of Medical Science, Kumamoto, Japan and Kumamoto University Hospital.

Body: Background: The measurement of ESR1 mutations in plasma cell-free DNA (cfDNA) may transform the management of recurrent metastatic breast cancer (MBC) patients. We aimed to investigate the clinical significance of sequential measurements of ESR1 mutations in MBC patients.

Methods: A total of 59 patients (113 plasma samples) with breast carcinoma were enrolled in this study. Cases were selected if archival plasma samples were available from PBC before and after treatment and from MBC gathered more than twice at the time of progression. cfDNA was isolated from the 17 PBC patients (34 plasma samples) and from the 42 MBC patients (99 plasma samples). To investigate any changes in each cfDNA ESR1 mutation before and after treatment, we analyzed the difference with cfDNA ESR1 mutations ratio in the first blood sample using droplet digital polymerase chain reaction (ddPCR).

Results: The median changes in cfDNA ESR1 mutations ratio in the PBC group tended to be lower than that in the MBC group. The maximum change of each ESR1 mutation ratio in the PBC groups was used as the minimum cutoff for determining increases in cfDNA ESR1 mutation ratio. An increase in cfDNA ESR1 mutations was found in 13 plasma from 12 (28.6%) out of 42 MBC patients. 83.3% (10/12) of MBC patients with increase cfDNA ESR1 mutations showed a poor response to treatment. Interestingly, 12 MBC patients with increase cfDNA ESR1 mutations showed various response to endocrine therapy.

Abbreviations: ER, estrogen receptor; PgR, progesteron receptor; HER2, human epidermal growth factor receptor 2; PBC, primary breast cancer; MBC, metastatic breast cancer receptor; cfDNA, cell-free DNA; ET, endocrine therapy; BOR, best overall response; LET, letrozole; PD, progressive disease; LN, lymph node; LHRHa, luteinizing hormone releasing hormone agonist; ANA, anastrozole; Ful, fulvestrant; EE2, ethinylestradiol; PR, partial response; EXE+EVE, exemestane+everolimus; SD, stable disease; hdTOR, high dose toremifene.
In survival analysis, increase cfDNA *ESR1* mutations may predict a shorter duration of post-endocrine-therapy effectiveness ($P = 0.0033$).

**Conclusions:** We show that sequential measurements of the recurrent *ESR1* mutation in plasma cfDNA of MBC patients is a feasible and useful method of providing relevant predictive information.
Title: Reduced serum B-cell maturation antigen levels predict poor outcome in metastatic breast cancer patients in a phase 3 randomized 2nd-line hormone therapy trial

Ali SM M, Leitzel K, Li M, Udd K, Wang J, Sanchez E, Chen H, Berenson J and Lipton A. Penn State Hershey Medical Center, Hershey, PA; Lebanon VA Medical Center, Lebanon, PA and Institute for Myeloma & Bone Cancer Research, West Hollywood, CA.

Body: Background: B-cell maturation antigen (BCMA) is a member of the tumor necrosis factor receptor family and has two ligands, B-cell activating factor (BAFF) and a proliferation inducing ligand (APRIL). These ligands activate cell proliferation and inhibit apoptosis of normal and malignant B-cells including in multiple myeloma (MM) cell lines. Berenson et al have recently reported that circulating BCMA levels are elevated in B-cell malignancies and can be used to monitor disease and predict PFS and OS for patients with MM, Waldenstrom’s macroglobulinemia and chronic lymphocytic leukemia (CLL). On the other hand, recent studies have shown that serum BCMA levels are very low among patients with MM in complete remission with low antibody levels and those with primary immune deficiencies specifically those with combined variable immune deficiency and X-linked agammaglobulinemia. Studies of the potential role of serum BCMA for patients with solid tumors has not been evaluated to date.

Methods: The pretreatment serum from 139 patients with hormone receptor-positive metastatic breast cancer who were enrolled in a phase 3 randomized clinical trial of second-line hormone therapy was evaluated using an ELISA for BCMA. The BCMA ELISA was from R&D Systems (Minneapolis, MN). Serum BCMA was correlated with TTP using categorical serum BCMA cutpoints.

Results: Pretreatment serum BCMA levels had a median of 55.61 ng/ml, an interquartile range of 34.20 and 78.79 ng/ml, and full range from 3.99 to 1193.26 ng/ml. In univariate analysis for TTP, reduced serum BCMA correlated with shorter TTP at the following dichotomous cutpoints: 15 ng/ml [HR=2.60, p=0.064, n=6 (4.3%) of patients below cutpoint]; 20 ng/ml [HR=2.88, p=0.005, n=10 (7.2%) of patients below cutpoint]; 25 ng/ml [HR=2.16, p=0.023, n=13 (9.4%) of patients below cutpoint]; and 30 ng/ml [HR=1.77, p=0.016, n=27 (19.4%) of patients below the cutpoint].

Conclusions: In a phase 3 randomized clinical trial of second-line hormone therapy among patients with hormone receptor-positive metastatic breast cancer, reduced pretreatment serum BCMA was associated with shorter TTP. This may be due to the association of reduced serum BCMA with immune deficiency; and, thus, lead to shorter TTP among patients with metastatic breast cancer. Evaluation of serum BCMA as a new biomarker to predict outcomes for breast cancer and other solid tumor patients deserves further study.
Clinical utility of serial monitoring of circulating tumor DNA (ctDNA) in patients with neoadjuvant chemotherapy (NAC) for locally advanced breast cancer (LABC)

Kim J-Y, Park D, Jung HH, Bae SY, Yu JH, Lee SK, Kim SW, Lee JE, Nam SJ, Ahn JS, Im Y-H and Park YH. Samsung Medical Center, Seoul, Korea; Samsung Genome Institute, Samsung Medical Center, Seoul, Korea; Biomedical Research Institute, Samsung Medical Center, Seoul, Korea; Samsung Medical Center, Seoul, Korea and SAIHST, Sungkyunkwan University, Seoul, Korea.

Body: Introduction: Circulating tumor DNA (ctDNA) is a new biomarker which could guide further treatment. Characterization of tumor mutation profiles is required for informed choice of therapy, given that biological agents target specific pathways and effectiveness may be modulated by specific mutations. It would have clinical utility for neoadjuvant setting also. Thus, we assess the potency of ctDNA to predict tumor response to neoadjuvant chemotherapy (NAC) in locally advanced breast cancer (LABC).

Methods: We performed targeted deep sequencing of 30 plasma DNAs and 10 matched germline DNAs from 10 LABC patients. Serial plasma DNAs were collected at diagnosis, after 1st NAC and curative surgery. For the target enrichment, we designed RNA baits covering a total of ~202kb regions of human genome including a total of 83 cancer-related genes. We constructed the sequencing libraries according to the optimized protocol that we recently reported and sequenced on Illumina HiSeq2500 aiming a mean sequencing depth of ~10,000. After excluding unmapped reads, PCR duplicates and off-target reads, the coverage depths for plasma DNA and germline DNA samples were 2,627x and 4,833x on average, respectively. NAC response was measured by residual cancer burden (RCB) score, calculated as a continuous index combining pathologic measurements of primary tumor and nodal metastases for prediction of distant relapse-free survival.

Results: We analyzed ctDNA and primary tumor tissues from 10 patients with LABC scheduled NAC followed by operation in Samsung Medical Center. Of ten LABCs, one excluded from analysis because of angiosarcoma of breast. Five samples were triple-negative breast cancers (BCs), 2 were HER2 positive BCs and others were ER positive BCs. In tumor response, 1 patient had pathologic complete response (pCR), 1 had RCB class I, 4 and 3 patients did RCB class II and III. Of 83 genes, in analysis of ctDNA at BC diagnosis, we found 2 to 6 mutations in each samples and 3 mutations were detected averagely. Most common mutation was TP53 (6 patients), followed by PIK3CA mutation. By measuring these mutations in serial ctDNA, we found that ctDNA had disappeared after first cycle of NAC in patient with pCR. In two patients with RCB class I, ctDNA had decreased by more than 10 percent (the level of ctDNA(pg/ml): 455.9 to 30.4, 5.8 to 0.0) of primary plasma sample after first NAC. Two patients increased level of ctDNA had tumor response with RCB class III and one patient had distant tumor recurrence within 3 months after curative surgery. However, correlation between the level of ctDNA and initial stage was not observed.

Conclusions: This preliminary result suggests that serial monitoring of ctDNA would be a potential surrogate marker to predict tumor response and recurrence during NAC in LABC patients. Further results with long-term outcomes are warranted.
Title: Determination of a serum progranulin (GP88/PGRN) level associated with overall survival in metastatic breast cancer patients

Serrero G, Hawkins DM M, Yue B, Hicks D, Tait N and Tkaczuk KR R. A&G Pharmaceutical Inc., Columbia, MD; University of Minnesota, Minneapolis, MN and University of Maryland Greenebaum Comprehensive Cancer Center, Baltimore, MD.

Body: Imaging technologies are the methods of choice in the standard of care (SOC) to monitor therapy response in metastatic breast cancer (MBC) patients. However, such methods are expensive and have limited sensitivity to detect disease response in a timely manner. Measurement of the circulating tumor markers such as CA15-3, CA27.29 and CEA has provided additional minimally invasive methods in disease management of MBC patients. While useful, they have limitations in providing clinicians with a reliable insight into real-time disease monitoring. Understanding of real-time biological processes may provide better biomarkers of the disease state and thus aid real-time clinical management of MBC patients by identifying circulating disease associated biomarkers. Thus, addition of such new circulating biomarkers may improve the management of MBC patients. We have characterized a target biomarker that would fit these criteria, the 88kDa glycoprotein Progranulin (GP88). GP88 is expressed in tumor tissue and not in normal mammary tissue counterpart and is secreted in the circulation of BC patients. Biological studies have established GP88 as one of the critical drivers for breast cancer cell proliferation, survival, invasiveness and drug resistance. Clinical studies have demonstrated that elevated GP88 tumor levels were prognostic for recurrence and that breast cancer patients had a statistically elevated GP88 serum level than healthy individuals. Using tissue and serum tests to detect and quantify GP88 could provide an new strategies for identifying patients at high risk of recurrence and monitoring disease progression in BC patients undergoing therapy. In the present study, we examined whether GP88 serum levels were elevated in MBC patients and whether GP88 serum levels were correlated to patient overall survival.

Under an IRB approved protocol, 92 MBC patients that met the inclusion criteria and were undergoing therapy at the UMGCCC Breast Clinic were consented and enrolled. Clinical and disease characteristics along with serum CA15-3 values were collected as part of the study. Serum samples were collected from each patient during therapy and subsequently the patients were monitored. The serum was stored at -80C until tested for GP88 using a GP88 enzyme linked immunoassay developed in our laboratory.

Statistical analysis using Kaplan-Meier functions established whether there was a correlation between GP88 serum level and overall survival in MBC patients. By analyzing the KM plots at different GP88 cut points, we identified two populations with distinct survival characteristics. When examined more thoroughly the difference in overall survival of patients with <60ng/ml and >60ng/ml was statistically significant (P=0.0002). Correlation analysis of serum GP88 and CA15-3 were performed and will be presented.

We conclude that circulating levels of GP88 in MBC patients are correlated with overall survival. It would appear that patients that can be managed to have a GP88 below 60ng/ml will survive longer. Thus measuring circulating GP88 levels would provide additional information to that available in today's SOC for monitoring. This valuable insight into real-time disease status will assist clinicians in patient management.
Title: Differential expression of exosomal miRNAs between breast cancer patients with recurrence and no-recurrence

Sueta A, Yamamoto Y, Tomiguchi M, Takeshita T, Ibusuki M and Iwase H. Kumamoto University Graduate School of Medical Science, Japan.

Body: Background
In recent years, there has been a concerted effort to identify biomarkers derived from body fluid in various cancers. Exosomal microRNA (miRNA) has been used as one of useful diagnostic or prognostic biomarkers. We aimed to investigate the prognostic role of the exosomal miRNAs in serum samples derived from patients with primary breast cancer. Additionally, we evaluated whether the exosomal miRNA in serum reflect the origin of primary tumor by means of comparing their expression levels between in serum and tumors.

Patients and Methods
Exosomes in serum sample (500uL) were extracted using ExoQuick (System Biosciences) and miRNAs were isolated using SeraMir™ Exosome RNA Amplification Kit (SBI). We compared the miRNA profile derived from exosome between the patients with breast cancer with recurrence (n=16) and without recurrence (n=16) by miRNA PCR array. Further, we examined the expression of miRNA derived from tumor tissues in the patients with breast cancer recurrence (n=35) and without recurrence (n=39) by qRT-PCR. All samples were collected before treatment and surgery.

Results
Of the 384 miRNAs, 11 miRNAs were significantly expressed; three miRNAs (miR-338-3p, miR-340-5p, and miR-124-3p) were significantly up-regulated and eight (miR-29b-3p, miR-20b-5p, miR-17-5p, miR-130a-3p, miR-19a-5p, miR-195-5p, miR-486-5p, and miR-93a-5p) were significantly down-regulated in the patients with recurrence compared to those without recurrence. Next, we evaluated expression of the above miRNAs in tumor tissues. The patients with recurrence have higher levels of miR-340 at their primary site as well as in the serum. On the contrary, miR-195-5p, miR-17-5p, miR-93-5p, and miR-130a-3p derived from tumor tissues that were down-regulated in the patients with recurrence in serum, were highly expressed in the patients with recurrence than those with no-recurrence. In logistic regression analysis, tumor size, miR-340-5p, miR-17-5p, miR-130a-3p, and miR-93-5p were significantly associated with breast cancer recurrence (each $P < 0.05$).

Conclusions
Several exosomal miRNAs at diagnosis may be useful biomarker to predict the breast cancer recurrence. Moreover, we showed the different expression pattern of miRNAs between tumor tissues and serum. These findings may suggest selective mechanism of release of exosomal miRNA by cancer cells to regulate their progression. Further studies to confirm our results are needed.
Circulating cell-free DNA (CFD) measured by a simple fluorescent assay to predict relapse in triple negative breast cancer patients receiving neoadjuvant chemotherapy: A biomarker substudy of prospective observational study (NCT02001519, NCT02001506)

Park K, Woo M, Kim JE, Ahn J-H, Jung KH and Kim S-B. Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea and Medical Oncology and Hematology, Pusan National University Yangsan Hospital, Yangsan, Korea.

**Background:** Prior technique to measure cell free DNA (CFD) is labor-intensive and expensive, while, recently developed fluorescent CFD assay is more simple and convenient. The aim of this study was to evaluate the role of CFD measured by a fluorescent assay as a biomarker of patients with triple negative breast cancer (TNBC) received neoadjuvant chemotherapy.

**Methods:** We prospectively enrolled patients with TNBC, clinical stage II or III (T>1.5cm or lymph node > 1.5cm), who were scheduled for neoadjuvant chemotherapy. Patients received 4 cycles of adriamycin 60 mg/m2 plus cyclophosphamide 600 mg/m2 (AC) followed by 4 cycles of cisplatin or docetaxel, and surgery. Plasma samples were obtained from patients before initial chemotherapy (baseline-CFD) and after 4 cycles of AC neoadjuvant chemotherapy (AC-CFD).

**Results:** This study included 72 patients who met the inclusion criteria. The mean levels of baseline-CFD and AC-CFD were 239±68 ng/mL and 210±66 ng/mL, respectively, and the CFD level was significantly decreased after AC chemotherapy. The baseline-CFD was not associated with initial tumor characteristics. (T stage 1-2 vs. 3, p=0.313; N stage 0 vs. 1-3, p=0.317) There was no statistically significant difference between patients with response (CR or PR) to AC chemotherapy and those without response in terms of baseline-CFD, AC-CFD, and change of CFD between two values. (p=0.814, p=0.839, p=0.927) With 33.6 months of median follow up, there were 18 cases of relapse. Relapsed group showed numerically higher level of baseline-CFD, although it was not statistically significant. (relapse, 259 ng/mL; non-relapse, 233 ng/mL; p=0.161) We performed a ROC curve analysis of baseline-CFD for relapse, and found an area under the curve of 0.62 (95% CI, 0.46-0.78) at 222 ng/mL. Patients with baseline-CFD above 222 showed higher relapses than those below 222. (HR, 2.75; 95% CI, 0.96-7.84; p = 0.059)

**Conclusions:** The baseline-CFD obtained using a simple and convenient fluorescent assay could predict relapse, suggesting baseline-CFD as a potential biomarker for risk stratification of TNBC.
Title: An international multicenter study to evaluate reproducibility of automated scoring methods for assessment of Ki67 in breast cancer

Rimm DL L, McShane LM M, Leung SCY CY, Bai Y, Bane AL L, Bartlett JMS MS, Bayani J, Chang MC C, Dean M, Denkert C, Enwere E, Galderisi C, Gholap A, Hugh JC C, Jadhav A, Kornaga E, Laurinavicius A, Levenson R, Lima J, Miller K, Pantanowitz L, Piper T, Ruan J, Srinivasan M, Virk S, Wu Y, Yang H, Hayes DF F, Nielsen TO O and Dowsett M. Body: Background: The nuclear proliferation biomarker Ki67 has multiple potential roles in breast cancer, including prognosis-based decisions, but unacceptable between-laboratory variability has limited its clinical value. The International Ki67 Working Group (IKWG) has undertaken a systematic program to determine whether Ki67 immunohistochemistry can be analytically validated and standardized across laboratories. Technological advances and broader availability of devices for automated assessment of stained slides raise the possibility that these machines may improve on reproducibility of traditional pathologist-based visual Ki67 assessment.

Aims: To characterize reproducibility of automated machine-measured Ki67 expression using slides previously analyzed in the IKWG phase 3 study that evaluated reproducibility of visual Ki67 assessment.

Methods: Two sets of 30 previously stained slides containing core-cut biopsy sections of breast tumors were circulated to 14 laboratories for scanning and automated assessment of Ki67 expression. Sites were instructed to return average and maximum percentage of tumor cells positive for Ki67 for each slide, where maximum is designed to reflect “hot spot” analysis. Two laboratories returned scores from 2 operators; not all laboratories reported values for maximum Ki67 scores. Different operators were treated as distinct laboratories in analyses. Sixteen and 10 score sets were available for average and maximum Ki67 analyses, respectively, encompassing 7 unique scanner and 10 software platforms. Pre-specified analyses included evaluation of reproducibility across all laboratories as well as within a subgroup limited to those using Aperio scanners. The primary reproducibility metric was intraclass correlation coefficient between laboratories (ICC), regardless of device platform or software. Results: Geometric means across 30 cases for 16 operators ranged from 11.06% to 38.11% with overall mean 16.75% (95% CI:14.45-19.42) for average scores. Geometric means for 10 operators ranged from 16.44% to 68.73% with overall mean 25.16% (95% CI: 18.71-33.84) for maximum scores. ICC for automated average scores across 16 operators was 0.83 (95% CI; 0.73-0.91) and ICC for maximum scores across 10 operators was 0.63 (95% CI: 0.44-0.80) although one outlier lab dramatically affected results. For the laboratories using the Aperio platform (8 score sets), ICC for automated average scores was 0.89 (95% CI; 0.81-0.96). These results are similar to ICC of 0.87 (95%CI; 0.81-0.93) reported using these same slides in the Phase 3 visual assessment reproducibility study in which observers counted 500 cells per slide (Leung et al, NPJBrCancer, in press).

Conclusions: Between-laboratory reproducibility for automated machine assessment of average Ki67 is similar to that for pathologist-based visual assessment of Ki67. However, the observed ICC was markedly numerically lower for the maximum score method compared to the average method, suggesting that the maximum score may not be useful as a reproducible measure of proliferation. Automated average scoring methods show promise for standardization of Ki67 scoring, supporting future studies to clinically validate Ki67.
Title: Intratumoral heterogeneity of Ki67 expression in early breast cancers exceeds variability between individual tumours

Focke CM M, Decker T and van Diest PJ J. Dietrich Bonhoeffer Medical Center, Neubrandenburg, Germany and University Medical Center Utrecht, Utrecht, Netherlands.

Body: Background
Regional differences in proliferative activity are commonly seen within breast cancers, but little is known on the degree of intratumoral heterogeneity of Ki67 expression. Our aim was to study intratumoral heterogeneity of Ki67 expression in early breast cancers and its association with clinicopathological features like estrogen receptor (ER) status, grade and histological type.

Methods
The Ki67-labelling index (Ki67-LI) was assessed in hot, cold and intermediate spots of 233 invasive breast cancers by counting a total of 1020 cells, according to a protocol of the International Ki67 in Breast Cancer Working Group. Differences between the spots per tumor were further analyzed for clinicopathological subgroups defined by ER status, grade and histological type.

Results
All clinicopathological subgroups showed significant differences in Ki67-LI between hot, intermediate and cold spots (p <0.001). The coefficient of variance (CV) between the spots was higher in ER positive than in ER negative cancers (72.6% vs 49.2%, p <0.001), and was highest in grade 3 (96.12%), grade 1 (87.27%) and invasive lobular tumors (83.59%), and lowest in medullary (26.48%) cancers. Nested analysis of variance indicated that in both ER positive and ER negative cancers, variance in Ki67-LI within tumours contributed more to the total variance (56% for ER positive, 60% for ER negative cancers) than the variance between tumors.

Conclusion
Intratumoral heterogeneity in Ki67-LI is an ubiquitous phenomenon across various pathological subgroups of breast cancer that may impact assessment of Ki67 levels for clinical decision making, and sheds new light on recommended cut-offs.
Title: High concordance of ER, PR, HER2 and Ki67 by central IHC and FISH with mRNA measurements by GeneXpert® breast cancer stratifier assay

Body: Current methods for the assessment of ER, PR, Her2, and Ki67 using FFPE tissues are hard to standardize and difficult to perform in Low and Middle Income Countries (LMIC). The GeneXpert® breast cancer stratifier assay (RUO) (BC Strat) is a cartridge-based, RT-qPCR assay of \textit{ESR1}, \textit{PGR}, \textit{ERBB2}, and \textit{MKi67} mRNAs using FFPE specimens. The assay is fast (<2 hours, including <10 minutes of hands-on time) and easy to perform.

The aims of this study were: 1) to evaluate the concordance of BC Strat using different IHC antibodies and scoring methods in a preliminary dataset (Part I); and 2) to assess concordance between BC Strat and high quality standard methods in an expanded dataset (Part II).

\textbf{Methods}

\textbf{Part I: IHC Antibody Variability}

To assess BC Strat concordance with various IHC antibodies, 155 invasive ductal carcinoma blocks were sourced from 3 sites. Twenty-four adjacent slide sections from each block were prepared and shipped to different labs for BC Strat analysis (Cepheid) or IHC and FISH testing. Table 1 summarizes the IHC antibodies and scoring methods used in each reference lab.

\begin{table}[h]

\hline
\end{tabular}
\caption{IHC antibodies and scoring methods used in reference labs}
\end{table}

*HER2 FISH (all with PathVysion kit) was performed at USC

\textbf{Part II: Concordance Study}

522 invasive ductal carcinoma FFPE samples were sourced from 5 sites. All BC Strat analysis was performed at Cepheid and all IHC and FISH was performed in the Press laboratory at USC. Overall percent agreement (OPA), positive percent agreement (PPA), and negative percent agreement (NPA) between BC Strat and IHC were determined.
Results

Part I: IHC Antibody Variability
Table 2 summarizes the OPA for BC Strat analysis and IHC performed with different IHC antibodies and scoring methods. Slightly better concordance for ER and PR was observed between the BC Strat and the IHC methods performed at USC. Discordant IHC results were also observed among the reference labs’ standard methodologies.

Table 2: Overall Percent Agreement between IHC and BC Strat

*for IHC 2+(equivocal), FISH HER2/CEP17 ratio was examined

Part II: Concordance Study
Of the 522 samples tested, 499 (96%) yielded valid results for both BC Strat and IHC (IHC and FISH for Her2). OPA between BC Strat and IHC was 98% for *ESR1*, 91% for *PGR*, 93% for *ERBB2* (IHC and FISH, 97% for Her2 IHC excluding IHC2+), and 81% for *MKi67*.

Conclusion
BC Strat assay measurements for *ESR1*, *PGR*, *ERBB2* and *MKi67* mRNA expression in FFPE breast tumor tissues are highly concordant with IHC and FISH performed by high quality reference labs. Further investigations using clinical outcomes from independent studies including prospective-retrospective clinical trials are in progress.
Title: Concordance of local immunohistochemistry with TargetPrint microarray based assessment of ER, PR and Her2 and BluePrint molecular subtyping in the Symphony Triple A study

Kuijer A, Straver M, Elias S, Smorenburg C, Wesseling J, Linn S, Rutgers E, Siesling S and van Dalen T. Diakonessenhuis, Utrecht, Netherlands; University Medical Center Utrecht, Utrecht, Netherlands; Netherlands Cancer Institute, Amsterdam, Netherlands and Comprehensive Cancer Center, Utrecht, Netherlands.

Body: PURPOSE: A decade ago intrinsic biological breast cancer subtypes have been identified which have proven to be of clinical importance in terms of outcome and response to systemic treatment. The aim of the current study is to assess concordance between breast cancer subtypes determined by local immunohistochemistry (IHC) assessment of estrogen receptor (ER), progesterone receptor (PR) and Her2-receptor status and microarray based molecular subtyping in a subset of ER+ early stage breast cancer patients.

PATIENTS AND METHODS: In this prospective observational multicenter study information on local pathology assessment and BluePrint/TargetPrint results were obtained in ER+ Dutch early stage breast cancer patients in whom a 70-gene profile (MammaPrint) was used as they were enrolled in clinical trial based on the existence of controversy regarding the additional value of adjuvant CT. Local IHC assessment of ER, PR and Her2 status were compared with microarray based assessment (TargetPrint/BluePrint) of these characteristics. Reclassification of ER and PR overexpression was assessed by a McNemars test and by Spearman correlation. Furthermore, concordance between the clinical subtypes based on local pathology (Luminal-type: ER+/PR+/Her2-; Her2-type: Her2+ disease) and molecular subtyping was assessed.

RESULTS: Between January 2013 and December 2015 660 patients, treated in 31 hospitals, were enrolled. In 564 (85%) BluePrint and/or TargetPrint was performed in addition to the 70-GS. The majority of patients had ER+/Her2- disease and TargetPrint reclassified 1% (n = 7) of patients as ER-negative (r = 0,250, p <0,001). TargetPrint reclassified 7% (n = 40) and 2% (n = 11) of patients for PR and Her2 status respectively (table 1, r = 0,580, p <0,001 for PR).

). Based on IHC 545 (98%) patients were regarded as luminal-type and the remaining 2% as Her2-type. BluePrint reclassified 2% of the clinical luminal-type patients: 4 (1%) patients were reclassified as basal-type and 3 (0%) patients as Her2-type. Of the clinical Her2-type patients 80% (n=8) was reclassified by BluePrint as molecular luminal-type

**Conclusion:** In the current study we observe a high concordance between microarray-based assessment of ER, PR and Her2 and local pathology in Dutch ER+ early stage breast cancer patients. In the small subset of ER+ patients who are considered candidates for 70 GS use and who have HER2+ tumors by IHC molecular typing of HER2 status is of additional value.

Title: A comprehensive molecular analysis of medullary breast carcinoma: A model of immunomodulatory triple negative breast cancer subtype

Body: Medullary breast carcinoma (MBC) is a rare subtype of triple negative breast cancer (TNBC) with specific genomic features within the spectrum of basal-like carcinoma. The frequent association between BRCA constitutive mutation and MBC phenotype has been reported previously. In this study including 19 MBC and 36 non-MMB basal-like carcinoma (BLC), we refine the genomic and transcriptomic knowledge about this entity. Using pan genomic Affymetrix genome-wide human SNP6.0 array, we show that i/ MBC harbour more copy number alterations and losses of heterozygocity than BLC and that ii/ the high frequency of BRCAness genomic trait among MBC. Unsupervised and supervised analysis of GeneChip Uman Genome U133 Plus 2.0 Array transcriptomic generated data confirmed that MBC clearly differ from BLC in terms of gene expression level, with 92 genes overexpressed and 154 genes underexpressed in MBC over BLC. Immune response and inflammatory response are the most differentially represented pathways in MBC over BLC. Pro apoptotic gene BCLG is by far the more overexpressed gene in MBC. A validation study conducted with RT-QPCR among 526 breast tumors from all molecular subtype confirmed the specificity of BCLG overexpression in MBC, which was confirmed at protein level using immunohistochemistry. Moreover, we show that a vast majority of MBC belong o the immunomodulatory TNBC subtype according to Lehman et al. Finally, we confirm the better prognosis of MBC toward BLC. Our observations epitomize the importance of developing DNA repair targeting drugs and immunotherapy based trials in order to improve the outcome of such a specific entity.
Title: Improvement in risk predictive value of Nottingham prognostic index by determining GP88 tumor tissue expression for estrogen receptor positive breast cancer patients

Serrero G, Hawkins DM M, Bejarano PA A, Ioffe O, Tkaczuk KR R, Elliott RE E, Head JF F, Phillips J, Godwin AK K, Weaver J, Hicks D and Yue B. A&G Pharmaceutical Inc., Columbia, MD; University of Minnesota, Minneapolis, MN; Cleveland Clinic Florida, Weston, FL; University of Maryland Greenebaum Comprehensive Cancer Center, Baltimore, MD; EEH Breast Cancer Research and Treatment Center, Baton Rouge, LA; University of Kansas Medical Center, Kansas City, KS and University of Pennsylvania School of Medicine, Philadelphia, PA.

Body: Background: The Nottingham Prognostic Index (NPI), which includes nodal status, tumor size and histological grade was established to provide predictive value information on post-surgery survival for primary breast cancer patients. Attempts to improve NPI's performance have included addition of other biomarker expression and morphological features such as vascular invasion. In the present study, we investigated whether expression of the autocrine growth and survival factor GP88 (progranulin), known to be overexpressed in breast cancer, whereas it is negative in normal mammary tissue, would improve NPI's predictive value.

Methods: We examined the tumor tissue GP88 expression by immunohistochemistry (IHC) in formalin fixed paraffin embedded tissue sections from 508 cases of estrogen receptor positive (ER+) invasive ductal carcinoma (IDC) with known clinical outcomes (disease-free and overall survivals) and with known NPI. GP88 IHC tumor tissue expression was determined using an anti-GP88 antibody (clone 6B3) developed in our laboratory. GP88 expression was scored (0, 1+, 2+, 3+) by two board certified pathologists and classified into two IHC score groups of GP88 < 3+ (0, 1+, 2+) and GP88 = 3+. The correlation between GP88 scoring, NPI and disease-free (DFS) and overall survival (OS) outcomes was then examined by Kaplan Meier analysis, Cox proportional Hazard (CPH) ratio and Pearson's $\chi^2$ test.

Results: Kaplan-Meier survival graphs categorized by NPI scores (< 3.4, 3.4-5.4, and >5.4) and by GP88 expression (< 3+ and 3+) showed that for each NPI subgroup, patients with GP88 IHC score of 3+ had a worse disease-free survival (DFS) and overall survival (OS) than patients within the same NPI subgroup with tumors that had GP88 IHC score < 3+. When adjusted for NPI, high GP88 score was highly significantly associated with recurrence with a hazard ratio of 3.30 (95% CI 2.12 to 5.14).

Conclusions: The data suggest that measuring GP88 tumor tissue expression by IHC at time of diagnosis for breast cancer patients with primary ER+ IDC could provide recurrence prediction and survival information complementary to that provided by the determination of NPI alone and thus may be useful for risk management of patients diagnosed with breast cancer.
**Title:** High concordance of a closed system, near point of care, RT-qPCR breast cancer assay for HER2 (ERBB2) mRNA compared to both IHC/FISH and quantitative immunofluorescence

**Body:**

**Background**
Reliable assessment of HER2 receptor status in breast cancer by either IHC or FISH does not unequivocally define receptor expression, due to their semi-quantitative nature, and as many as 10-15% of cases fall into the ASCO/CAP "equivocal" category. Historically, RNA measurements by PCR, including using several commercially available platforms, have been tested, but have not gained broad acceptance for assessment of HER2. However, RNA measurement, as a continuous value, has potential for use for adjudication of the equivocal category. In the current study, we used a real-time quantitative reverse transcription polymerase chain reaction (RT-qPCR) assay (GeneXpert® Breast Cancer Stratifier RUO Assay, Cepheid, Sunnyvale, CA, USA) for ERBB2 (HER2) mRNA on the GeneXpert® (GX) platform (Cepheid), which utilizes a closed-system, single-use cartridge, automated system. The RT-qPCR results from GX were then compared with results from clinical HER2 IHC/FISH assays following ASCO/CAP 2013 HER2 testing guidelines (Wolff et al JCO 2013) and quantitative immunofluorescence (QIF).

**Methods**
Multiple cores (1mm in diameter) were retrospectively collected from 80 formalin-fixed paraffin-embedded (FFPE) tissue blocks with invasive breast cancer seen by Yale Pathology Labs between 1998 and 2011. Tissue cores were processed as lysates for testing at Yale in the automated GX assay. Briefly, gene-specific reverse transcription was performed, followed by RT-qPCR (TaqMan) and ERBB2 mRNA results were expressed as the difference in cycle threshold values (delta Ct) between the endogenous control transcript (CYFIP1) and the ERBB2 mRNA transcript. Results from IHC and FISH were extracted from the pathology reports for the Yale CLIA lab and QIF for each case was measured as previously described (Carvajal et al, JNCI 2015).

**Results**
Quality control testing showed that the GX platform shows no case to case cross contamination on material from routine histology practices. Concordance between RT-qPCR and IHC/FISH was 91.25% (sensitivity = 0.87; specificity = 0.94; PPV = 0.89; NPV = 0.92) using a pre-defined delta Ct cut-off (dCt ≥ -1) for HER2 (+) based on prior concordance studies with HER2 IHC/FISH. Concordance between RT-qPCR and QIF was 99% (sensitivity = 0.97; specificity = 1.0; PPV = 1.0; NPV = 0.98) using dCt ≥ -1 and the pre-defined cut-point for positivity by QIF.

**Conclusions**
The GX closed system RT-qPCR assay shows greater than 90% concordance with the ASCO/CAP 2013 HER2 IHC/FISH scoring. Additionally, the GX RT-qPCR assay is highly concordant (99%) with the continuous variable HER2 QIF assay, and may better reflect the true continuum of HER2 receptor status in invasive breast cancer. These initial results suggest that rapid, closed system molecular assays may have future value for the adjudication of the ASCO/CAP HER2 equivocal category. This pilot study did not include ASCO/CAP 2013 “equivocal” cases, but that effort is underway.
**Title:** Simultaneous analyses of HER2 gene and protein status can more precisely predict pathological complete response (pCR) to neoadjuvant trastuzumab with chemotherapy in primary HER2-positive breast cancer

Horii R, Nitta H, Ito Y, Iwase T, Ohno S and Akiyama F. Cancer Institute, Japanese Foundation for Cancer Research, Tokyo, Japan; Ventana Medical Systems, Inc., Tucson, AZ and Breast Oncology Center, Cancer Institute Hospital, Japanese Foundation for Cancer Research, Tokyo, Japan.

**Body:** **Background:** HER2-positive breast cancer is characterized by overexpression of HER2 protein and/or amplification of the HER2 gene, assessed by immunohistochemistry (IHC) and *in situ* hybridization (ISH), respectively. According to the 2013 ASCO/CAP guidelines on HER2 testing in breast cancer, both protein and gene status can be classified into three categories: positive, equivocal and negative. Gene-protein assay (GPA) is a newly developed technique, in which IHC and dual color ISH (DISH) are simultaneously performed on a single slide. HER2 GPA slides allow bright-field analyses of both protein and gene expression status of each cell. Breast cancer cells can be classified into nine types based on the combination of protein and gene expression with GPA.

**Purpose:** We aimed to elucidate the relationship between the results of HER2 GPA analysis and the therapeutic effects of trastuzumab-based treatment.

**Methods:** Fifty three (53) patients with HER2-positive breast cancer, who underwent neoadjuvant trastuzumab with chemotherapy, were analyzed for HER2 status and clinical outcome. First, HER2 protein and gene status in a pre-therapeutic biopsy material from each patient were separately assessed according to the ASCO/CAP guidelines using HER2 GPA slides. Second, all cancer cells in five representative microscopic images of GPA slides were assessed to determine protein expression and to count the gene copy number at individual cell levels. Finally, we investigated the relationship between the mixture composition of the nine cell types and pathological complete response (pCR) of trastuzumab-treated breast cancer.

**Results:** The GPA results were concordant with the results of IHC in 98% of samples, and with DISH results in 100%. Two hundred eighty nine (289) cancer cells per patient were assessed on average, ranging from 137 to 490 cells. The mean proportion of type A cancer cells was 64%, ranging from 0% to 98%. Patients who had 50% or more of type A cancer cells achieved pCR in 72% of cases (28/39), while patients with less than 50% of type A cancer cells achieved pCR in 7% of cases (1/14) (*P*<0.0001). The mean proportion of type C cancer cells was 7%, ranging from 0% to 60%. Patients who had 10% or more of type C cancer cells achieved pCR in 10% of cases (1/10), while patients with less than 10% of type C cancer cells achieved pCR in 65% of cases (28/43) (*P*=0.0016).

**Conclusion:** HER2 GPA analyses can more precisely predict therapeutic effect of trastuzumab-based treatment in primary HER2-positive breast cancer. Our study suggests that the HER2 GPA approach would further improve precision therapy in HER2-positive breast cancer.

Publication Number: P1-03-09

Title: Highly reproducible decentralized gene expression analysis of ESR1, PGR, ERBB2 and MKi67 on an automated, standardized molecular diagnostics platform, GeneXpert

Body: Background: Accurate assessment of ER, PgR, HER2, and Ki67 status using FFPE samples from patients with breast cancer is critical for appropriate patient management, yet immunohistochemistry (IHC), the most common method of assessing these markers, suffers from inherent variability due to pre-analytical/analytical factors and subjective interpretation by pathologists. Here we describe the GeneXpert (GX) Breast Cancer Stratifier RUO Assay (BC Strat), a real time quantitative PCR assay (RT-qPCR) kit which exhibits robust, highly reproducible mRNA measures of \textit{ESR1}, \textit{PGR}, \textit{ERBB2} (\textit{HER2}) and \textit{MKi67}. The aims of this study were: 1) To assess the impact of variability contributed by pathologist-to-pathologist differences in the selection of the tumor area to be assayed, inter-laboratory assay performance, and macrodissection (MAC) vs. no macrodissection (nonMAC) on decentralized BC Strat results; and 2) to assess preliminary concordance of BC Strat with central IHC and FISH results.

Materials & Methods: The GX BC Strat is a cartridge-based RT-qPCR assay performed on the GeneXpert® Instrument (Cepheid) that automates RNA purification, RT-qPCR amplification and detection of mRNA of target genes (\textit{ESR1}, \textit{PGR}, \textit{ERBB2}, and \textit{MKi67}) and a control gene (\textit{CYFIP1}) after sample preparation. Results are reported as delta cycle threshold (dCt) measurements (\textit{CYFIP1 Ct - target gene Ct}) in less than 2 hrs.

Thirty-two invasive ductal carcinoma FFPE blocks were sourced based on varying levels of ER, PgR, HER2, and Ki67 expression and % tumor cell content/tumor area. Adjacent sections from each block were prepared as slides and sent to 3 external GX testing sites and a reference lab. Each site used its own pathologists/technicians to determine the % tumor cell content/tumor area, perform MAC or nonMAC, prepare lysates, and perform GX testing. Reference IHC/FISH was performed by Geneuity/MPLN (Maryville, TN, USA). Site-to-site concordance in GX results for MAC or nonMAC samples using pre-defined assay cutoffs per marker were analyzed, as were % tumor cell content/tumor area assessments between pathologists.

Results: BC Strat testing of 32 FFPE breast cancer samples with MAC demonstrated excellent GX site-to-site concordance in positive/negative status calls for ESR1 (100%), PGR (100%), ERBB2 (97%), and MKi67 (97%). In most cases, MAC vs. nonMAC had minimal impact on final positive/negative calls for GX, resulting in high overall concordance for MAC vs. nonMAC for ESR1 (91%), PGR (99%), ERBB2 (99%), and MKi67 (95%). The assay also demonstrated a strong overall concordance with IHC for ESR1 (97%), PGR (81%), ERBB2 (98%, IHC/FISH), and MKi67 (89%).

Conclusion: Decentralized performance of the GX BC Strat Assay is feasible and minimally affected by differences in tumor area selection and MAC techniques across tumors with a range of sizes, invasive tumor cell contents, and expression levels of ER, PgR, HER2, and Ki67. GX BC Strat dCt results across sites are highly reproducible and show good concordance of results with central lab IHC and \textit{HER2} FISH results. These results suggest standardized, decentralized testing of \textit{ESR1}, \textit{PGR}, \textit{ERBB2} and \textit{MKi67} by the GX BC Strat in local pathology labs is feasible.
Title: HER2 expression in clinical breast cancer samples: A novel detection methodology for HER2 protein quantitation using fluorescent nanoparticles

Background: The human epidermal growth factor receptor-2 (HER2) is a member of a family of transmembrane tyrosine kinase receptors that play an important role in regulated normal cell growth and differentiation. The over-expression of HER2 in a subset of 15-20% of invasive breast cancers has an important bearing on prognosis, as HER2-positive tumors are associated with an aggressive clinical course and poor outcome. Targeting HER2-overexpression has been shown to be a remarkably effective therapeutic modality; however testing of tumor samples to assess the HER2 status of the patient's breast cancer is required. Clinical assays to assess the HER2 status in patients being considered for targeted therapy include immunohistochemistry (IHC), which detects protein over-expression, or fluorescence in situ hybridization (FISH), which detects gene amplification. Both the IHC and FISH methodologies have limitations. Given that the target of the currently approved drugs is the receptor protein, novel detections systems that could more accurately and quantitatively detect HER2 protein in clinical samples over a broad dynamic range would be advantageous and may be clinically helpful.

Material and Methods: A novel detection technology using streptavidin-coated Phosphor Integrated Dot fluorescent nanoparticles (PID) has been developed that can be visualized by fluorescence microscopy and used for quantitative immunofluorescence detection of protein in clinical samples using computer assisted image analysis. In the current study, PID-nanoparticles were used to analyze HER2 protein expression in breast cancer cell lines and 120 well characterized breast cancer samples. These results have been compared with HER2 IHC and HER2 FISH analysis.

Results: The expression levels of HER2 protein from 8 breast cancer cell lines was evaluated by antibody-binding capacity with FACS analysis. Formalin fixed paraffin embedded cell pellets for these cell lines were prepared and used for quantitative HER2 analysis by PID. The PID score/cell for each of these cell lines showed a strong linear correlation with antibody-binding capacity sites/cell by FACS analysis (R² = 0.94). For the 120 breast cancer samples, PID score/cell was measured and compared against HER2 IHC membrane intensity measure by image analysis (Aperio) and HER2 FISH results. The HER2 PID score/cell showed a correlation coefficient of R²=0.72 versus the average HER2 copy number per cell by FISH, compared with a correlation coefficient of R²=0.41 for HER2 IHC membrane intensity measured by Aperio. For the HER2/CEP17 ratio, the correlation coefficient for the PID score/cell was R²=0.79 compared with a correlation coefficient of R²=0.32 for the HER2 IHC membrane intensity.

Conclusions: PID-nanoparticles demonstrate great potential for the quantitative measurement of protein of clinical interest in routine clinical samples with morphologic confirmation of the tissue being studied. Further studies looking for PID-score thresholds for HER2 gene amplification and correlations with clinical outcome data are warranted and ongoing.
Title: Analytical validation for the RT-qPCR based multiplex mRNA measurements of ER, PgR, HER2, and Ki67 from FFPE tumor tissue using the GeneXpert breast cancer stratifier assay

Body: BACKGROUND: Accurate assessment of ER, PgR, HER2 and Ki67 status is crucial for breast cancer therapy and patient management. Immunohistochemistry (IHC) assays have been standard diagnostic tools but they are complex and time-consuming to perform and may not be readily available in decentralized laboratories, particularly in low-to-middle income countries. Molecular diagnostics can be a sensitive and accurate alternative to the traditional IHC, and the GeneXpert Breast Cancer Stratifier assay RUO (BC Strat), a single use cartridge-based assay performed on the broadly distributed GeneXpert® Instrument (GX) platform, streamlines a technically demanding RT-qPCR process to provide easy, robust, and reproducible ESR1, PGR, ERBB2, and MKi67 mRNA measurements from a 4 µm thick, formalin-fixed paraffin embedded (FFPE) breast tumor section in less than 2 hours.

METHODS: Analytical validation of the BC Strat assay included studies of Linearity/Dynamic Range, Analytical Sensitivity (Minimum Assay Input), Specificity (Potential Interfering Substances), Carryover Contaminations, and Kit and Specimen Slide Stabilities. Both in-vitro RNA transcript (IVT) and/or clinical breast cancer tissues were used as sample input materials. Assay results for each analyte were generated from cycle threshold (Ct) values, and final positive/negative test results for each target were also reported as delta Ct values, where dCt = Ct [CYFIP1 Reference] – Ct [Target], using dCt cutoffs previously derived from a clinical sample cohort.

RESULTS: The BC Strat assay demonstrated ≥3 log Linear Dynamic Range covering 5-7 logs sample input for all 4 Target dCts with R²≥0.95 independently. The assay currently requires minimal sample input equivalent to CYFIP1 Ct≤35 (Ct=33.5 ±1.5Ct SD) from 20 replicates of 5-level serial sample dilutions using two independent assay lot materials. It is acceptably robust against non-tumor tissues, DCIS, necrotic and/or hemorrhagic cells, lymphocytes, and genomic DNA contaminants. No carryover contamination from the same GeneXpert module was observed over 20 repeat tests during 9 consecutive days. Current real-time data supports assay stability at 5, 30, 37, 45 and 50°C for at least 3 months with minimal performance impact. Sectioned FFPE breast tumor tissues generated consistent dCt results when stored at 4°C and 30°C for up to 1 month before BC Strat assay testing.

CONCLUSIONS: The analytical validations of the BC Strat assay demonstrate an easy and robust mRNA detection with high sensitivity, specificity, reproducibility, and stability in order to aid medical pathologists and clinicians to more rapidly and objectively determine ESR1, PGR, ERBB2, and MKi67 mRNA status in breast cancer. Although stability studies out to 37 months are ongoing, current data suggest the assay is stable for at least 3 months over a wide range of temperatures. The GeneXpert Breast Cancer Stratifier assay potentially offers a rapid, standardized, and cost-effective solution to streamlining complex molecular diagnostics available for use in local pathology laboratories worldwide.
Title: A simulation study depicting the inconsistency of adjuvant online compared to genomic testing when determining the benefit of chemotherapy

Khawaja S, Thomas D, Udayasankar S, Munir A, Huws A, Shariha Y and Holt S. Prince Philip Hospital, Llanelli, United Kingdom.

Body: Background: Prognostic factors have been used for years to determine the benefit of adjuvant chemotherapy in breast cancer. However, reporting of the size and grade of the tumor are affected by interobserver variability in reporting. This can result in a change in the results of adjuvant online and an impact on decision making of chemotherapy. On the contrary, genomic testing such as oncotype Dx is reproducible. The purpose of our study was to assess the effect of pathological discordance on the adjuvant online results on a cohort of patients who also underwent oncotype Dx testing.

Materials and Methods: A total of 143 patients' histologies were included in this study. The results of the Phase III WSG-Plan B trial concerning central vs. local grade discrepancy rates were utilized to randomly change the grade of the tumors. 61 percent of grade 1 cancers were upgraded to grade 2 and 2% upgraded to grade 3. 4 percent of grade 2 cancers were downgraded to grade 1 and 26% were upgraded to grade 3. 1 percent of grade 3 cancers were downgraded to grade 1 and 25% were downgraded to grade 2. Likewise, change was made in the size of the tumor in 20 percent of patients. 8 to 10mm, 18-20, 28-30, and 48-50mm changed to 11, 21, 31 and 51mm respectively. 11-13mm, 21-23, 31-33, and 51-53mm was changed to 10, 20, 30, and 50mm. Ten percent of patients had the ER and Her 2 status changed.

Results: The simulation results showed that when the grade was only altered, the spearman correlation of the predicted 10 year mortality on adjuvant online with the original data was significantly changed from 1 to a result of 0.788. When the changed size was additionally added, the coefficient was 0.836. With the altered ER status, the result was 0.749 and with the Her 2 change, the spearman correlation was minimally changed to 0.742. The scattergrams showed a large number of outliers when the alteration in size was added to the altered grade.

Conclusion: Our simulation study confirms that with minimal changes in the clinical parameters because of the lack of perfect correlation between pathologist's results, there is a significant difference in the 10 year predicted mortality on adjuvant online. This is one step further in understanding the lack of correlation between adjuvant online and oncotype Dx, and the inconsistency of chemotherapy decision making with the sole use of adjuvant online.
Title: Immunohistochemistry cannot be used to detect PD-L1/JAK-2 amplification

Linnaus ME E, Kosiorek H, Ocal IT T, Dixon L, Barrett MT T, Gawryletz CD D, Anderson KS S, McCullough AE E, McEachron TA and Pockaj BA A. Mayo Clinic Arizona, Phoenix, AZ; Center for Personalized Diagnostics, Biodesign Institute, Arizona State University, Tempe, AZ and Translational Genomics Research Institute (TGen), Phoenix, AZ.

Body: Introduction: We have previously identified a 9p24.1 amplicon targeting PD-L1/JAK2 (PDJ) in subset (26.7%) of triple negative breast cancer (TNBC) patients. The PDJ amplicon is common in newly diagnosed and chemotherapy treated TNBCs and is associated with a worse prognosis. Our goal in this study was to determine whether immunohistochemistry (IHC) evaluation could identify those patients who harbor the PDJ amplicon.

Methods: TNBC patients from 1999 to 2015 whose tumors were flow-sorted and evaluated by array-based comparative genomic hybridization (CGH) were identified; paraffin slides were obtained for IHC staining evaluation of JAK-2, phosphorylated STAT3 (pSTAT3), and PD-L1. Pathologic analysis consisted of scoring the stains for intensity (0-3+) and the relative percent of tumor cells with positive staining; positive score was defined as 3+ for any percent staining. Statistical analysis of IHC staining was performed to determine association with the PDJ amplicon defined by focal 9p24.1 copy number gain with CGH log2 ratios of >1.0 for each sorted TNBC sample.

Results: Eleven of 43 TNBC patients evaluable by IHC had the PDJ amplicon. There was no association between PDJ amplification and IHC staining for JAK-2, pSTAT3, or PD-L1 regardless of staining intensity or percentage tumor cells positive. Table 1 describes PDJ amplicon status and positivity for JAK2, pSTAT3 and PD-L1. Of PDJ-positive samples, 64%, stained positive for JAK2, 27% positive for pSTAT3, but 0% for PD-L1 in tumor cells. However, in the PDJ-negative group, 69% still stained positive for JAK2, 19% positive for pSTAT3, and 9% for PD-L1.

Table 1: PDJ amplicon status and IHC staining

<table>
<thead>
<tr>
<th></th>
<th>JAK2 (3+) (n;%)</th>
<th>pSTAT3 (3+) (n;%)</th>
<th>PD-L1 (3+) (n;%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>PDJ -</td>
<td>22;69%</td>
<td>6;19%</td>
<td>3;9%</td>
</tr>
<tr>
<td>PDJ +</td>
<td>7;64%</td>
<td>3;27%</td>
<td>0;0%</td>
</tr>
</tbody>
</table>

JAK2: Most PDJ-positive samples (10/11, 91%) showed some JAK-2 staining. Although one had only 1+ staining at 5% of the cells, the majority (7/11, 64%) had staining of 3+ and ≥10% of the cells with 2 patients demonstrating 3+ staining of 75% and 90% of the cells. However, those patients without the PDJ amplicon also exhibited JAK2 staining, with 66% (n= 22) of PDJ-negative cases staining strongly for JAK2 (3+) and ≥ 10% of cells. pSTAT3: All but one PDJ-positive case demonstrated some staining (1+ or greater) for pSTAT3; the staining intensity and percent positivity were much less than the JAK-2 staining with only 2 cases (18%) having 3+ staining of ≥10%. Similar staining was seen in the PDJ-negative cohort; 75% of PDJ-negative patients had some pSTAT3 staining (1+ or greater) and 1 patient (5%) exhibited 3+ staining ≥ 10%. PD-L1: Finally, the PD-L1 staining was low overall with only 18% of PDJ-positive cases demonstrating some staining for PD-L1. Notably, only one case stained 3+ with 20% positivity while the majority of the samples had a 2+ intensity encompassing 5-50% of the cells.

Conclusions: IHC staining for JAK2, pSTAT3, or PD-L1 was not associated with the presence of the PDJ amplicon. Notably positive IHC staining for JAK2 was observed for both PDJ-positive and PDJ-negative tumor cells, thereby nullifying its application as a screening tool for PDJ amplification. Alternative methods, such as fluorescence in situ hybridization, are needed to identify PDJ-positive patients for further study.
Title: Assessment of stromal characteristics in ductal carcinoma in situ of the breast: An inter-observer variability study

Van Bockstal M, Lambein K, Smeets A, Nevelsteen I, Neven P, Christiaens M-R, Libbrecht L and Floris G. Ghent University Hospital, Ghent, Belgium; AZ St Lucas Hospital, Ghent, Belgium; University Hospitals Leuven, Leuven, Belgium; University Hospitals Leuven, Leuven, Belgium; University Clinics Saint Luc, Brussels, Belgium; University Hospitals Leuven, Leuven, Belgium and Laboratory of Translational Cell & Tissue Research, University of Leuven, Leuven, Belgium.

Body: Aim. Ductal carcinoma in situ (DCIS) is considered to be a non-obligate pre-invasive precursor of invasive ductal carcinoma. We previously showed that DCIS with a predominantly myxoid periductal stromal architecture is associated with an increased risk of both overall and invasive recurrence. The aim of this study is to determine a cut-off for the assessment of myxoid stroma and stromal inflammation in DCIS, based on inter-observer variability. Here, preliminary results of the histopathological analysis of 285 DCIS patients are presented, in which the consistency of assessment of stromal features is compared to the reproducibility of other morphological characteristics.

Methods. Hematoxylin/eosin stained tissue sections of 285 DCIS lesions were retrieved from the archives of the Department of Pathology of Leuven University Hospitals, Leuven, Belgium. The following characteristics were independently scored by two pathologists: nuclear grade, intraductal calcifications, extensive comedonecrosis, DCIS architecture, stromal architecture and stromal inflammation. Nuclear grade was scored as low, intermediate or high grade. Intraductal calcifications were scored as absent or present. Extensive comedonecrosis was defined as eosinophilic necrotic debris in >50% of ductal lumina. DCIS architecture was categorized as non-solid or solid, with a cut-off at 50% of ducts presenting with solid growth. Myxoid stroma was defined as loosely arranged collagen fibers interspersed with an amorphous, slightly basophilic substance. Stromal architecture was classified into 4 categories (0%, 1-33%, 33-66% or >66% myxoid stroma). By applying identical cut-offs, stromal inflammation was subdivided into absent, mild, moderate or extensive periductal inflammation. All features were dichotomized, using different cut-offs. Kappa values were determined to assess inter-observer variability.

Results. Nuclear grade was dichotomized as low grade versus intermediate/high grade (κ 0.500), and as grade low/intermediate versus high grade (κ 0.507). The kappa value for scoring myxoid stromal architecture was highest by dichotomization with a cut-off at 33% (κ 0.566), compared to κ 0.454 and κ 0.501 when using 1% and 66% as a cut-off, respectively. A similar analysis for stromal inflammation revealed that the highest kappa value was obtained by dichotomization as 'absent to mild' versus 'moderate to extensive' inflammation (κ 0.724). Dichotomization with cut-offs of 1% and 66% resulted in lower kappa values of κ 0.564 and κ 0.670, respectively. Scores for extensive comedonecrosis showed substantial agreement (κ 0.604). Scores for solid versus non-solid DCIS architecture (κ 0.507), and presence or absence of calcifications (κ 0.664) showed moderate and substantial agreement, respectively.

Conclusions. Adequate prognostic markers require robustness of assessment, i.e. low inter-observer variability and thus high reproducibility. The dichotomous assessment of stromal features in DCIS resulted in similar or even higher kappa values compared to the dichotomous scoring of other histopathological characteristics. This study demonstrates the robustness of dichotomous assessment of both stromal architecture and stromal inflammation.
Clinicopathologic and immunophenotypic characterization of angiomatosis of the breast: A rare vascular entity mistaken for low-grade angiosarcoma

McIntire PJ, Ginter PS S and Shin SJ J.  Weill Cornell Medicine, New York, NY.

Angiomatosis of the breast is a rare, benign vascular lesion often mistaken for low-grade angiosarcoma (LGAS), particularly in core biopsy material. While the histopathologic features of this entity have been described in occasional published reports, it has not been well characterized by immunohistochemistry including proliferation (Ki-67) index. We sought to better characterize this entity, particularly in finding distinguishing features from LGAS. Cases of mammary angiomatosis were identified in our breast pathology consultation files spanning 16 years (2000-2015). All available clinical and pathological material for each case were reviewed. Immunohistochemistry for CD31, D2-40 and Ki-67 was performed on a representative whole tissue section from each case. Eight cases from seven patients were identified for study. For one patient, both the primary and recurrent tumors were evaluated. All patients were female with a mean age of 48 years (range: 19-63 years). All were unilateral (left: 5/8, right: 3/8). Most presented with a palpable abnormality or mass (5/8) while fewer were detected by imaging (3/8). The mean tumor size was 4.1 cm (range: 2-9 cm). All cases showed variable sized ectatic, thin walled vessels lined by flat normochromic endothelium diffusely infiltrating stroma. Where present, lesional vessels infiltrated between terminal duct lobular units (TDLUs) but not into the intralobular stroma of TDLUs. Most cases (6/8) showed a combination of lymphatic-appearing and hemangiomatous appearing vessels, the latter notably lined by thin muscular walls. Of the remaining 2 cases, one case showed only lymphatic-appearing vessels and the other showed only hemangiomatous -appearing vessels. CD31 was diffusely positive in all cases. Lymphatic-appearing vessels were D2-40 positive in all but one case. D2-40 was negative or weak in 5/8 hemangiomatous-appearing vessels. Ki-67 indices were <1% in all but one case (5%). Overt features of malignancy including endothelial cell nucleoli, endothelial tufting, papillary formations, solid/spindle cell foci, blood lakes, mitoses, and necrosis were absent in all cases. Mammary angiomatosis is a rare vascular lesion which typically presents as a palpable mass. Despite its characteristic diffuse and infiltrative growth, angiomatosis does not invade into intralobular stroma, an important distinction from LGAS. They are immunoreactive for CD31 and variably so for D2-40. A low (<1%) Ki-67 index helps to distinguish angiomatosis from LGAS which typically shows a higher (>20%) index.
Title: Tumor-infiltrating lymphocyte (TIL) assessment distilled into two binary parameters in triple-negative breast cancer (TNBC)

Cui X, McIntire PJ J, Ginter PS S, Irshaid L, Chen Z and Shin SJ J. Weill Cornell Medicine, New York, NY.

Body: Background TILs provide prognostic and potentially predictive value, particularly in TNBC. The 2014 International TILs Working Group guidelines for TIL assessment include multiple parameters including quantification of TILs as a continuous variable, TIL location (stromal versus intratumoral), and grading extent of stromal lymphocytic aggregates. Such multi-parameter assessment is onerous for the practicing pathologist and prone to considerable inter-observer variability and low reproducibility. We sought to identify a simplified method to assess TILs at the microscope while maintaining prognostic value in TNBC.

Design Quantification of mononuclear TILs was performed on a representative H&E slide from 76 cases of primary invasive TNBC. Percent stromal mononuclear TILs (sTILs) within the entire tumor area were estimated. Tumors were defined as LPBC or non-LPBC using a cutoff of ≥50% sTILs. TIL location was recorded as only sTILs or both sTILs and intratumoral TILs (iTILs). Stromal lymphoid aggregates were classified as no aggregates, rare aggregates, well-developed aggregates or aggregates with germinal centers. Statistical analyses were performed using disease-free survival (DFS) (range: 16 to 196 months, mean: 110 months) as a primary endpoint.

Results Improved DFS was noted for LBPC \[0.25; 95\% confidence interval (CI) 0.08–0.76, P = 0.0149\]. When classifying peritumoral lymphoid aggregates, only the presence of well-developed stromal lymphoid aggregates was significantly associated with improved DFS \[0.11, CI: 0.01–0.94, P = 0.0440\]. The absence of intratumoral lymphocytes trended toward decreased DFS \[2.54, CI: 0.94–6.89, P = 0.0667\].

Conclusion Our findings suggest that morphologic TIL assessment in TNBC can be simplified by evaluating 2 binary parameters: 1) classifying a given tumor as LPBC and 2) the presence of well-developed stromal lymphoid aggregates to predict a given patient's risk of recurrence. Additional independent studies are necessary to validate our findings.
Title: Epigenome-wide association study for breast cancer risk using whole genome and target captured bisulphite sequencing: A pooled case-control study nested in the breakthrough generations study

Body: Background: The field of epigenetic epidemiology has rapidly advanced and recent work has discovered epigenetic markers of breast cancer risk in white blood cell (WBC) DNA. Using Epigenome-Wide Association Studies (EWAS) on the Illumina 450k methylation array, we and others have shown epigenome-wide hypomethylation (-0.2%, p<2.2x10^{-16}) in incident breast cancer cases compared with controls in several prospective cohorts. We have proposed a mechanism that involves cancer risk exposures, lifetime and environmental events, that alter the epigenome and stably modifies an individual's cancer risk. However, more work is needed to establish the clinical utility of this observation, the underlying causes of this variation and to determine whether the 1.7% of CpG sites targeted by the 450k array are representative of the remaining 98% of the epigenome that has not yet been interrogated. Our overall aim is to identify epigenetic traits within the epigenome that are associated with the risk of developing breast cancer.

Methods: We conducted an EWAS using whole genome bisulphite sequencing (WGBS) of WBC DNA from incident breast cancer cases (n=548) compared to matched controls (n=548) from a prospective cohort (Breakthrough Generations Study) using a DNA pooling approach. Eight DNA pools were prepared in sequencing libraries and sequenced on the Hiseq2500 at PE100bp reads, resulting in ~10-fold coverage per CpG, per library, across ~20 million mappable CpG sites. Each pooled sample was also analysed in triplicate on the Illumina 450k methylation array for validation. We used Agilent target capture bisulphite sequencing (TCBS) for technical validation in a subset of breast cancer cases (n=48) and matched controls (n=48), individually barcoded and sequenced on the MiSeq at PE150bp, aiming for >1000 fold coverage of 425 kb targeted sequence.

Results: Interrogation of specific genomic regions showed that gene-body methylation averages tended to be hypomethylated in cases, while CpG island averages identified both hypo- and hypermethylation. We have validated the same direction of change in 40/51 CpG islands that were covered by the Illumina 450K methylation array and have developed a target capture panel for validation of 960 gene body regions and 224 CpG island regions that were identified as significantly different between cases and controls (average -11%, FDR<5%). Analysis of TCBS data is ongoing.

Conclusions: Results indicate that epigenome-wide hypomethylation and methylation in specific sites, particularly gene bodies, measured in pre-diagnostic blood samples may be predictive of breast cancer risk, and may thus be useful as a risk biomarker.
The presence of predicted neo-antigens in any given tumor is highly correlated with total somatic mutational burden of the same tumor genome. However, many potential neo-antigens are never transcribed, translated, or presented as antigens, partially because they lie in regions of the genome that are transcriptionally-repressed by cytosine methylation of promoter-CpG islands. Treatment with DNA methyltransferase inhibitors (DNMTi) can hypothetically lead to re-expression of many potential neo-antigens. Furthermore, the presence of neo-antigens have been linked to immunotherapy outcomes in patients. Our hypothesis is that tumors with reduced mutational burden can be maximized for neo-antigen presentation by activating transcription and translation of these sequences through DNMTi treatment. Our preliminary results showed that the DNMTi guadecitabine (SGI-110), a second-generation hypomethylating agent, treatment decreases methyl-cytosine in genomic DNA both in vitro and in vivo. In addition, SGI-110 treatment enhances MHC-II expression on murine mammary carcinoma MMTV-Neu cells upon IFN-γ stimulation in vitro and increases T-cell infiltration in vivo. Currently, we are performing whole-exome-sequencing and RNA-sequencing to track somatic mutations from DNA to RNA. We will further track somatic mutations from RNA→MHC-presented peptide sequences using MHC immunoprecipitation followed by mass spectroscopy analysis. In addition, we will explore the role of guadecitabine therapeutic priming on response to αPD-L1 immunotherapy. These studies will provide a pre-clinical data to evaluate the potential for combined epigenetic and immune-therapy in a clinical trial for breast cancer.
Title: Cross-talk between RNA methyltransferase and demethylase regulates breast cancer growth and progression

Subbarayalu P, Eedunuri VK K, Timilsina S, Rajamanickam S, Viswanadhapalli S, Abdelfattah N, Onyeagucha BC C, Cui X, Mohammad TA A, Huang TH-M, Huang Y, Chen Y and Rao MK K.  Greehey Children's Cancer Research Institute, University of Texas Health Science Center at San Antonio, San Antonio, TX;  University of Texas Health Science Center at San Antonio, San Antonio, TX;  The University of Texas at San Antonio, San Antonio, TX;  University of Texas Health Science Center at San Antonio, San Antonio, TX and  University of Texas Health Science Center at San Antonio, San Antonio, TX.

Body: The importance of RNA methylation in biological processes has just begun to emerge. However, our understanding of the role and mechanism by which RNA methylation may play a role in tumorigenesis is unclear. Here, we report that RNA N6-adenosine methyltransferase protein METTL14 supports breast cancer growth and progression. We show that METTL14 mediates its pro-tumorigenic function by activating the expression of RNA binding protein HuR and consequently inducing the transcriptional stability of key cell cycle-associated genes, TGFβ and its signaling partners as well as HMGA2, VEGF and PDGF that are known to play critical roles in cancer growth and metastasis. Importantly, m6A RNA methylation levels of METTL14 target genes were significantly lower in breast cancer patients compared to normal matched controls. The decreased RNA methylation level resulting in increased activity of these target genes in breast cancer patients is regulated by a feedback loop between RNA demethylase ALKBH5 and METTL14. Our results reveal that ALKBH5 regulates the expression of METTL14 and HuR, which in turn transcriptionally stabilizes ALKBH5. Furthermore, we demonstrate that like METTL14, ALKBH5 also supports breast cancer growth and progression. Taken together, these findings suggest that a collaboration between RNA methylation and demethylation machinery may set up a threshold of RNA methylation that ensures the stability of genes that play a vital role in normal cell proliferation; and any perturbation of that threshold may lead to uncontrolled expression/activity of those genes resulting in tumor growth and progression.
Title: DNA methylation landscapes of breast cancer progression to brain metastasis: A pre-clinical study

Orozco JIJ, Bustos MA, Nelson N, Hsu SC, Cheung G, Bostick PJ, Lucci A, DiNome M, Kelly DF, Hoon DSB, and Marzese DM. John Wayne Cancer Institute, Santa Monica, CA; Sequencing Core Center, John Wayne Cancer Institute, Santa Monica, CA; Baton Rouge General Medical Center, Baton Rouge, LA; The University of Texas MD Anderson Cancer Center, Houston, TX; John Wayne Cancer Institute, Santa Monica, CA and Brain Tumor Center, Providence Saint John's Health Center, Santa Monica, CA.

Body: Due to improvements in overall survival rates, breast cancer brain metastasis (BCBM) is a major life-limiting condition with rising incidence. The molecular mechanisms involved in breast cancer (BC) progression to brain metastasis are still poorly understood. We have demonstrated that DNA methylation, a key epigenetic regulatory mechanism, is involved in BC progression to metastatic disease. Here, we characterized the BCBM DNA methylation landscapes according to their molecular subtypes.

Methods: This study included 22 BCBM specimens from 19 patients (ER+/PgR+/HER2- (n=6), HER2+ (n=7), and ER-/PgR-/HER2-(TNBC; n=6)) and primary BC specimens with paired molecular subtypes. After microdissection, we generated genome-wide DNA methylomes using HM450K BeadChips. Results: Multidimensional scaling revealed that DNA methylation patterns specifically clustered BCBMs according to their respective molecular subtypes. Additionally, we observed that while ER+/PgR+/HER2- BCBM showed a significant global hypermethylation, HER2+ and TNBC BCBMs presented a significant global hypomethylation compared to the respective primary BC specimens. Hypermethylation on ER+/PgR+/HER2- BCBMs mainly affected CpG islands and was significantly enriched in regions overlapping tumor-related genes, such as APC2, CREB3L1, and GLI3; and a large number of developmental genes, including HOXA9, HOXA10, HOXB13, and PAX6 (Table 1). On the other hand, hypomethylation on HER2+ and TNBC BCBMs significantly overlapped with conserved intergenic cis regulatory elements. Two significantly affected regions included enhancer elements associated with NEUROD1, a neurogenic differentiation factor, and MYT1L, a Pan-neural transcription factor associated with neuronal differentiation, suggesting an acquisition of brain-like properties (Table 2). Conclusions: Our study suggests a significant role of DNA methylation reprogramming during BC progression to brain metastasis and describes the existence of molecular subtype-specific DNA methylomes. Altogether, this data offers new insight into the complexity of this clinical complication.

Title: RNA immunoprecipitation reveals lncRNA-protein interactions in basal-like breast cancer

Northwood K, Saunus J, Milevskiy M, Lakhani S and Brown M. School of Chemistry and Molecular Biosciences, University of Queensland, St Lucia, Brisbane, Queensland, Australia; School of Medicine and UQ Centre for Clinical Research, Herston, Brisbane, Queensland, Australia and Pathology Queensland, Royal Brisbane and Women's Hospital, Herston, Brisbane, Queensland, Australia.

Body: Interactions between long non-coding RNAs (lncRNAs) and proteins contribute to the epigenetic regulation of gene expression, and defects in such interactions have been implicated in several diseases, including cancer. Basal-like breast cancer accounts for approximately 15% of all breast cancer and is a major clinical problem given its poor survival and lack of responsiveness to targeted breast cancer treatments. DNA methylation is non-random and is much more pronounced in basal-like breast cancer (BLBC) compared to other molecular subtypes of breast cancer, raising the possibility that hypermethylation could be important in the genesis of BLBCs. LncRNAs are aberrantly expressed in multiple subtypes of breast cancer, including BLBC, and are considered to have significant prognostic potential. In order to explore the potential roles of DNA methylation and lncRNAs in BLBC, we investigated lncRNA-protein interactions using bioinformatics and molecular techniques, focusing on proteins that actively perform DNA methylation - the DNA methyltransferase (DNMT) family. Our novel bioinformatic methods revealed that BLBC may be sub-classified according to methylation profile in a way that could predict disease survival. We then identified candidate lncRNAs that are over-expressed in BLBC and statistically predicted to interact with DNMT proteins. Using RNA immunoprecipitation of BLBC cell lines, we have identified potential lncRNA-protein interactions that may be involved in epigenetic remodelling in BLBC. The role of these lncRNAs in epigenetic gene regulation and BLBC is currently being explored.
Network integration of epigenomic data: Leveraging the concept of master regulators in ER negative breast cancer

Worsham MJ J, Chen KM Mei, Datta I, Stephen JK K, Chitale D and Divine G. Henry Ford Health System, Detroit, MI.

Background: There has been relatively little advancement in changing the management of women with estrogen receptor (ER) negative breast cancer (BC), mainly due to a dearth of actionable therapeutic targets. Therefore, understanding the underlying biology of such a complex disease is necessary for bringing new therapeutic treatments to light. A key question in cancer genomics is how to distinguish ‘driver’ or essential alterations, which contribute to tumorigenesis, from functionally neutral or ‘passenger’ alterations that go along for the ride. The majority of published studies investigating driver genes have focused primarily on genomic mutations which have led to novel study designs (basket trials) where patients with a rare mutation, regardless of tumor histology, are matched to a drug expected to work through the mutated pathway. This dominant focus on mutations has overshadowed consideration of inclusion of epigenetic information. This study illustrates network integration of epigenomic data to prioritize ER negative specific methylated genes as potential epigenetic drivers of aggressive disease.

Methods: Causal Networks are small hierarchical networks of regulators whose activity can be modulated by the expression of downstream target genes to enhance understanding of the effect of upstream master regulators on disease or function. A master regulator is a gene or drug positioned as the central or master hub that has the ability to command or influence downstream events. Causal Network Analysis (CNA) was used to find networks that connect upstream master regulators with a 16 candidate methylation gene signature differentiating ER negative from ER positive BC. The 16 ER-negative specific gene methylation signature (AHNAK, ALPL, ANXA2R, CCND1, CIRBP, CPQ, DST, EGFR, ESR1, GPRC5B, HERC5, IL22RA2, MITF, OBSL1, POU3F3, RB1CC1) was identified via our drill-down approach starting from a discovery approach (Illumina 450k BeadChip) followed by expression verification, significant rankings in biological pathways (Ingenuity Pathway Analysis), confirmation by targeted sequencing using Illumina MiSeq, and additional filtering in 450K TCGA data sets.

Results: CNA software identified 4 hierarchical networks and their corresponding master regulatory molecules, diethylstilbestrol, transcription regulator SP1, MSH2, and 15-ketoprotaglandin E2. Diethylstilbestrol and SP1 had direct regulatory influence (depth level 1) to the candidate molecules ALPL, CCND1, EGFR, ESR1 and CCND1, CIRBP, EGFR, ESR1, respectively.

Conclusion: In this study, direct regulatory influence, noted for 5/16 candidate genes indicates additional rationale for further consideration and validation of ALPL, CCND1, CIRBP, EGFR, ESR1 as potential epigenetic driver targets in ER negative BC. As cancer therapies become increasingly more specific and begin to move past cytotoxic agents, determining the molecular features of a tumor that predict response to a given drug has become increasingly essential to match patients with optimal therapy. Currently epigenetic therapy in the form of hypomethylating agents (e.g: decitabine) exhibit clinical efficacy in patients with AML and MDS including those patients not responding to cytotoxic therapy.

Title: Environmental influence on epigenetic markers in the development of breast cancer

He C, Wu W, Gao H, Nephew K, Li L, Schneider B, Han J and Liu Y.  Indiana University, Indianapolis, IN.

Body: Aberrant DNA methylation plays an important role in breast cancer initiation and progression. We hypothesize that environmental risk factors contribute to causal alterations in DNA methylation and that such causal changes have already occurred prospectively in normal breast tissue before tumor occurrence. In order to test this hypothesis, normal breast tissue from healthy women must be used. We therefore conducted an integrative molecular epidemiological study that combined the environmental regulation of DNA methylation in normal breast tissue and the differential DNA methylation profiling in tumor and normal breast tissue. We examined for the first time the environmental impact on DNA methylation in normal breast tissue from healthy women and determine the association of these epigenetic changes with breast cancer development. Potentially causal DNA methylation markers identified from our study has the potential to make a major scientific and clinical impact in understanding breast cancer etiology as well as developing novel, more effective prevention and treatment strategies.

Title: Non-nuclear SUMO dynamics regulate mammary epithelial cell transformation

Karami S, Lin F-M, Kumar S, Ren J, Bahnassy S and Bawa-Khalfe T. University of Houston, Houston, TX and University of Texas MD Anderson Cancer Center, Houston, TX.

Body: Objective: The reversible SUMO-posttranslational modification of protein substrates regulates various cellular processes and consistently is important for normal cell physiology. Disruption of SUMO enzymatic components supports onset of various pathophysiological disorders, including cancer. Our recent study identified a splicing event that differentially modulates expression of 2 SENP7 isoforms. The novel SENP7 variant SENP7S is the predominant SUMO protease in normal mammary epithelia; however onset of precancerous ductal carcinoma in situ (DCIS) reduces SENP7S significantly and stays low in all breast cancer (BCa) subtypes. Inversely, the full-length SENP7L isoform is upregulated in BCa and directly leads to BCa metastasis. Unlike SENP7L, SENP7S isoform contribution to carcinogenesis is unclear. Our objective is to define the biological function of this novel deSUMOylase SENP7S in normal versus cancerous epithelial cells.

Results: Consistently with mRNA levels, protein levels of the 2 SENP7 isoforms are also inversely expressed in human BCa versus normal mammary epithelia. SENP7S is localized in the cytosol of MCF10-2A unlike other SUMO proteases including SENP7L that are predominantly nuclear enzymes. Beta-catenin and a component of the Beta-catenin destruction complex, Axin1 are substrates for SENP7S catalytic activity as in the absence of SENP7S, Beta-catenin and Axin 1 are both SUMOylated. Consistently, SENP7S regulates Beta-catenin signaling pathway. SUMOylated Axin1 loses its interaction with Beta-catenin, allowing the Beta-catenin to escape ubiquitylation and further proteasomal degradation. SUMOylated Beta-catenin translocates to the nucleus and activates multiple target genes that potentiate cell proliferation. Increase in cell proliferation and anchorage dependent growth of non-cancerous MCF10-2A cells was observed with inhibition of SENP7S. Additionally, SENP7S depletion potentiates anchorage independent growth of MCF10-2A with significantly greater number and size of spheroids. In comparison to the control. Loss of SENP7S also potentiates the self-renewal properties of the cells, indicative of mammary epithelial cell transformation.

Conclusion: SENP7S modulates Beta-catenin stability and signaling and consequently is critical for normal mammary epithelial cell physiology. Loss of SENP7S, as observed in DCIS, initiates mammary epithelial cell transformation.
Title: The missing link: Chemicals, epigenetics and breast cancer

Maund PR, Ermler S, Widschwendter M and Silva E. College of Health and Life Sciences, Brunel University, Uxbridge, Middlesex, United Kingdom; Institute of Environment, Health and Society, Brunel University, Uxbridge, Middlesex, United Kingdom and University College London, London, United Kingdom.

Body: In spite of its high incidence worldwide, only 10-15% of breast cancers can be attributed to hereditary factors, leaving a substantial proportion with unknown causes. Evidence suggests that 26.8% of new breast cancer cases relate to extrinsic factors, such as lifestyle and environmental exposures. Whilst we have increased our knowledge surrounding factors like alcohol and obesity, little is known in regards to chemicals in the environment (e.g. pesticides) or consumer goods (e.g. plasticisers, such as Bisphenol A, and preservatives). Previous research has proved inconclusive, with effects only observed at concentrations considerably higher than what has been identified in human tissues. Furthermore, we have not identified a mechanistic link for many compounds. It has been suggested that epigenetics could provide insight, being defined as ‘the link between the environment and our genome’ and research has identified that environmental chemicals can impact on breast cancer development through the epigenome. However this has mainly been undertaken using unrepresentative chemical concentrations and immortalised cell lines – a model significantly different from the human breast.

The presented research aims to investigate the relationship between low-dose chemical exposures (similar to concentrations found in human tissues) and breast carcinogenesis. In order to represent the human breast as closely as possible, primary mammary epithelial cells (HMECs) were grown in three-dimensional co-cultures on a Matrigel base with fibroblasts (HMF) and endothelial (HMMEC) cells. This system allowed for stromal-epithelial interaction within an in vitro environment, a crucial factor that has, so far, not been included within much of the previous research. We then exposed the cultures to environmentally relevant concentrations of Bisphenol A (BPA), ranging from 1 nM to 100 nM. These concentrations promoted morphological changes of epithelial 3D structures (acini), which resemble those seen in the early stages of breast carcinogenesis (i.e. filled lumen, uncontrolled proliferation and deformed acini). Utilising Illumina 450k arrays we observed changes in the epigenetic profile of cells in response to the same levels of BPA. In turn, from RNA-sequencing analysis, we confirmed that these changes result in alterations to the gene expression.

From these preliminary findings, we suggest that BPA is involved in early breast carcinogenesis by altering the epigenome. Increasing our understanding of chemical contributions to cancer development not only provides opportunities for cancer prevention, but also allows for more effective risk model development, aiding in identifying individuals at high risk for screening programmes. We therefore outline future work to investigate the impact of chemical mixtures, not just individual chemicals, within this model to further our understanding of the true impact of chemical exposures on the breast.
Introduction: Strategies are needed for the identification of a poor response to treatment and determination of appropriate strategies for breast cancer patients. As an integral component in the tumor’s genetic profile, knowledge of somatic copy number aberrations can lead to insights into the tumor’s genetic history and may allow for more accurate prognosis and most appropriate treatment for the patient. By quantifying the number of copies of each allele at each variant loci rather than the total number of chromosome copies, allele-specific copy number (AsCN) estimation is an important step to the characterization of tumor genomes. In this study, AsCN profile was generated and used to predict the poor prognosis breast cancer patients.

Methods: The blood DNA samples from 56 Taiwanese breast cancer patients were collected from Sep 2005 to May 2015. There are 24 patients were administrated with chemotherapy (42.85%), and 9 patients were recurrent (16.07%), 5 patients were metastasis (8.92%). Affymetrix Human SNP 6.0 microarray chip was utilized to detect the alleles and copy number (CN) variations. The state of CN was distinguished from the intensity of the CN probe on the array. These states of CN were created from unpaired analysis with reference samples (HAPMAP Asian 44 samples), and utilized BRLMM-P+ algorithm from Affymetrix. The AsCN profile of patients were established with HMM algorithm, and analyzed by unpaired analysis in Partek Genomic Suite 6.6 (Partek Inc., St. Louis, MO, USA).

Results: Four allele-specific imbalance regions which located on gene ABCB11 in 2q31.1, PREX2 in 8q13.2, GPHN in 14q23.3, and mir8062 in 20p 12.3 were detected and highly related to the poor prognosis of chemotherapy. The mean of CN state of these regions was lower than 1.2. The most significant region is the located on gene mir8062 in 20p12.3 (hsa-mir-8062), 22 of 54 patients were detected to bring this imbalance region on genome. The function of this miRNA is not clear now, and needs more investigated.

Conclusions: We have demonstrated the feasibility of finding the association of allele-specific imbalance regions on genome with the poor prognosis in breast cancer by generating the AsCN profile from patients. This preliminary result shows these alleles-specific imbalance regions of the genome have the possibility of playing the important role in the recurrent and metastasis of breast cancer.
Title: The epigenetic landscape of oestrogen receptor-alpha positive breast cancer

Patten DK K, Corleone G, Kate G, Dimitri HJ J, Palmieri C, Raoul CC C and Luca M. Imperial College London, London, United Kingdom; Charing Cross Hospital, Imperial College Healthcare NHS Trust, London, United Kingdom and Liverpool University, Liverpool.

Body: Background
Oestrogen receptor-alpha (ER-α) positive primary breast cancer carries a 30%-40% relapse rate owing to the development of endocrine resistance. Although the mechanisms underlying endocrine resistance in breast cancer remain unclear, recent evidence suggest that epigenetic reprogramming plays a central role. The aim of our study is to study the epigenetic landscape of ER-α positive breast cancer in primary and metastatic breast cancer tissue samples.

Methods
We collected 55 (39 primary + 16 metastatic samples) fresh frozen breast cancer tissue samples which were processed for chromatin immunoprecipitation followed by high throughput sequencing (ChIP-seq). Using histone mark H3K27ac we mapped the entire repertoire of regulatory regions. We developed a novel computational approach in analysing this unique dataset in order to account of the intra-sample heterogeneity, allowing us to identify potential molecular signatures responsible for cancer progression.

Results
All samples possessed at least 50% tumour cellularity and all primary samples were confirmed as ER-α positive whilst the metastatic samples were utilised based on a previous background of ER-α positive primary breast cancer. Hormonal status and histological reports were obtained for all tumour samples. Downstream analysis was based on 47 tumour samples which provided 90% and 100% coverage of all active enhancers and promoters, respectively, with no difference in peak size between the two groups. The tumour samples exhibit a high degree of heterogeneity in enhancers, with promoters showing a much higher conservation rate. However, we also identified a cluster of enhancers common to the majority of patients. Using our custom workflow, we de-convoluted heterogeneous and shared enhancers and identified novel transcription factors (TFs) independently enriched in the two cluster of enhancers. Some of this TFs have a significant prognostic value in a meta-analysis of 1466 ER-α positive expression profiles (O.S. p=0.00016). Further proof of concept using a highly shared enhancer identified SLC9A3R1 as a potential new oncogene for ER-α positive breast cancer. Finally, we used epigenetic stratification to improve breast cancer diagnosis and prognosis. Overall, our work represents the first systematic annotation of ER-α breast cancer's epigenome. This work should form the basis for future characterization of the epigenetic drivers of breast cancer progression.

Title: Landscape of somatic mutations in inflammatory breast cancer whole-genome sequences

Li X, Krishnamurthy S, Kumar S, Reddy S, Woodward W, Reuben J, Hatzis C, Ueno NT T, Gerstein M and Pusztai L.  Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT;  Morgan Welch Inflammatory Breast Cancer Research Program and Clinic, Houston, TX and  Yale University, Yale Cancer Center, Section of Breast Medical Oncology, New Haven, CT.

Body: **Goal:** Inflammatory breast cancer (IBC) is a rare, aggressive form of breast cancer that is characterized by a highly metastatic phenotype. Numerous previous attempts failed to identify, recurrent, IBC-specific gene expression or DNA copy number alterations. We performed whole genome sequencing (WGS) of IBC biopsies obtained before any therapy to define a comprehensive genomic landscape of this disease.

**Methods:** Illumina paired-end whole genome sequencing (WGS) of 20 IBC (n=9 ER+, n=11 ER-) and matched normal samples were performed with median coverage of 60X and 40X for cancer and normal, the percentages of mapped reads were 99.3% and 99.2%, respectively. We identified germ-line and somatic variants, indels as well as large scale structural variants, using GATK Haplotype Caller, MuTect and CREST, respectively. We performed the same analysis on WGS data from 23, age, race and ER and HER2 matched, non-IBC (n=12 ER+, n=11 ER-) from the TCGA for comparison. Variants in both coding and noncoding sequences were categorized by FunSeq to identify potential drivers. Mutation clustering in each gene, as well as significantly mutated non-coding regulatory modules, were identified using LARVA. DeconstructSigs were used to decompose the mutational spectrum of each cancer into 30 validated, mutational signatures provided by COSMIC. Contributions of each validated signature to mutations in IBC vs. non-IBC were compared using Welch's t-test.

**Results:** We identified 118,818 somatic variants in the IBC samples (median: 3,856; minimum: 1,109; maximum: 24,815) including 1,060 variants (~0.9%) in coding regions. 5,287 somatic indels and 5,959 large scale structural variants were detected including 1,028 insertions and 1,857 deletions. Recurrent, non-synonymous mutations were detected in the coding region of GRIN2A gene in 3/20 IBC samples (15%), (previously reported as a potential driver mutation in 1.7% of breast cancers). Other significant mutations in coding regions included GRHL1, PIK3R2, ESR1, FLG2 and etc. Three DNase I hypersensitive sites (DHSs) in non-coding regions were altered in 20% (4/20) IBC samples vs. fewer than 8.7% (2/23) in non-IBC. Mutational frequency of GATA3 is 80.0% vs. 47.8% (p=0.03), and PTEN is 45.0% vs. 73.9% (p=0.05), in IBC vs. non-IBC samples when including both coding and non-coding variants. Contributions of mutational signature 9, that is associated with polymerase η, were significantly higher in IBC cohort than non-IBC cohort (p-value=0.056).

**Conclusion:** This is the first whole genome sequencing analysis of IBC and comparison with the results from non-IBC. We identified promising candidate drivers in the coding sequence and in non-coding regulatory modules of expressed genes. We also identified mutational signature 9, and mutations in several DHS as significantly more frequent alterations in IBC compared to non-IBC.
Title: Genomic, transcriptomic and immune features of breast cancer according to the patient's body mass index at diagnosis

Body: Background: According to the latest estimates, 39% of women worldwide are either overweight or obese. This percentage varies by country with estimates as high as 63% in the USA. High body mass index (BMI) has been recognized as a risk factor for developing breast cancer (BC), especially estrogen receptor (ER)-positive and triple-negative BC in post and premenopausal women, respectively. Additionally, increased BMI has been associated with adverse survival, although several studies reported discrepant results across the different BC molecular subtypes. To the best of our knowledge, no study has so far explored the relation between the BMI of the patient and the genomic, transcriptomic and immune features of the associated tumor.

Material and methods: We collected the BMI at diagnosis for the BC patients included in the whole genome and transcriptome sequencing substudy of the International Cancer Genome Consortium (Nik-Zainal et al. Nature 2016). BMI was available for 381/560 of the initially sequenced patients. We investigated the association of BMI with classic clinico-pathological variables, mutational burden, substitution/rearrangement signatures, genomic drivers, transcriptional features and tumor infiltrating lymphocytes (TILs) in all patients and in the subgroups defined by the ER, PgR and HER2 as well as by menopausal status.

Results: The only clinico-pathological variable associated with BMI was the age at diagnosis. Henceforth, all results were further adjusted for age. A higher number of substitutions was associated with increased BMI in ER+/HER2- and HER2+ BC with a low statistical evidence. Specifically, substitutions belonging to signature 1A (C>T substitutions at NpCpG) were significantly associated with BMI in these two subtypes. The numbers of indels, numbers of rearrangements or rearrangement signatures showed no evidence of association with BMI. For 31 known oncogenic drivers present in at least 2% of the tumors, we observed that CCNE1, FGFR1, IGFR1 amplifications were significantly associated with increased BMI, while PTEN and CDKN2A alterations were associated with lower BMI in triple-negative tumors. In ER+/HER2- BC, CDH1 and TBX3 alterations were significantly associated with increased BMI. In HER2+ BC, MYC amplifications were associated with lower BMI. At the transcriptomic level, BMI was positively correlated with leptin expression in postmenopausal ER+/HER2-, and with PTEN expression in triple-negative BC, respectively. Proliferation-based expression signatures were inversely correlated with BMI in triple-negative BC. Finally, nearly no tumor from obese patients presented a strong lymphocytic infiltration, especially in triple-negative BC.

Conclusion: This study is, to the best of our knowledge, the first report of a comprehensive genomic, transcriptomic and immune characterization of BC according to patient BMI. Although the present findings need to be validated in an external dataset, they suggest that BMI impacts BC biology and could influence targeted and immune treatment strategies especially in triple-negative BC.
**Title:** The genomic landscape of breast metaplastic carcinoma

**Body:** Introduction: Metaplastic breast carcinoma (MBC) is a rare histologic type of triple-negative breast cancer (TNBC), characterized by the presence of cells displaying squamous and/or mesenchymal differentiation. The transcriptomic profiles of MBCs have been reported to vary according to the type of metaplastic elements. The somatic genetic alterations that underpin this breast cancer subtype remain to be fully characterized. Here we sought to define the genomic landscape of MBCs, whether different subtypes of MBC would be driven by distinct constellations of genetic alterations, and to investigate functionally the impact of mutations affecting WNT pathway genes using non-malignant breast epithelial cells.

**Methods:** Thirty-five MBCs were retrieved from the pathology department of the authors' institutions and classified into the MBC histologic subtypes. All but one of the MBCs were of triple-negative phenotype. DNA was extracted from microdissected tumor-normal pairs and subjected to whole-exome sequencing. Somatic genetic alterations were identified using state-of-the-art bioinformatics algorithms. The genomic profiles of MBCs were compared to those of 69 common type TNBCs from The Cancer Genome Atlas. Overall mutation rates were compared using the Mann Whitney U test, and the frequency of mutations in each gene was compared using Fisher's exact test. RNA was extracted from a subset of MBCs and subjected to WNT signaling pathway activation analysis with the RT² Profiler PCR Array. Triple-negative non-malignant breast epithelial cells (MCF10A and MCF12A) and cancer cell lines were utilized for 2D and 3D functional studies.

**Results:** Whole-exome analysis revealed that MBCs displayed a median of 103 (15-344) somatic mutations, which did not differ from the median number of somatic mutations in common type TNBCs (76, range 14-233). The most frequent recurrently mutated cancer genes included TP53 (69%) and PIK3CA (29%). MBCs more frequently harbored mutations in PI3K pathway genes than common type TNBCs (57% vs 22%, P<0.05), including mutations affecting PIK3CA (29% vs 7%), PIK3R1 (11% vs 0) and PTEN (11% vs 1%). MBCs also more frequently harbored mutations affecting WNT signaling pathway genes (46% vs 26%, P<0.05), including AXIN1 (6% vs 1%), WNT5A (6% vs 0) and APC (3% vs 0). MBC subtype analysis revealed that PIK3CA mutations were only detected in non-chondroid MBCs (53% vs 0), CHERP mutations were only found in chondroid MBCs (25% vs 0), whereas USP5 mutations only found in squamous MBCs (33% vs 0). MBCs with somatic mutations in WNT pathway genes had significantly higher WNT pathway activation than MBCs lacking mutations in these genes (P=0.0244). Consistent with the mesenchymal phenotype frequently exhibited by MBCs, in vitro experiments provided functional evidence that aberrant WNT pathway activation induces an epithelial-to-mesenchymal transition (EMT) phenotype, with downregulation of epithelial markers and upregulation of EMT transcriptional inducers.

**Conclusions:** MBCs are significantly enriched for mutations affecting PI3K and WNT pathways, highlighting the importance of the dysregulation of the WNT pathway in MBC carcinogenesis. Moreover, our findings suggest that specific mutations are significantly associated with distinct histologic subtypes of MBCs.
Title: Intra-tumor genetic heterogeneity and histologic heterogeneity within metaplastic breast cancers: Genotypic-phenotypic correlations

Geyer FC C, Burke KA A, Papanastatiou AD D, Macedo GS S, Brogi E, Norton L, Wen YH, Weigelt B and Reis-Filho JS S. Memorial Sloan Kettering Cancer Center, New York, NY and Memorial Sloan Kettering Cancer Center, New York, NY.

Body: Introduction: Metaplastic breast carcinoma (MBC) is characterized by the presence of neoplastic cells displaying squamous and/or mesenchymal differentiation. Morphologic intra-tumor heterogeneity is frequent in MBCs and reported to be reflected at the transcriptomic level: whilst squamous and chondroid MBCs are preferentially of basal-like subtype, spindle cell MBCs are of claudin-low subtype. Likewise, histologically distinct components within MBCs have been shown to display distinct focal copy number alterations. Here we sought to investigate whether histologically distinct components within MBCs would be underpinned by different mutational profiles and mutational signatures.

Methods: Ten MBCs with two histologically distinct components (spindle, chondroid, osseous, squamous and/or ductal) were retrieved from the Department of Pathology of the authors' institution. The distinct components of each case and, in two cases, two regions of the same component were separately microdissected. DNA extracted from tumor samples (n=22) and matched normal tissues was subjected to whole-exome sequencing. Somatic genetic alterations were identified using state-of-the-art bioinformatics algorithms. Somatic mutations were classified as clonal (i.e., present virtually in all tumor cells) or subclonal using ABSOLUTE and FACETS. Mutational signatures were defined using non-negative matrix factorization.

Results: Medians of 146 (56-290) somatic mutations and 108 non-synonymous somatic mutations (39-222) per tumor component were identified. The histologically distinct components of each case harbored identical clonal TP53 mutations. Additional recurrent mutations in cancer genes included those affecting PI3K pathway genes (PIK3CA, 2 cases; PIK3R1, 2 cases). Shared mutations between components of each case ranged from 34% to 99% of all mutations, with a median of 84%, of which 24% (12%-53%) were truncal (i.e., shared by and clonal in both components). Private mutations (i.e., found in only one component) ranged from 1% to 66%, with a median of 16%, of which 72% (0-100%) were non-synonymous and 1% (0-52%) were clonal. In two cases, the comparison of two histologically similar regions revealed less heterogeneity, with 94% (87%-100%) of shared mutations, whereas in these samples the median of private mutations was 6% (0-13%), of which 70% (0-100%) were non-synonymous and none were clonal. Private non-synonymous mutations affecting cancer genes included those in PIK3R1, MED12 and NOTCH1. The mutational signatures (e.g. aging or BRCA) were concordant between distinct components of each case; however, differences in the mutational signatures were observed between truncal somatic mutations and mutations restricted to individual components.

Conclusions: MBCs display substantial genetic intra-tumor heterogeneity, which is more overt between histologically distinct components than between regions of similar histology. Our data suggest a genotypic-phenotypic correlation and corroborate the notion that distinct components within MBCs, although clonally related, may be driven by distinct somatic genetic alterations.
Title: Comparison of genotyping results from tissue and circulating DNA (ctDNA) in patients with metastatic breast cancer

Malvarosa G, Spring L, Juric D, Moy B and Bardia A. Massachusetts General Hospital, Boston, MA.

Body: Introduction: Robust clinical genotyping assays are crucial to accelerate development of targeted therapies toward tumor-specific oncogene pathways. Indeed, there has been an explosion in the development of genotyping assays and stratified enrollment in clinical trials based on molecular characteristics of the tumor. However, availability of tissue can be a significant barrier for genotyping, particularly patients with estrogen receptor positive (ER+) breast cancer, who frequently have bone only metastasis. Detection of mutations in circulating tumor DNA (ctDNA) represents an attractive alternate strategy. However, there is a paucity of data comparing genotyping results from tissue and ctDNA, and potential clinical utility for patients with metastatic breast cancer.

Methods: Analysis of ctDNA was based on Guardant 360 panel (2015), a next-generation sequencing (NGS) based assay that covers point mutations in 70 genes (complete or critical exon coverage) with select amplifications, fusions, and indels, using NGS Illumina HiSeq platform, validated to detect alterations in samples with at least 2% ctDNA. Molecular profiling of tissue was based on the institutional lab-developed test “Snapshot-NGS assay”, utilizing a multiplex polymerase chain reaction (PCR) technology called Anchored Multiplex PCR (AMP) for single nucleotide variant (SNV) and insertion/deletion (indel) detection in genomic DNA targeting hotspots and exons in 39 genes using NGS Illumina MiSeq platform, validated to detect SNV and indel variants at 5% allelic frequency or higher in target regions.

Results: In the analytical dataset, a total of 42 patients with metastatic breast cancer (median age 62) at our institution had ctDNA and tissue Snapshot-NGS results available. Out of these, 95% had at least one genetic alteration detected in ctDNA, before start of a new therapy. The common genetic alterations in ER+ disease (n = 33) included PIK3CA (39.4%), ESR1 (27.3%), and AKT1 (15.2%); HER2+ disease (n = 2) included PIK3CA and CCND1; TNBC (n = 7) included TP53 (71.4%). Gene amplifications in FGFR, PIK3CA, CCND1, MYC, and KRAS were also noted. In general, the average number of molecular alterations was higher in ctDNA than the tissue specimen (mean = 5.1 vs 1.1; p < .001). Of 34 patients with actionable alterations detected in ctDNA, 76.5% of these patients did not have actionable alterations detected in tissue. Of 29 patients with actionable alterations detected in tissue (primary or metastatic), 13.8% of these patients did not have any actionable alterations detected in ctDNA.

Conclusion: A significantly higher number of genomic alterations were detected in ctDNA compared to tissue, including actionable alterations linked to potential targeted therapies. Given these findings and the difficulties with tissue-based genotyping assays, blood based biomarker assays might provide an alternative and effective way to obtain a comprehensive molecular profile, and potentially guide management decisions for patients with metastatic breast cancer.
Title: Estrogen receptor 1 (ESR1) mutations in circulating tumor DNA (ctDNA): A guide to the management of advanced breast cancer (ABC)

Body: Background: Estrogen receptor (ER)-α is expressed in about 70% of breast cancers and drugs that target the receptor function, selective estrogen receptor modulators (SERM) and aromatase inhibitors (AIs) represent the standard of care for patients (pts) with ER+ breast cancer. Nevertheless, prolonged exposure to endocrine therapy may result in acquired resistance and subsequent progression of disease. Recent evidence showed that activating mutations (muts) in the ligand-binding domain of ER-α occur in approximately 20% of pts exposed to endocrine therapies and those genomic abnormalities may represent the driver of endocrine resistance. In this context, ctDNA provides a non-invasive source for real-time next generation sequencing (NGS) studies, in order to understand the biology of ABC and guide and monitor treatment.

Methods: We conducted a retrospective review of 91 pts with ABC, including 57 pts with ER+ tumor, who had longitudinal assessment of their disease by ctDNA analysis. At the time of baseline sampling, 50/57 pts had stage IV cancer. The total number of blood samples collected was 184. 38 (67%) pts had serial samples. The average number of samples for each pt was 3 (range 1-7). The plasma-based assay was performed utilizing Guardant360 (Guardant Health, CA), a digital NGS technology to sequence a panel of > 50 cancer genes.

Results: Among the ER+ subgroup (57 pts), we identified 11 pts (19%) harboring ESR1 muts in ctDNA. All 11 pts had metastatic disease: 2 (18%) had bone metastases, 2 (18%) had visceral metastases, 7 (64%) had both sites of disease. The median age was 55 years (range 33-73). 5 pts had inflammatory breast cancer. The most common ESR1 muts were: Y537S (6/11, 55%), D538G (4/11, 36%) and Y537N (3/11, 27%). 7 pts carried polyclonal muts. At the time of testing, 10 pts had already failed at least 1 line of endocrine therapy (average 2, range 1-5), including 6 pts that had received a fulvestrant-containing regimen, 8 pts ≥ 1 line of AIs. After the mut detection, 5 pt were on endocrine therapy and 4 pts were started on/continued chemotherapy. ESR1 muts disappeared in 2 pts (fulvestrant-palbociclib and chemotherapy respectively) who achieved stable disease as best response. Three pts continued to harbour muts and then progressed (one died). 2 pts had tissue NGS and ESR1 mut was not identified. Progression free survival and overall survival were 8 months (ms) and 21.5 ms in ESR1+ subpopulation versus 6.2 ms and 22.2 ms in the ESR1- pts (p = 0.78 and p = 0.97, respectively). At the time of analysis 5 pts were dead, 6 were currently alive.

Conclusions: We observed that ESR1 muts, a known driver of endocrine resistance, occurs at a high frequency in heavily pre-treated estrogen receptor positive ABC. Blood-based diagnostics can be used to identify ESR1 muts sometimes not detected by tissue-based sequencing of the metastatic lesions indicating tumor heterogeneity and allowing dynamic monitoring of ABC.
Comprehensive genomic profiling of clinically malignant phyllodes tumors of the breast reveals frequent mutation of NF1 and other genes associated with PI3K and RAS pathway activation

Background: Malignant or metastatic breast phyllodes tumors (MPT) are exceptionally rare, and the underlying genomic drivers are still being elucidated. Recent studies report frequent mutations in the RAS and PI3K pathways but have not commonly reported mutations in NF1. Comprehensive genomic profiling (CGP) can measure mutation load (TMB) and identifies all four classes of oncogenic alterations, including rearrangements and copy number loss that commonly affect tumor suppressors such as NF1, and can direct personalized treatment strategies.

Methods: CGP using hybridization capture of 3,769 exons from up to 315 cancer-related genes and select introns of 28 genes commonly rearranged in cancer was applied to ≥50ng of DNA extracted from 21 consecutive MPT and sequenced to high, uniform median coverage (>400X). TMB was determined as mutations/Mb on 1.1 Mb of sequenced DNA.

Results: The 21 MPT featured a median age of 51 yrs (range 14-70 yrs). CGP was performed on the primary MPT in 15 cases and on metastasis biopsies in 6 cases. TMB for all MPT was low (<10 mut/Mb), and all evaluable tumors (17/21) were microsatellite stable (MSS). The most commonly mutated genes were TP53 (57.1%), TERT (56.3%), NF1 (52.4%), MED12 (38.1%), CDKN2A/B (33.3%), and MLL2 (33.3%). 19/21 (90.5%) MPT harbored clinically relevant genomic alterations (CRGA) associated with therapies available on the market or under investigation in late stage clinical trials. Additional alterations in the PI3K/AKT/MTOR, RAS/RAF/MEK, and FGFR pathways were identified (see table); the PI3K/AKT/MTOR pathway was mutated in 10/21 (47.6%) of samples. Although CDKN2A/B loss was found in 6/11 tumors with NF1 mutation and only 1/10 NF1 wild-type samples, the co-occurrence was not significant (p<0.07). No significant correlation exists between the occurrence of NF1 mutations and mutation of MED12, TERT, the PI3K pathway, or other genes in the RAS/RAF pathway (NRAS, BRAF, EGFR). Targetable KIAA1549-BRAF or FGFR3-TACC3 fusions were identified in 2/21 (9.5%) tumors. Responses to targeted treatments will be presented.

Conclusions: More than 90% of MPT feature CRGA, including alteration of NF1, which was by far the most common targetable GA in this study. 52.4% of MPT had alterations predicted to result in loss of NF1 activity. NF1 mutation does not significantly co-occur with mutations in any other gene or pathway commonly altered in MPT. Other tumors with underlying NF1 mutations have responded to the MEK inhibitor selumetinib, suggesting MEK inhibitors may be relevant for the treatment of MPT. Other targetable alterations, including known gene fusions, are common in MPT. Thus, MPT may benefit from combination targeted therapy, warranting further investigation in the clinical trial setting.

Title: Comprehensive genomic profiling of 8,654 breast carcinoma reveals therapeutically targetable molecular subtypes beyond those defined by hormone-receptor expression

Body: Background: Breast carcinomas (BC) are commonly classified into 4 subtypes based on hormone receptor expression: basal, luminal A, luminal B, and HER2 overexpressed. Comprehensive genomic profiling (CGP) reveals targetable genomic alterations (GA) across all four mutation classes, as well measuring tumor mutational burden (TMB), and can redefine BC classification into therapeutically relevant subtypes. Testing with immunohistochemistry or hotspot testing can miss a substantial number of targetable alterations and cannot measure TMB.

Methods: DNA was extracted from 40 µm of FFPE sections for 8654 consecutive BCs. CGP was performed on hybridization-captured, adaptor ligation-based libraries (mean coverage >500X) for up to 315 cancer-related genes and select introns from up to 28 genes frequently rearranged in cancer. Sequences were analyzed for substitutions, small insertions/deletions, copy number changes, and rearrangements. TMB was determined by counting non-driver, non-germline alterations across 1.1 Mbp of sequenced DNA. Clinically relevant GA (CRGA) are GA linked to therapies on the market or under evaluation in clinical trials. Immunotherapy (IO) sensitivity is defined as TMB >20 mut/Mbp or mutation of specific DNA repair pathways.

Results: The table below outlines 7 distinct functional or signal transduction pathways commonly altered in BC. Several are targetable with therapies that are FDA approved for an oncology indication. Mutations can also be found in other targetable kinases such as RET, ROS1, and RAF. 6959 (80.4%) tumors harbor a GA in at least one pathway, and 2697 (31.2%) BC harbor alterations in just one pathway (unique cases). Only 9.8% of BC would be HER2-positive by IHC. Almost 4% (352/8654) of cases harbor rearrangements or gene fusions that may not be detectable with other assays. Mutations in ESR1 characterize an eighth category of tumors with acquired resistance to endocrine therapy; 796/8654 (9%) samples harbor ESR1 alterations.

Conclusions: CGP can identify CRGA and TMB that can stratify tumors by predicted sensitivity to a variety of therapies, including HER2- or mTOR-targeted therapies, immunotherapies, and other kinase inhibitors. 80% of BC harbor targetable GA, and 30% of samples harbor mutations in only one pathway. CGP can provide crucial information for identifying which of several treatment modalities is most appropriate for these 30% of patients. High levels of TMB and most GA would not be identified by IHC or hotspot testing, but can be detected by next-generation sequencing. CGP is a powerful tool for guiding treatment across therapeutically distinct, but targetable, pathways.

Title: Association of co-amplicons with immune infiltration in subtypes of HER2-Positive breast cancer

Singh S, Gilmore H, Somlo G, Abu-Khalaf M, Sikow W, Harris L and Varadan V. Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH; City of Hope National Medical Center, Duarte, CA; Yale Comprehensive Cancer Center, Yale University School of Medicine, New Haven, CT; Women and Infants Hospital, Warren Alpert Medical School of Brown University, Providence, RI and Cancer Diagnosis Program, National Cancer Institute, Rockville, MD.

Body: Background: HER2+ breast cancers are heterogeneous at both clinical and molecular levels. We and others have determined that the HER2-Enriched subtype exhibits the highest rate of pathologic complete response (pCR) to neoadjuvant chemotherapy and trastuzumab (T), while the HER2-Basal subtype is resistant to anti-HER2 therapy (Carey et al, JCO 2015; Varadan et al, CCR 2016). Additionally, we reported that signatures of immune cell infiltration and immune cell subsets evaluated after one dose of T can predict pCR to preoperative T and chemotherapy (Varadan et al, CCR 2016). Given recent evidence for improved immune response with increasing mutational load, we chose to characterize the association of somatic mutations and copy-number alterations with subtypes of HER2+ breast cancer and immune modulation after one dose of T.

Methods: Fresh tumor core biopsies were taken at baseline and 2 weeks after one dose of either T or nab-paclitaxel (N) from 60 patients with stage II-III HER2+ cancers enrolled on a multicenter trial (BrUOG 211B). All patients then received 18 weeks of T+N+carboplatin. PAM50 subtyping was performed using gene expression data from patient tumor biopsies and tumors were classified into HER2-Enriched, HER2-Luminal and HER2-Basal subtypes. Whole-exome sequencing (WES) was performed on a total of 86 samples (49 baseline, 37 brief-exposure), sequenced at an average depth of 90X. Somatic mutations were detected by applying multiple mutation-detection algorithms on the WES data, followed by stringent quality control using public and in-house variant databases, and mutation data curated from 11,000 tumors sequenced by the TCGA. Somatic copy-number alterations were estimated using a published algorithm, ENVE (Varadan et al, Genome Med 2015) that robustly detects somatic copy-number alterations in WES tumor profiles. We employed previously defined gene-expression signatures (Varadan et al, CCR 2016) of total immune infiltration and immune cell subsets, to assess for association with genomic aberrations.

Results: HER2-Basal tumors exhibited lower average copy number for HER2 and were less likely to have high-level amplifications of co-amplicons (e.g. 11q13, 20q13) with the exception of the MYC amplicon (8q24). They also exhibited a non-significant (P=0.33) trend towards higher mutational burden (Avg=85) compared to HER2-Luminals (Avg=79). A majority of somatic mutations (62%, 2282/3666) persisted after a single-dose of either T or N, while 17% (624/3666) were not detectable after brief-exposure. There was no association between immune infiltration and mutational burden in any HER2 subtype. Tumors harboring FGFR1 (8p11) amplifications exhibited higher gene-signature levels for macrophages (P=0.0073) and T-cells (P=0.0493) but not B-cells (P=0.213).

Conclusions: The HER2-Basal subtype is less likely to respond to trastuzumab-based neoadjuvant therapy and exhibits lower numbers of common amplicons. The disappearance of mutations after brief-exposure to therapy may be due to either tumor heterogeneity/sampling or clonal selection. The association of 8p11 amplifications with increased T-cell infiltration suggests that this amplicon may play an immunogenic role in HER2+ breast cancer. These results warrant further investigation in larger cohorts.
Hypothesis:
Endocrine therapy (ET) is an effective treatment for estrogen-receptor positive (ER+) breast cancer; however, more than 80% of women will develop endocrine resistance. ER ChIP-seq studies in clinical samples show tumors likely to relapse have a unique set of ER binding sites that correlate with gene signatures predicting clinical outcome. Understanding how several factors, including transcriptional co-activator-complexes, influence ER binding location is crucial to improving treatment. MLL3, which is recurrently mutated in ~7% of ER+ cases, is a member of one such complex that interacts with ER. It is a histone methyltransferase that marks active enhancers. We hypothesized that mutation of MLL3 may change the genomic landscape of enhancers and thus change binding patterns of ER, altering response to ET.

Methods:
To elucidate transcriptional consequences of MLL3 mutation in ER+ breast cancers, we leveraged TCGA ER+ breast cancer RNA-seq data. We used a gene-by-gene multivariate linear model to identify differentially expressed genes (DEGs) between MLL3-mutant and wild-type (WT) samples. This data was compared to DEG found in-house RNA-seq data for MLL3-mutant MCF7 cells, MLL3-WT ZR751 cells, and MLL3-knockdown (KD) ZR751 cells to identify a testable MLL3-mutant signature. ChIP-seq data for ER and H3K4me1, the histone mark made by MLL3, was then produced using these cell lines in order to pinpoint genes with changes in both H3K4me1 and ER-binding upon MLL3 mutation/KD. This gene list was compared to DEG found through RNA-Seq. To illuminate inherent differences between MLL3-WT and mutant/KD cells in response to ET, Cell-Titer Blue, Cell-Titer Glo, and Caspase-Glo assays were performed using DMSO, 4-OHT, and Fulvestrant.

Results:
TCGA RNA-seq data revealed MLL3-mutant ER+ breast cancers have differentially expressed transcriptional regulators, including ER itself. iRegulon analysis showed enrichment for DEG-regulated by ER-tethering factor SP1, a phenomenon suggested to be associated with more aggressive behavior. ChIP-seq data revealed substantial shifts in both ER-binding locations and H3K4me1 marks upon MLL3 mutation/KD. Interestingly, annotated peaks for MLL3-KD ZR751 showed overlap with those of MLL3-mutant MCF7, and GREAT analysis of new ER binding sites in MLL3-KD ZR751 showed an up-regulation of signatures associated with endocrine resistance. Indeed, MLL3-KD ZR751 cells were more resistant to 4-OHT/Fulvestrant than MLL3-WT ZR751.

Conclusions:
Loss of MLL3 function leads to a massive shift in H3K4me1, indicating a shift in the genomic landscape of enhancers. This shift is associated with a shift in ER binding as well as alterations in gene expression. Pathway analysis of these genes suggest that loss of MLL3 function may increase endocrine resistance, and indeed, cell lines with loss of MLL3 function are more resistant to ER inhibition than MLL3-WT cell lines. This work demonstrates that loss of MLL3 function leads to shifts in the enhancer landscape, alterations in ER binding and regulation of gene expression, and contributes to more aggressive tumor behavior.
**Title:** Comprehensive comparison of breast cancer molecular portraits by African and European ancestry in the cancer genome atlas

Huo D, Hu H, Rhie SK K, Gamazon ER R, Cherniack AD D, Liu J, Yoshimatsu TF F, Pitt JJ J, Hoadley KA A, Troester M, Ru Y, Lichtenberg T, Sturtz LA A, Shelley CS S, Mills GB B, Laird PW W, Shriver CD D, Olopade OI I. University of Chicago; Chan Soon-Shiong Institute of Molecular Medicine at Windber; University of Southern California; Vanderbilt University; The Eli and Edythe L. Broad Institute of MIT and Harvard; University of North Carolina at Chapel Hill; Nationwide Children's Hospital, Columbus; University of Wisconsin; University of Texas MD Anderson Cancer Center; Van Andel Research Institute and Walter Reed National Military Medical Center.

**Body:**

**Background:** African American breast cancer patients have worse survival rates than European American patients. Although racial differences in the distribution of breast cancer intrinsic subtype are known, it is unclear if there are other inherent genomic differences contributing to this racial outcome disparity.

**Methods:** We defined patient race based on genomic ancestry and compared multiple molecular features of breast cancer between 154 black and 776 white patients in The Cancer Genome Atlas (TCGA). We examined the contribution of these molecular features to survival outcomes using Cox proportional hazards models. We also estimated the heritability of breast cancer subtypes using a mixed effect model.

**Results:** Compared to whites, black patients had higher odds of basal-like (odds ratio=3.80, p<0.001) and HER2-enriched (odds ratio=2.22, p=0.027) breast cancers in reference to luminal A subtype. Beyond differences in relative frequency of intrinsic subtypes, black and white patients had distinct gene expression, protein expression, and somatic mutation landscapes. However, the majority of these molecular differences were eliminated after adjusting for subtype; in the subtype-adjusted models, we found 142 genes, 16 methylation probes, 4 copy number segments, 1 protein, and no somatic mutation were differentially expressed or present between black and white patients. Using the top 40 differentially expressed genes, we built a race-enriched gene signature, which had excellent capacity of distinguishing breast tumors from black versus white patients (c-index=0.852 in the validation dataset). We also estimated the heritability of breast cancer subtype (basal vs. non-basal) to be 0.436 (p=1.5x10^{-14}) and showed that two genetic variants (rs1078806 in FGFR2, rs34084277 in BABAM1) were associated with intrinsic subtype and can partially explain racial differences in subtype frequencies.

**Conclusion:** On the molecular level, once intrinsic subtype frequency differences are accounted for, there are few genomic or proteomic differences observed between blacks and whites. More than 40% of breast cancer subtype frequency differences may be due to genetic ancestry. These results suggest that future studies are warranted to investigate genetic and non-genetic factors that contribute to the development and progression of breast cancer subtypes in order to reduce racial disparity.
Body: Introduction: Clonal heterogeneity in cancer is associated with resistance to therapies and evolution of metastatic disease. Clinical management of breast cancer relies on the status of estrogen (ER), progesterone (PR), and Her2 receptors in diagnostic biopsies. Results for these biomarkers rely on IHC and FISH assays that incorporate staining intensity and percentage of positive cell numbers for each sample of interest. Heterogeneous results for one or more of these biomarkers suggest the presence of multiple tumor populations within a biopsy. However the impact of clonal heterogeneity on clinical biomarkers has not been rigorously evaluated.

Methods: We interrogated the clonal composition of 3 treatment-naïve surgically excised invasive ductal carcinomas. Patient #1 cancer, (pT2, pN0) was grade 3, ER+, PR+, and Her2-- with a germ line \textit{BRCA2}^Q49X mutation. Patient #2 cancer (pT2, pN0) was grade 3, ER+ PR- Her2+. Patient #3 was a locally advanced cancer with both axillary and supraclavicular lymph node (LN) involvement (pT2, pN3c, and was grade 3, ER+PR-Her2+ by core but found to be ER+PR-Her2- on the resection specimen. We applied DNA content flow cytometry to multiple (8-18) mapped biopsies in each case. Each sorted tumor population was interrogated with whole exome sequencing, and whole genome array comparative genomic hybridization (aCGH). Single cell analysis of aneuploid populations present in the primary tumor and lymph nodes in patient 3 was done to further assess clonal heterogeneity.

Results: Tumor from patient #1 had a single ploidy with stable copy number profiles including an interstitial 13q deletion that converted a germ line \textit{BRCA2}^Q49X mutation to homozygosity, and a clonal homozygous deletion in \textit{Numb} in each of 4 tumor biopsies. Tumor from patient #2 had a dominant ploidy (3.2N) in each of 10 (A1-A10) primary tumor biopsies but with a second co-existing ploidy (3.6N) in one (A2) biopsy. A homozygous somatic \textit{BRCA2}^{3129X} mutation was identified in all 10 biopsies and in both ploidies; however the genomes had heterogeneous aCGH profiles. In contrast, 12 primary biopsies from Patient #3 contained 6 distinct ploidies with highly aberrant but homogenous genomes, characterized by \textit{SARC} amplification, homozygous deletion of \textit{ROBO1} and \textit{ROBO2}, and clonal mutations in \textit{TP53}, \textit{NF1}, and \textit{PIK3CA}. One of the ploidies, (5.8N) was present in an adjacent node and another (5.0N) in both the adjacent and distant nodes. Single cell analyses of the 5.0N and 5.8N populations revealed that allele frequencies of driver mutations were stable in the tumor and become homozygous in the LNs. There were no \textit{Her2} amplicons or mutations in biopsies analyzed in Patients #2 and #3 further contradicting the heterogeneous staining for ER, PR and Her2.

Conclusion: Tumor heterogeneity includes variations in ploidies, copy number aberrations, and allele frequencies. However even highly aberrant aneuploid genomes can be stable within multiple primary and lymph node sites. Rigorous interrogation of flow sorted tumor populations, in contrast to inferring heterogeneity in bulk samples, identifies driver aberrations in single biopsies, challenges heterogeneous results with clinical biomarkers, and distinguishes allelic heterozygosity from tumor heterogeneity in highly aberrant aneuploid tumor genomes.

Title: The metastatic breast cancer project: Translational genomics through direct patient engagement

Body: Background: The Metastatic Breast Cancer Project is a nationwide research initiative that directly engages patients through social media and advocacy groups and seeks to empower them to share their samples and clinical information to accelerate research. Because the vast majority of patients are treated in the community setting, we sought to determine the feasibility of remotely obtaining tumor and saliva samples as well as medical records from a large cohort of metastatic breast cancer (MBC) patients who receive their care in diverse settings around the country.

Methods: In collaboration with patients and advocacy groups, we developed a website to allow MBC patients across the U.S. to participate. Enrolled patients are sent a saliva kit and asked to mail back a saliva sample, which is used to extract germline DNA. We contact participants' medical providers and obtain medical records and part of their tumor biopsy. Whole exome and transcriptome sequencing is performed on tumor and germline samples. Clinically annotated genomic data are used to identify mechanisms of response and resistance to therapies. The database will be shared widely with researchers. Study updates and discoveries are shared with participants regularly.

Results: In the first 8 months, 2285 MBC patients from all 50 states enrolled. 2163 (95%) completed the 16-question survey about their cancer, treatments, and demographic information. 1232 completed the online consent form permitting acquisition and analysis of medical records, tumor tissue, and saliva samples. 556 saliva samples have been received. Initial medical record and tumor sample requests have been made for patients who have provided saliva samples. To date, we have obtained medical records from 102 patients (93% success rate) and tumor samples from 32 patients (77% success rate). Whole exome and transcriptome sequencing has been successfully completed on initial samples received and is ongoing for additional samples.

Conclusions: Partnering directly with patients through social media and advocacy groups enables rapid identification of thousands of patients willing to share tumors, saliva, and medical records to accelerate research. This approach allows for rapid identification of patients with rare phenotypes such as extraordinary responders, who have been challenging to identify with traditional approaches. Remote acquisition of medical records, saliva samples, and tumor tissue for patients located throughout the U.S. is feasible. Genomic analysis and medical record abstraction for these patients is underway. As data is generated, a clinically annotated database will be shared widely with the research community.

Title: Copy number aberration-induced gene breakage analysis identifies recurrent FOXP1 fusions in breast cancer

Body: Background: Genomic instability is a critical feature of breast cancers, which manifests in genome-wide copy number aberrations (CNA), often causing “gene breakage” and the generation of fusion genes. We aimed to identify aborted transcripts with underlying CNAs and to investigate the molecular landscape of breast cancers harbouring such events.

Methods: A walking student's t-test algorithm was applied to Affymetrix Exon 1.0ST array data of 123 breast cancers to identify regions of aborted transcription and overlaid with DNA breakpoints derived from matched Affymetrix SNP6 ASCAT-segmented copy number. Aborted transcripts were investigated as potential fusion gene partners through RNA-seq analysis of 151 breast cancer samples (TCGA) and 51 breast cancer cell lines (BCCL) using ChimeraScan. Clinical correlates were established for clinicopathological features, genomic instability measures, and gene expression-based molecular classifiers including PAM50, TNBCtype, IntClust subtypes and immune signatures.

Results: One hundred and six genes with recurrent CNA-induced aborted transcription were identified. Aborted transcription showed hormone receptor subtype-specificity for 7 genes ($n_{TNBC}$=1, $n_{Non-TNBC}$=6) and was less prevalent in samples of IntClust 2 and IntClust 4 subtypes ($p$: 0.0043, 0.0011). Aborted transcripts were more frequently observed in samples with greater copy-neutral loss of heterozygosity ($p$:0.012), while aborted transcription of 54/106 genes significantly affected enrichment of 27 tumor-infiltrating lymphocyte subpopulations.14 aborted transcripts were found as a fusion gene with one partner in RNA-seq of TCGA and BCCL, while 19 were involved in multiple fusion events (range=1-6, median=2). Nine of 106 genes displayed gene breakage and fusion events exclusively in samples with an enriched tandem duplication phenotype. Notably, FOXP1, localised to a tumour suppressor locus at 3p14.1, reported the highest number of fusion configurations ($n$=6) with concurrent aborted transcription across all RNA-seq datasets ($n_{PRADA}$=9, $n_{TCGA}$=38, $n_{BCCL}$=6).

Conclusion: CNA-induced gene breakage affects the molecular landscape of breast cancers and is linked with many genomic configurations of interest including copy-neutral loss of heterozygosity and tandem duplications. In particular, the role of recurrent gene fusions of the tumour suppressor, FOXP1, in tumourigenesis warrants further investigation.
Title: Multi-omics and immuno-oncology profiling reveal distinct molecular signatures of young Asian breast cancers

Body: Breast cancers (BC) in younger, premenopausal patients (YBC) tend to be more aggressive with worse prognosis, higher chance of relapse and poorer response to endocrine therapies compared to breast cancers in older patients. The proportion of YBC (age \( \leq 40 \)) among BC in East Asia is estimated to be 16-32\%, significantly higher than the 7\% reported in Western countries. To characterize the molecular bases of Asian YBC, we have performed whole-exome sequencing (WES) and whole-transcriptome sequencing (WTS) on tumor and matched normal samples from 134 Korean BC patients consisting of 74 YBC cases (age \( \leq 40 \)) and 60 OBC cases (age \( > 40 \)). We then performed comparison analyses and integrative analyses with the TCGA BC cohort consisting of 1,116 tumors from primarily Caucasian patients, also grouped by age into YBC (age \( \leq 40 \)), IBC (40 < age \( \leq 60 \)) and OBC (age \( > 60 \)).

Somatic mutation prevalence analysis identified 7 significantly mutated genes and the same top three genes – TP53, GATA3 and PIK3CA – were reported by the TCGA BC study. To identify differentially expressed (DE) genes and pathways in YBCs vs. OBCs, we performed logistic regression analyses while controlling for the confounding effects of tumor purity and stage. We were surprised to see a significant overlap in DE pathways between a comparison of adjacent normal tissues in younger vs. older TCGA cohorts and a comparison of YBC vs. OBC tumors, indicating that normal tissue compartment could contribute to observed differences between bulk tumors. To separately examine molecular signatures from tumor, stroma and normal compartments, we used non-negative matrix factorization (NMF) analyses to virtually dissect bulk tumor expression data and identified 14 factors including 3 factors associated with normal tissues, 1 factor associated with stroma and 1 factor associated with tumor infiltrating lymphocytes (TIL). Integrative analyses of tumor associated factors and DE pathways revealed that estrogen response, endocrine therapy resistance, and oxidative phosphorylation pathways are up-regulated in YBCs compared to OBCs while cell cycle and proliferation pathways are up-regulated in Asian OBCs. Interestingly, many immune and inflammation pathways correlated with the TIL factor were significantly upregulated in OBCs vs. YBCs. Using gene expression signatures representing distinct immune cell types, we classified our cohort into four subtypes of varying TIL activities and observed significant enrichment of the TIL-high subtype in OBCs compared to YBCs. These observations were confirmed by IHC analyses of four TIL markers (CD45, CD4, CD8 and CD163) in 120 tumors.

To our knowledge, this is the first large-scale multi-omics study of Asian breast cancer and would significantly contribute to the compendium of molecular data available for studying young breast cancers. The major landmarks in the molecular landscape looked similar across BCs of different ethnicities and ages, however, we have identified a number of distinguishing molecular characteristics associated with Asian YBC. The sources for some signatures were further traced to non-tumor intrinsic compartments, indicating that tumor microenvironment may play potentially important roles in driving the carcinogenesis of young breast cancers.

Title: An integrated molecular analysis of invasive lobular carcinoma

Lal S, McCart Reed A, Nones K, Wockner L, Song S, Lakhani S and Simpson P. University of Queensland Centre for Clinical Research and the School of Medicine, Brisbane, Queensland, Australia; Pathology Queensland, Brisbane, Queensland, Australia and Queensland Institute of Medical Research, Brisbane, Queensland, Australia.

Body: Background: Invasive lobular carcinoma (ILC) is the most commonly diagnosed special histological type of breast cancer, accounting for up to 15% of all cases. Accumulating data suggests the biology and clinical features of ILC differ to those of the more commonly diagnosed Invasive Carcinoma of No Special Type (IC-NST), including evidence of there being an overall worse long term outcome associated with ILC. Several large-scale molecular profiling studies have recently been published regarding ILC, highlighting molecular heterogeneity and important drivers of tumour behaviour. We hypothesize that an integrative analysis of gene expression and DNA copy number data will identify novel drivers, and prognostic and predictive biomarkers of lobular phenotype.

Methods: Gene expression and copy number data from ILC tumours profiled in-house (n=25), METABRIC (n=125) and TCGA (n=145) were assembled and analysed. Integration of genome and transcriptome data was performed using two methods. Firstly, by Spearman correlation with a meta-analysis by combining gene level correlation coefficients from each study using a random effects model, weighting each study with inverse variance. Secondly using ANOVA, followed by combining gene level p-values across studies using Stouffers Z-score. Disease specific survival was examined at an individual gene level and using all genes simultaneously (via a Cox Boost analysis) to identify gene expression changes that are associated with poor outcome.

Results: DNA copy number profiling identified recurrent gains (1q, 8q, 16p), losses (11q, 16q) and amplifications (1q32, 8p12-p11.2, 11q13). 11q13 amplifications were prevalent at a higher frequency in patients with poor outcome compared to patients with better outcome. The integrative analysis identified 1928 candidate genes whose expression was associated with gene copy number; as expected being enriched from genome regions highlighted above. One hundred and sixty of these genes were of prognostic significance in the METABRIC ILC cohort, several are known cancer drivers (e.g. PBX1, CCND1) and five new candidates are being investigated as novel prognostic biomarkers by immunohistochemistry.

Conclusions: An integrated molecular analysis of ILC has identified a large number of gene expression changes that are dictated by gene copy number in ILC. Some of these are expected to influence tumour behavior and to highlight aggressive cancers with poor prognosis.
Interrogating the impact of pregnancy on breast cancer biology using DNA copy number profiling

Body: Background

Epidemiological evidence indicates a clear relationship between pregnancy and breast cancer (BC) risk. However, little is known regarding the impact of pregnancy on BC biology. DNA copy number aberrations (CNAs) play an important role in breast carcinogenesis. BC during pregnancy is a rare disease but yet could serve as a good model to study the impact of pregnancy on BC biology.

Methods

We retrospectively included 54 pregnant and 113 non-pregnant BC patients matched for age and stage with complete clinico-pathological, gene expression and 5-year follow-up data. CNAs were assessed using Affymetrix OncoScan FFPE arrays. We identified the CNAs associated with pregnancy using a multivariate logistic regression adjusted for classical clinico-pathological features. We further evaluated their impact on gene expression.

Results

After quality control, CNA profiles were obtained for 38 pregnant and 87 non-pregnant BC patients. We identified 13 regions with copy number gains, 11 of which were more frequently gained in pregnant compared to non-pregnant controls and 5 regions with copy number loss, 3 of which were more frequently lost in pregnant patients ($p \leq 0.05$). Of interest, we identified 4 genes previously identified as driver event associated with CNAs in breast cancer (S. Nik-Zainal et al, Nature 2016). AKT1 and CDKN2A/B were more frequently gained in the pregnant compared to the non-pregnant (23.7% vs. 8.0%, $p=0.068$ and 18.4% vs. 4.6% $p=0.036$) and ARID1B was less frequently gained in the pregnant cohort (2.6% vs. 13.8%, $p=0.02$). Interestingly, PAPPA which had been previously identified as a pregnancy-dependent oncogene (Takabatake Y. et al, EMBO Mol Med. 2016) was also more frequently gained in the pregnant compared to the non-pregnant patients (21.1% vs 5.8%, $p=0.03$). We next evaluated the effect of these CNAs on their own gene expression levels and found that AKT1 and CDKN2A/B CNAs were affected by gene-dosage effect.

Conclusions

In this study, we were able to identify several genomic alterations associated with pregnancy that could further elucidate the impact of pregnancy on BC risk. Moreover, by combining CNAs with gene expression, we were able to identify genes whose expression were associated with CNAs and therefore could be considered potential drivers of this rare disease.
Title: Genomic copy number alterations (CNA) associated with pCR in HER2-positive (HER2+) early-stage breast cancer (BrCa) patients receiving neoadjuvant trastuzumab (T)

Walsh N, Gullo G, Maguire A, O'Donovan N, Quinn C and Crown J. National Institute for Cellular Biotechnology, Dublin City University, Dublin, Ireland and St. Vincent's University Hospital, Dublin, Ireland.

Body: Introduction: Genetic alterations such as amplifications and deletions frequently contribute to tumorigenesis. These alterations can change gene expression which alters the normal cell growth and survival regulatory mechanisms. Characterisation of DNA copy number alterations (CNA) is important to understand cancer progression and response to therapy. The aim of this study is to determine patterns of CNAs in HER2+ early-stage BrCa patients achieving pathological complete response (pCR) to neoadjuvant T therapy.

Methods: Retrospective analysis of our database of 95 HER2+ BrCa (stages I-III) who received T neoadjuvantly revealed 46% (44/95) achieved pCR compared with 53% (51/95) who did not respond (NR). DNA from pre-treatment tumour biopsy specimens from neoadjuvant T therapy patients was extracted, and array-based comparative genomic hybridization (aCGH, n/uni2009/uni20098; 6 pCR:2 NR) was used to identify CNAs, which correlated with pCR. Pathway analysis was then used to identify functionally relevant genes in aberrant regions.

Results: aCGH analysis of DNA from pCR and NR identified distinct patterns of CNAs. HER2 amplicon was confirmed by IHC and aCGH in all samples. Although there was no significant difference in the average CNAs between groups (20±17 vs 17±2), there was greater variation in the range of CNAs in pCR (8-56 CNA) compared to NR (15-19 CNA). More gains and amplifications were observed in pCR patients with more deletions in the NR group. The most common chromosomal amplification region included chr8q12.1-q24 with 87.5% of all cases displaying gains. Of the 6 patients who achieved pCR, 50% displayed a deletion in chr9 spanning p24.3-p21.3, consistent with a deletion of tumour suppressor CDKN2A. No aberrations in chr9 were observed in NR cohort. The deleted genomic region contained 65 common protein-coding genes, with the interferon biological pathway as the most significant (p=1.03E-36).

Conclusions: Distinct genomic CNAs were observed between patients achieving pCR compared to NR. However, of the 8 pts characterised here, none have relapsed. Follow-up data revealed a relapse rate of 6.8% (3/44) vs 11.8% (6/51) in the pCR and NR groups, respectively. To further elucidate the immunological response, we will present CNA data patterns on relapse and response and compare the impact of CNAs, immune-related proteins and pCR as surrogate predictors for outcome.
**Title:** Homologous recombination deficiency in PD-L1, PD-L2, Jak2 (PDJ) amplified triple negative breast carcinoma

Gawryletz CD D, Anderson KS S, Northfelt DW W, Kosiorek HE E, Linnaus ME E, Ocal IT T, McCullough AE E, Pockaj BA A and Barrett MT T. Mayo Clinic, Phoenix, AZ; Center for Personalized Diagnostics, Biodesign Institute at Arizona State University, Tempe, AZ; Mayo Clinic, Phoenix, AZ; Mayo Clinic, Phoenix, AZ; Mayo Clinic, Phoenix, AZ and Mayo Clinic, Scottsdale, AZ.

**Body: Introduction:** Homologous recombination (HR) is essential for repairing double-stranded DNA breaks. Tumors deficient in DNA HR display high levels of copy number aberrations including amplifications, deletions, and breakpoints. Studies in BRCA\textsubscript{mut} cancers have shown that HR deficiency (HRD) renders triple negative breast carcinoma (TNBC) sensitive to carboplatin or Poly(ADP-ribose) polymerase (PARP) inhibitors via a synthetic lethal interaction, as previously described. Clinical observations in breast and other solid tumors suggest that the HRD phenotype may arise independently of BRCA1/2 mutation. The implications of HRD enrichment in PD-L1, PD-L2, Jak2 (PDJ) 9p24.1 amplified TNBC are not known. Our goal was to determine the HRD status in PDJ enriched tumors, and the potential association of the PDJ amplicon with a BRCA like HRD phenotype.

**Methods:** Archival fresh frozen and formalin-fixed paraffin embedded (FFPE) tumor samples from 41 patients with TNBC were obtained from 1998-2015. Tumor populations (diploid, tetraploid, and aneuploidy) were sorted using DNA content flow cytometry and interrogated with oligonucleotide array comparative genomic hybridization (aCGH). Tumor homologous recombination deficiency (HRD) scores were calculated by number of interstitial aberrations (IA) in their genomes (HRD-IA). A cut-off of < 40 (low), ≥ 40 (high) or ≥ 50 (very high) was assigned based on our studies of known BRCA\textsubscript{mut} tumors. Data were compared between HRD groups using chi-square, ANOVA F-test or log-rank test.

**Results:** 14/41 (34%) TNBC patients had high HRD-IA score and 6/41 (14.6%) had very high HRD-IA score. The median age was 61.8 years (SD = 12.8), the average tumor size was 3.1cm (SD = 2.6), 42% were node positive, 24% were pre-menopausal, 19% were Black, Hispanic, or Asian/Pacific Islander. Genetic testing was negative for BRCA1/2 mutations in 9/41 patients, including 3 high and very high HRD-IA score patients. There was no difference in the OS at 5-years [74% versus 59% (p = 0.907)] in the high HRD-IA group. 12/41 (29%) patients were PDJ+. In the PDJ+ patients, 4/12 (33.3%) had HRD ≥ 40 and 1/12 (8.3%) had HRD ≥ 50 compared to the PDJ- patients where 10/29 (34%) had high HRD-IA score and 5/29 (17%) had a very high HRD-IA score, p=0.463. Patients with inflammatory TNBC were significantly more likely to have high HRD-IA score 4/6 (66%) compared to non-inflammatory TNBC 8/31 (26%), p=0.05.

**Conclusions:** We describe a unique group of TNBC patients with similar patient characteristics, tumor size, nodal status, and stage when compared by low, high and very high HRD-IA score. For inflammatory TNBC, there was statistically significant percentage of patients with a high HRD-IA score. We did not see a statistically significant correlation with 9p24.1 amplification based on HRD-IA score which has been suggested in other data sets. The HRD-IA score did not statistically impact OS but there was a suggestion that those with a higher score may have an improved OS potentially due to chemotherapy sensitivity. Further study with a greater number of patients to adequately power the study is needed to determine whether our initial findings can be confirmed and whether the HRD-IA score can be used to define a specific subset of TNBC patients.
Title: Comparing the frequency and types of genetic aberrations between older and younger women with metastatic breast cancer at the University of North Carolina at Chapel Hill

Body: Background: Targeted therapies have the potential to revolutionize cancer treatment in older adults as they are often oral, convenient, may be better tolerated than cytotoxic chemotherapy, and can be tailored to an individual's biomarker profile. We explore the frequency and distribution of potentially actionable genomic alterations among older (≥65) and younger (<65) patients (pts) with metastatic breast cancer (MBC).

Method: Next generation genetic sequencing (UNCseq™) of a dynamic panel of target genes was prospectively offered to pts with MBC treated at the University of North Carolina at Chapel Hill (UNC). DNA libraries were prepared separately from a retrieved archival FFPE tumor sample and a matched normal sample from each pt. Relevant targets were enriched by custom Agilent SureSelect hybrid capture baits using standard protocols. Samples were sequenced on Illumina HiSeq 2000/2500 platforms. Mutational findings were reviewed by a molecular tumor board. Variants identified to be potentially actionable underwent confirmatory testing in a CLIA approved laboratory. Confirmed findings were inserted into the pt's EMR accessible by both the pt and the treating oncologist. Two-sided Fisher's exact test was used to compare percentages between age-specific groups.

Results: As of 3/31/16, results were available for 140 pts. 19% were 65 years or older. Breast cancer clinical subtypes were: HR+/HER2- 49%, HER2+ (HR any) 17%, TN 34% and metastatic location was: bone only 5%, visceral only 44%, bone & visceral 51%; no significant differences were observed between older and younger age groups. Older pts were more likely to be Caucasian compared to younger patients (92% v 75%, p=0.06). Overall, older patients had a higher total number of mutations compared to younger patients (see Table) (p=0.04). Mutation types were similar between age groups, although a trend for more PIK3CA mutations among older patients was seen (37% v 20%, p=0.07).

Conclusion: Genomic alterations may allow therapeutic tailoring in both older and younger patients with breast cancer. In this
cohort with metastatic disease, older patients had significantly more mutations, but no clear difference in mutational types was seen by age. The relative small number of older pts in this cohort limits generalization, but supports the need for more extensive characterization of molecular aberrations among older pts with metastatic breast cancer in the new era of targeted therapy. Research support by the University Cancer Research Fund, NCI Breast Cancer SPORE grant (CA58223), John A. Hartford Foundation and Susan G. Komen Foundation.
Title: A comparison of oncotype DX recurrence scores in a screen detected vs a symptomatic cohort of patients with breast cancer: A UK experience

Khawaja S, Parab A, Thomas D, Huws A, Munir A, Udayasankar S, Sharaiha Y and Holt S. Prince Philip Hospital, Llanelli, United Kingdom.

Body: Background:
In the Western World, it has been stated that breast cancers detected on a screening program are indolent. There have been many recent publications stating that breast screening is overdiagnosing and therefore overtreating patients with breast cancer. With the advent of genomic testing, it can now be determined which patients have an aggressive tumor requiring systemic chemotherapy. We therefore conducted a retrospective study in the UK on patients having oncotype DX testing in both screen detected and symptomatic cancers.

Materials and Methods:
Patients in our institution undergoing oncotype DX testing for invasive breast cancer which was ER positive and node negative were part of this study. The detection of the breast cancer was documented as either a screening case or a symptomatic one. The recurrence scores of the oncotype DX testing was then compared in the screening versus the symptomatic cohort.

Results:
155 patients were included in this study. They underwent Oncotype DX testing between 2008 to 2016. The age of the patients ranged from between 31 years to 78 years. Eighty-nine patients were reported to have a low recurrence score; 45 had an intermediate score; and 21 had a high result. Fifty eight patients were screen detected, while 97 patients were symptomatic presentations. In the screening population, 32 patients had a low recurrence score; 22 had an intermediate result and 4 had a high recurrence score resulting in the latter groups being considered for chemotherapy. In the symptomatic cohort, 57 had a low recurrence score; 23 had an intermediate result; and 17 had a high score.

Conclusion:
The results of our study depict that even patients in a screening cohort will have a high number of intermediate recurrence scores and some with a high recurrence score. This shows that the hypothesis that screening detects a majority of breast cancers which are indolent not requiring further systemic treatment should be looked at again in light of our results with genomic testing.
Title: The value of RNA-Seq for the detection of clinically actionable targets in breast cancer - A small cohort analysis

Meissner T, Amallraja A, Mark A, Andrews A, Connolly C, Young B, De P, Williams C and Leyland-Jones B. Avera Cancer Institute, La Jolla, CA and Avera Cancer Institute, Sioux Falls, SD.

Body:

Introduction

Next generation sequencing has facilitated the understanding of pathogenesis and molecular heterogeneity of breast cancer (BC) as well as accelerated the path towards precision medicine. DNA sequencing (DNA-Seq) based assays for the detection of mutations and alterations in solid and hematologic cancers are finding their way into clinical practice and are readily available as clinical products. RNA sequencing (RNA-Seq), so far being vastly applied in the research context, promises to expand the diagnostic, prognostic and therapeutic use of this technology in cancer. Beyond mutational status, RNA-Seq enables the detection of fusions, quantification of gene expression level, detection of differentially expressed genes, molecular based subtyping, and risk-stratification. In this study we analyzed RNA-Seq and copy number data from BC patients that had undergone DNA-Seq based diagnostics through commercial providers with the goal to detect additional actionable targets.

Materials and Methods

We included 18 BC patients (5/18 triple negative) that had previously undergone DNA-based targeted (321 genes) sequencing. RNA-Seq to a minimum of 75M reads (75pb) was performed using 100 ng of total RNA on the Illumina NextSeq 500 platform. STAR was used for alignment (hg19) and gene expression quantification (RefSeq). Fusions were detected using STAR-Fusion. DESeq2 was utilized to identify patient specific differentially expressed genes by analyzing samples individually against a set of 13 controls from healthy breast tissue generated in-house. Copy number variations (CNVs) were detected using the Nanostring CNV Cancer panel (89 genes) on the Nanostring nCounter platform. Differentially upregulated or amplified genes were queried against DGIdb and Gene Drug Knowledge database for suitable drug matches, limiting the queries to clinically actionable antineoplastic drugs.

Results

Analyzing the cohort of 18 BC patients, we detected on average 26 BC relevant genes (526 total, log2 FC > 2) to be upregulated per patient. Querying the upregulated genes against DGIdb, we found a total of 18 genes that had drug matches and fulfilled the criteria of being actionable antineoplastic drugs, with 17/18 samples having a minimum of two gene targets (avg: 4). Most frequent upregulated genes were TOP2A (83%), AURKA (61%), AURKB (56%), RET (39%) and FGFR3 (28%). In the case of CNVs, 12/18 patients showed at least one gene target with clinically actionable drugs associated. This was observed across 12 gene targets that were amplified (avg: 3) and 4 gene targets that underwent deletions (avg: 1). Most frequent CNVs included MYC (14%) and CCND1 (12%). 4/7 patients having an AURKA overexpression also showed an AURKA amplification on the CNV assay. 10/18 patients had fusions events, with an average of three fusions per patient, including GAB2-WNT11, PAK1-TENM4 and FGFR2-CEP55 fusions.

Conclusions

We show that RNA-Seq and copy number assays provide additional clinical value by detecting suitable drug targets beyond traditional DNA-based approaches. We are conducting further analysis on how these additionally derived drug targets could improve the current treatment schedule of those patients.
Title: Utilities and challenges of RNA-Seq based expression and variant calling in a clinical setting

Young B, Mark A, Meissner T, Amallraja A, Andrews A, Connolly C, Williams C and Leyland-Jones B. Avera Cancer Institute, La Jolla, CA and Avera Cancer Institute, Sioux Falls, SD.

Body: Introduction
Variant calling based on DNA samples has been the gold standard of clinical testing since the advent of Sanger sequencing. The use of DNA variants has proved a great value to guide treatment in cancer patients. However, DNA based analysis will not inform about expression status of the gene harboring a particular variant. RNA has long been used to monitor expression. To this point RNA assays and analysis are confined to the research laboratory and rarely used clinically except in specifically defined gene signatures such as PAM50 and OncoType Dx. Beyond expression, RNA has the ability to confirm expression of DNA variants and identify fusion events. We hypothesize that the combination of DNA and RNA based data will allow the determination of variant specific expression status and improve clinical diagnostics. It has been previously shown that RNA sequencing (RNA-Seq) based variant calls are highly accurate and confirm DNA based variant calls. In this study we investigated the utility of RNA-Seq as a diagnostic assay integrated with DNA based sequencing data.

Materials and Methods
Targeted DNA sequencing of 321 genes was performed on 37 patient samples (FFPE), including 22 breast cancer samples by a commercial vendor. RNA-Seq on the same patient samples was performed using 100ng of total RNA. Libraries were run on the Illumina NextSeq 500 with a minimum of 75M paired 75bp reads. To evaluate RNA-seq expression reproducibility, replicates of 6 normal ovarian tissue samples (min. 50M reads) were run in sets of triplicates. STAR was used for alignment (hg19) and gene expression quantification (RefSeq). RNA-Seq based variant calling was performed using the SNPiR pipeline. Based on the results of the commercial assay, DNA based variants were examined for expression of the corresponding genes and ability to confirm variants in the RNA-Seq data.

Results
RNA expression data showed no corresponding gene expression for at least one single nucleotide variant (SNV) in 9/37 patients analyzed (24.3%). In 18/37 patients (48.6%) SNV corresponding expression was in the lowest quartile of expression values. Variant calls could be confirmed by RNA-Seq for 95/455 SNVs, with adequate coverage in 263 of the remaining 360 variant locations (median coverage: 34). Of these, a homozygous reference call was made in 166/263 SNVs. Concordance for RNA-Seq gene level expression data between replicates was > 0.995.

Conclusions
These findings suggest that RNA-Seq based data can provide clinical value when using gene expression values in combination with DNA based variant calls. We found gene level expression to be highly reproducible and will further investigate the use of spike in controls to determine clinically usable expression ranges and lower limit of expression values. To our knowledge, it has not been shown that RNA-Seq based variant calls are reproducible which is the focus of our current research as this will be one requirement for usage in a regulated environment. While our use of RNA Seq is currently limited to gene expression level data, we have demonstrated a clinically relevant benefit to using RNA Seq data as an additive feature to the current standard of DNA variant calling.
Desforges P, Saleh R and Nathaniel B. McGill University Health Canter, Montreal, QC, Canada.

Body: Background: Breast cancer is the most common malignancy among women. With the introduction of improved imaging techniques and the general population's awareness of breast cancer, increasing numbers of patients are more frequently diagnosed at a very early stage. The Oncotype DX Recurrence Score (ODX) is commonly used to estimate recurrence risk and chemotherapy benefit in ER positive, node negative breast cancer. Earlier studies showed that women with Oncotype DX Recurrence score results of 11 or less had excellent outcomes which proved that thousand of patients worldwide can forgo chemotherapy and its harmful side effects based on a low Recurrence score. Now another test called the Mammaprint has been approved by the United States (US) Food and Drug Administration to assess the risk of cancer relapse. The primary study objective was to evaluate the concordance of patient results with Oncotype Dx (ODX) when compared to the 70-gene signature Mammaprint (MP), the 80-gene signature of BluePrint (BP) and TargetPrint (TP)

Methods: This retrospective clinical study was carried out in the Oncology Department at the Royal Victoria Hospital (RVH), part of the MUHC. Eighty-six consecutive patient-slides node negative hormone positive breast cancer tissue tested with the Oncotype DX between October 2008 and September 2014 were included. Further inclusion criteria were age > 18. These same slides were then analyzed and classified with MammaPrint as low or high risk by Agendia Laboratories. BluePrint (BP) and TargetPrint (TP) analysis were also performed by Agendia Laboratories.

Results:
Of the 16 ODX RS between 0 and 11, 13 were low risk by MP (81 % agreement) and 16 were low risk by BP (100% agreement). Of the 50 ODX low RS cases, 33 were low risk by MP (66 % agreement) and of the 9 ODX high RS, 7 were high risk by MP (78 % agreement). Of ODX intermediate risk cases (27), 14 of were MP low risk (52 %), (48 %) 13 were MP high risk. Of BP low risk luminal tumors, 33/49 (67%) were ODX low, 14/49 (29%) ODX intermediate, and 2/49 (4%) ODX high risk. BP class was correlated with ER, PR and HER2 results. Overall agreement between clinical ER, PR, HER2 (IHC+FISH) results with TP results were 98% (81/83), 83% (69/83), 99% (82/83), and percent positive agreement for HER2 was 0/1 (of unequivocally HER2 positive cases identified correctly by TP).

Conclusion:
Our results show that there is a high concordance between ODX RS of 11 or less and low risk Mammaprint and Blueprint scores. When the ODX RS is above 11, our study shows that there are real differences in risk stratification between MP and ODX. At this point, there is no consensus seen when Oncotype DX is above 11.
Title: Patterns of translational dysregulation in models of estrogen receptor(+) and (-) breast cancer

Vaklavas C, Myers RM M, Grizzle WE E and Blume SW W. University of Alabama at Birmingham, Birmingham, AL and HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Body: Although our understanding of transcriptional dysregulation in cancer has expanded dramatically over the recent years, comparatively little is known about dysregulation in gene expression at the translational level. Yet, gene expression is extensively modulated at the level of translation. Leveraging the unbiased nature of next generation sequencing, we utilized the ribosome profiling strategy to characterize the translational profiles of a representative ER(+) (T47D) and ER(-) (SUM159) breast cancer cell line and compared them with the profiles of non-malignant human mammary epithelial cells (HMECs). The overarching hypothesis is that cancer cells differ from their non-malignant counterparts not only at the level of transcription but also at the level of translation and coordinate changes in transcription and translation lead to the phenotypic hallmarks of cancer.

The results show that the median translational efficiency was higher and more variable in malignant cells as compared to HMECs (HMECs 1.09; T47D 1.6; SUM159 1.29. Variance of the log2 transformed values, 2.37; 3.92; 4.16, respectively). When cells were deprived of serum for 24 hours, translation was uniformly upregulated but this upregulation was more pronounced in malignant cells. A larger number of genes were differentially expressed at the translational as compared to the transcriptional level between non-malignant and malignant cells. There was an imperfect correlation between RNA levels and translational efficiency. In addition, individual transcripts were translated with variable efficiency between malignant and non-malignant cells suggesting that the translation of the same RNA sequence is modulated in a context-dependent manner.

Although translation is globally upregulated in malignant cells, this upregulation is not uniform and the translational efficiency of multiple cancer-related mRNAs is not proportional to their abundance. For example, while the abundance of the CDK1 mRNA was not significantly different among the 3 cell lines, its translational efficiency was 1.5 and 2 times higher in the SUM159 and T47D cells, respectively. On the other hand, the mRNA of its cognate inhibitor CDKN1A was not only 4 times less abundant in the malignant cells but also half as efficiently translated as compared to HMECs.

Ribosome profiling has consistently revealed translation outside of canonical protein-coding regions. While in HMECs only 5.3% of unique ribosome protected fragments aligned to non-protein encoding transcripts, the respective fractions were 8% for T47D and 19.2% for SUM159 cells and were consistently higher in malignant cells across all conditions tested. We found that the translation of RNAs previously thought to be noncoding, especially lincRNAs, was pervasively upregulated and to similar levels in T47D and SUM159 cells as compared to HMECs.

Collectively, these results begin to unravel components of dysregulation in gene expression at the level of translation with important implications for the molecular pathophysiology of breast cancer and set the stage to advance such studies in primary human tumor samples.
Title: Genomic analysis of molecular discordance of paired primary and recurrent triple negative breast cancer

Body: Background: Triple negative breast cancer (TNBC) is a heterogeneous disease with several molecular subtypes: basal-like1 (BL1), basal-like 2 (BL-2), mesenchymal(M), mesenchymal-stem-like(MSL), immune-modulatory(IM) and unclassified (UNC) Molecular evolution of TNBC through chemotherapy selection pressure is well recognized but poorly understood. This study was carried out to perform paired genomic analysis of TNBC comparing primary breast cancer with recurrent/refractory disease. Here we report the result of the first10 paired tissue analysis.

Methods: 49 paired specimens were identified through an IRB-approved protocol via COH biorepository search (2002- 2015). miRNA and mRNA profiling of 22 samples were performed. The miRNA libraries were prepared and sequenced on Hiseq2500. Sequences were aligned to hg19 genome and miRNA expression levels were counted by in house built R scripts. Go and pathway annotation was performed using DAVID online tool. Affymetrix human Genechip 2.0st was used for mRNA expression profiling. Raw data were normalized and processed using Expression Console, and linear regression was performed using Limma to identify the differentially expressed genes between primary and recurrent/refractory TNBCs.

Result: Through mRNA profiling, we identified several unique gene expression patterns comparing the paired TNBC. Significant mRNA expression alterations were observed in: cell cycle, DNA repair and adhesion. Using Vanderbilt TNBC sub-classification tool, we have identified “phenotype shift” between primary and recurrent TNBCs. Of the 8 paired specimen analyzed, 3 paired tissue remain in the same subclass (2 in IM, 1 in M). Phenotype shift observed in: 1 from BL1 to BL2, 1 from BL2 to BL1, 1 UNC to IM; 1 MSL to UNC; 1 from M to UNC. 15 up regulated and 13 down regulated miRNAs were identified. Most significantly differentially expressed miRNA (with more than 4 fold expression changes, P-value < 0.001) included: miR-206, miR-203, miR-144, miR-16-2, miR-15b, and miR-20b (un-regulated) and miR-10b, miR-125b and let-7c(down-regulated). These miRNA genes are involved in regulation of hormonal receptor signaling, cell cycle, proliferation and metastases. Statistically significant differentially expressed miRNAs identified from our TNBC patient cohort will be further validated using RT-PCR.

Conclusion: A number of mRNA gene pathways and miRNAs showed differential expression between paired recurrent and primary TNBC tumor specimen. The underlying biology driven the phenotype shift is being studied. Further analysis to include a total of 49 paired TNBCs is currently underway.

Title: Evaluation of the Oncomine focus and comprehensive assays for therapeutic stratification in early hormone receptor positive breast cancers

Bayani J, Crozier C, Zhang NX, Amemiya Y, Quintayo MA, Yan FJ J, Dion D, Mccormack S, Yaffe M, Seth A, Feilotter H and Bartlett JMS MS. Ontario Institute for Cancer Research, Toronto, ON, Canada; Sunnybrook Health Sciences Centre, Toronto, ON, Canada; Queen's University, Kingston, ON, Canada and University of Toronto, Toronto, ON, Canada.

Body: Large-scale sequencing initiatives have revealed a wealth of common and novel variants as well as copy-number aberrations, across different solid tumours and hematological malignancies. The growing list of variants/aberrations can sometimes be matched to specific therapeutics. Such “actionable mutations/changes” hold promise for personalized treatment, as treatments could be tailored to molecular abnormalities, rather than disease site. In breast cancer, women with hormone positive early breast cancer continue to experience improved survival on adjuvant anti-hormone therapy, but even today, a significant number of women continue to progress. Therefore there is not only a need to identify those women for whom current therapies are insufficient, but to identify alternative therapeutic interventions. The ThermoFisher Scientific Oncomine™ Focus and Oncomine™ Comprehensive Assays (OFA and OCA) are based on the Ion Torrent™ next-generation sequencing platform and Ion AmpliSeq™ library preparation technology, coupled to the Oncomine™ Knowledgebase, for target selection, variant calling, and data annotations. Both panels interrogate the most referenced oncology biomarker variants that are matched to curated published evidence from clinical trials supporting the matching of driver genetic variants with relevant potential clinical therapeutic options. The ability to identify SNVs, CNVs and fusion events in a single assay provides an unprecedented approach to maximizing the molecular information to be derived from a single tumour sample. To explore the value of the Oncomine™ assays in early invasive breast cancers, we have performed a pilot study to assess the reproducibility and accuracy of the OFA and OCA from nucleic acids extracted from formalin-fixed paraffin embedded tissues. In addition to the sequencing and copy-number data generated by these assays, we will compare these results to copy-number information generated using the Oncoscan® (Affymetrix)copy-number assay as well as information derived by Multiplex Ligation-dependent Probe Amplification-based panels (MRC-Holland) and Fluorescent in situ Hybridization (FISH). Our preliminary analyses of 35 invasive breast cancers by Oncoscan® identified the frequent whole chromosomal gains of 2, 3, 5, 7, 18, 19 and 20; gains of 1q, 7p, 8q, 11p, 16p, 17q; losses at 1p, 8p, 11q, 13, 16q, 17p and chromosome 18. High level amplifications were also identified for breast cancer related genes such as ERBB2, CCND1, MYC, FGFR1; in addition to the frequent losses of TP53, RB1, CDKN2A. Copy-number changes were confirmed by locus-specific FISH and MLPA. Data generated from the OFA and OCA from these same samples will be compared to the other platform findings and provide a snapshot of the mutational landscape of early breast cancers across these pan-cancer panels. Having established the robustness and accuracy of the assays, the applicability of the OCA in the context of improved stratification for breast cancers for prognostic and predictive tests will be discussed.
**Title:** Melatonin treatment: A transcriptomic networks in a xenograft model of breast cancer

Jardim-Perassi BV V, Sonehara NM M, de Paula-Junior R, Chammas R, Coutinho LL L, Reis Júnior O, Alexandre PP P, Fukumasu H and Zuccari DAPC APC. Faculdade de Medicina de São José do Rio Preto, Laboratório de Investigação Molecular do Câncer, São José do Rio Preto, Sao Paulo, Brazil; Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil; Universidade de São Paulo, Escola Superior de Agricultura Luiz de Queiroz, Piracicaba, Sao Paulo, Brazil; Universidade Estadual de Campinas, Instituto de Biologia, Campinas, Sao Paulo, Brazil and Universidade de São Paulo, Faculdade de Zootecnia e Engenharia de Alimentos, Pirassununga, Sao Paulo, Brazil.

**Body:** Melatonin is a hormone produced by the pineal gland and has been shown different antitumor effects, as immunomodulatory, antioxidant, pro-apoptotic, anti-proliferative, anti-metastatic and antiangiogenic, however, the pathways by which melatonin exerts its action need to be identified. Thus, the aims of this study were to perform the transcriptome analysis to evaluate the pathways of melatonin action in triple-negative breast cancer. Triple-negative breast cancer cells (MDA-MB-231) were injected into the mammary gland of the athymic nude mice (n=10), which were treated with melatonin (40 mg/kg) or vehicle during 21 days. RNA-Seq libraries were created using Truseq RNA-Seq Library Prep Kit v2. The experiment was paired-end with 100nt read length, performed on the Illumina HiSeq2500 sequencer, producing about 30 million reads per library. To differentiate human and mouse expression, the alignment was performed to filter out mouse-like reads before mapping to the human reference and versa, and data were mapped against human (GRCh37/hg19) and mouse (NCBI37/mm9) genomes separately, using the TopHat software. The HTSeq was employed for analyses of read counts and DESeq2 was used to identify genes differentially expressed between melatonin treated and control tumors. Differentially expressed genes (DEGs) were identified based on a false discovery rate (FDR) q-value threshold of less than 0.05. Also, we applied Weighted Gene Co-expression Network Analysis (WGCNA) to detect clusters of highly co-expressed genes (modules). Results showed that animals treated with melatonin had smaller tumors volume than controls (p<0.05). RNA-Seq data showed that 57.24% of reads mapped uniquely to human, 29.66% reads in mouse and 11% reads mapping to both human and mouse genomes. In human tumor cells, there was no DEGs between melatonin treated and control group (adjP>0.05). In mouse cells, which represent the tumor microenvironment, there were 34 DEGs between animals treated with melatonin and controls (adjP<0.05). In tumors cells, we detected 714 differentially co-expressed genes (IK_{diff}>0.6), which were functionally enriched for GO terms like lipid metabolic process, response to drug, oxidoreductase activity and PPAR signaling (adjP<0.1). Also, we identified 3 gene modules strongly associated with melatonin treatment, which were related with metabolic pathways (adjP<0.1). In mouse cells, were detected 1345 differently co-expressed genes, which were enriched for signaling pathways like Wnt receptor, Hedgehog and TGF-beta (adjP<0.1). There were 3 gene modules strongly associated with melatonin treatment, which are enriched for regulation of translation and cell cycle, immune system process and T cell differentiation, regulation of action cytoskeleton and ErbB signaling pathway (adjP<0.1). Also, potential regulator genes for melatonin treatment were detected by generating clusters of co-expressed genes and individual analysis confirms these results. Transcriptomic network analysis coupled with other results showed that melatonin treatment controls the tumor growth, acting especially by metabolic pathways in tumor cells and modulating the tumor microenvironment.
Breast cancer in men is a rare disease. Less than 1 percent of all invasive breast cancers occur in men and the lifetime risk of men being diagnosed with breast cancer is 1 in 1000; very low compared to in 1 in 8 for women. Due to the absence of an elaborate lobular system in the male breasts, most male breast cancers tend to be ductal and invasive. Paget's disease, inflammatory breast cancer and ductal carcinoma in situ are the other relatively rare breast cancer types in males. While there are similarities between breast cancers in both genders, there are also significant differences between the two cancers in terms of demographics, progression etc.

In order to assess the genes and pathways affected in male breast cancer, we performed whole exome sequencing of tumors from 5 patients (all aged above 60 years) with male breast cancer (MBC). All tumors were ER, PR positive and Her 2 Negative by IHC. For the five patient tumors, we identified an average of 47,366 variants, 63% of which were within coding regions, spanning 14,314 genes. All tumors carried a total of 14,769 variants in common, of which ZNF717, CDC27 and mucin family genes were among the most polymorphic genes. A total of 33 premature stop variants were found common across all tumors. These included variants in genes such as ANAPC1 and CDC27 that are associated with APC/C, an important component for the ubiquitination and degradation of G1 and mitotic checkpoint regulators. CDC27, a core component of the anaphase-promoting complex (APC), is a cell cycle regulator, which participates in control of mitotic checkpoint and maintenance of chromosomal integrity. Aberrations in CDC27 are associated with disruption in the normal functioning of cell cycle. Members of the mucin family have been reported to promote tumorigenesis by multiple mechanisms including activation of ERBB2 gene, which makes these variants in the mucin family genes potential driver events. Identifying the transcriptional regulation targets of ZNF717 may explain the high frequency of variants in this gene in all MBC tumors.

Comparison of the common variants across all MBC patients with TCGA female breast cancers revealed 500 variants that were called as somatic mutations in TCGA female cohort. Of 200 genes that contained these 500 variants, we found enrichment of genes involved in cadherin signaling and WNT pathways, both of which are known to be involved in tumor progression. The finding of common gene mutations and pathways associated between male and female breast cancer suggest a common underlying mechanism driving both, male and female breast cancer.
Title: Genomic and microenvironmental intra-tumor heterogeneity in DCIS

Body: Intra-tumor heterogeneity drives neoplastic progression by supplying the fuel for natural selection among neoplastic cells. It also complicates screening and treatment of neoplasms. We hypothesize that the degree of intra-tumor heterogeneity in DCIS should predict which tumors are likely to become invasive and metastatic. We initiated a pilot project to test this hypothesis by comparing 9 cases of pure DCIS to 9 cases of DCIS with adjacent invasive disease. For each case, we sequenced the exome from two spatially distinct regions of DCIS as well as normal tissue taken from a lymph node with no tumor involvement. This required the development of new methods to extract high quality sequencing data from small amounts of DNA extracted from FFPE samples. We calculated the genetic divergence between the two tumor regions, defined as percent of the sequenced regions of the genome showing differences between the two samples that had sufficient sequencing coverage and quality scores for confident scoring. We also employed automated imaging analysis to score microenvironmental differences between the two tumor regions. These microenvironmental measures are based on ecological methods for measuring organismal interactions and habitats. We will present initial data on differences in phenotypic and genotypic intra-tumor heterogeneity comparing pure DCIS to DCIS associated with invasive breast cancer. Our methods can be readily translated to large tissue banks of FFPE samples from DCIS.
Title: Studying the interactome of breast cancer: The cancer cell map initiative

Body: Recent progress in genome sequencing has revealed numerous mutations in cancer genomes. But how many of these alterations result in changes in normal cellular processes is poorly understood. In addition, the biological functions of the majority of genes (e.g. BRCA1/2) with cancer-associated mutations have not been fully characterized, despite their expression and/or activity being highly correlated with cancer. Through years of study, it is becoming clear that cancer is a disease that arises not only because of defects in individual genes and proteins, but also because of the action of hallmark cellular processes and biological pathways. Therefore, what is urgently needed is to put the cancer genomic information into biological context by mapping mutated genes onto the complexes and pathways in which they function. The goal of this study is to uncover the comprehensive protein-protein interaction networks and pathways in various breast cancer subtypes to better understand how mutated cancer genes and genomes hijack and re-wire pathways and complexes during the course of breast tumorigenesis.

Here we catalog protein-protein interactions for more than 40 genes recurrently mutated in breast cancer, using affinity purification and mass spectrometry (AP-MS). To identify co-associated proteins, cDNA clones expressing each protein were tagged with 3xFLAG at either N or C-terminus and introduced into MCF10A (non-tumorigenic “healthy” control), MDA-MB-468 (basal-like), MDA-MB-231 (claudin-low) and MCF7 (luminal A subtype) cells using doxycycline-inducible lentiviral vectors. For proteins with prevalent mutations (e.g. PIK3CA-H1047R, AKT1-E17K), mutant cDNA clones were also analyzed in parallel. Our interaction network reveals subtype and mutation-specific protein-protein interactions, most of which are not previously reported. We anticipate the breast cancer interactome study will uncover many previously unidentified aberrant pathways and protein complexes uniquely operating in breast cancer cells, and thus pinpoint proteins central in these pathways and complexes that may potentially serve as distinct biomarkers or therapeutic targets for tumors having the same or similar subtypes and/or genomic mutations.
Evaluation of subclonality in the CTC and DTC compartment of patients with metastatic breast cancer using low pass whole genome and AmpliSeq panel sequencing

Brouwer A, van Dam P-J, Rutten A, Prové A, Peeters M, Van Laere S and Dirix L. Center for Oncological Research (CORE), University of Antwerp, Antwerp, Belgium; Oncological Center, GZA Hospitals Sint Augustinus, Antwerp, Belgium and Oncological Center, Antwerp University Hospital, Edegem, Antwerp, Belgium.

Body: Background
A growing understanding of the molecular biology of cancer and the identification of specific aberrations driving cancer evolution have led to the development of various targeted agents. Tumors can exhibit significant heterogeneity and this may change over time, also as the result of selective pressure. Circulating tumor cells (CTCs), shed from multiple tumor sites, have demonstrated to represent of the overall tumor burden. We report the results of an ongoing comparative study on mutation and copy number profiles of primary and metastatic tissue, CTCs, and synchronously isolated DTCs from metastatic effusions of patients with clinically progressive MBC.

Materials & Methods
CTCs and DTCs were enriched from 7.5 ml blood or effusion using the CellSearch system and were further purified and sorted with the DEPArray system. For this study we isolated both 70 single and 70 pools of 10-200 CTCs or DTCs, in order have enough power to detect 5% subclones and analyse heterogeneity. Single and pooled WBCs were isolated as technical controls. DNA was isolated and amplified using the Ampli1-kit and subjected to Illumina WGS and Ion Torrent AmpliSeq panel sequencing. Fresh frozen tissue from solid metastases and the primary tumor, and bulk CTC (CellSearch Profile) were sequenced as comparators for mutation and copy number profiles. DNA of buffy coat was sequenced to enable germline variant detection. For mutational analysis, only somatic variants with good quality metrics, >20x coverage, variant allele frequencies >10%, and being non-synonymous or splice site variants, were taken into account.

Results
AmpliSeq panel sequencing was performed on 153 unique samples of three patients with a mean coverage depth of 1000x. In patient 1, a PIK3CA hotspot mutation was found clonally in all tumor samples at heterozygous level. Furthermore, various private mutations were found in both CTCs and DTCs, however not in WBC, including several TP53 hotspot mutations. In patient 2, another PIK3CA hotspot was present in all CTCs at heterozygous frequencies. In patient 3, an enormous heterogeneity was observed between all CTC and DTC samples. For patient 3, disease evolution was detected during multiple events of progressive disease over 2 years. At the moment, low pass WGS for CN detection for all samples is being performed and results will be present prior to the SABCS.

Conclusion
Based on the mutational status we conclude that both clonal mutations as well as various private variants are present in single and pools of CTCs and DTCs. In addition to the detection of targetable aberrations, the evaluation of heterogeneity is of clinical importance, as the effect of targeting subclones is currently being explored in clinical trials.
Impact of heterogeneity of DCIS on immune cell infiltrations

Badve S, Gökmen-Polar Y, Harris AL, L Sui Y, Sevinsky C, Santamaria-Pang A, Ginty F, Tan PH and Gerdes MJ. Indiana University School of Medicine, Indianapolis, IN; University of Oxford, Oxford, United Kingdom; GE Global Research, Diagnostic Imaging and Biomedical Technologies, Niskayuna, NY and Singapore General Hospital, Singapore, Singapore.

**Body:** Background: Ductal carcinoma in situ (DCIS) accounts for at least 20% of breast cancers. Factors associated with recurrence of DCIS or progression to invasive carcinoma are not well delineated. The goals of the current study were to profile the epithelial and immune cells using the MultiOmyx hyperplexed immuno-fluorescent based analyses. This was coupled with semi-automated algorithms to characterize the inter-relationships between cell populations within individual DCIS lesions.

**Patients and Methods:** Analysis for 15 antibody markers (EGFR, Her2, Her4, S6, pMTOR, PCAD, CD44v6, NaKATPase, SLC7A5, CD4, CD8, CD20, CD68, and CD10) was performed on a single FFPE section containing 10-20 distinct ducts from 13 cases of DCIS. Briefly, approximately 40 fields of view (FOV) from digitized sections containing DCIS or normal tissue were sequentially (cyclically) stained for the 15 markers. Each cycle entailed staining with 2-3 markers followed by imaging, dye inactivation, and re-staining. DAPI was used for nuclear demarcation and for registration of the images, while S6, pan-cadherin, Na+K+ATPase and pan-cytokeratin were used for epithelial segmentation. K-means clustering was used to determine patterns of co-expression of markers at the single cell, duct, and patient levels. These clusters were then correlated with immune marker expression by tumor infiltrating lymphocytes (TILs) by marker type (CD4, CD8, and CD20) and tumor compartment (stromal versus intraepithelial).

**Results:** Analysis of the epithelial component in each of 13 cases of DCIS (n= 415 ducts) revealed 8 distinct expression patterns (clusters) using a panel of 7 markers (EGFR, Her2, Her4, pmTOR, PCAD, CD44v6, SLC7A5, and CD10). The frequency and distribution of clusters, annotated at the single cell level, showed that 4 DCIS’s were dominated (>80%) by a single cell phenotype represented by cluster groups 3 and 7 (high Her2), cluster 6 (High Her4 and SLC7A5 and low Her2), or cluster 4 (non-descript). In 5 pts, the pattern was more heterogeneous consisting of mixture of cell populations with 50-70% of the cells belonging to cluster 1 (moderate to high levels for all markers except EGFR and CD10). The remaining pts had a strong representation of cluster 4 and 5 (CD44v6 and phospho-mTOR) cells. The distribution of both intra-epithelial and stromal TILs in DCIS cases were either consisted of a mixed B-cell (CD20+) and T-cell response (n=4), or one dominated by T-cells. Cluster 2 (High EGFR and CD10) was associated with a largely T-cell response ($r_s = 0.83$, $P$ value = 0.0004), while Cluster 7 (strong HER2) was associated with a B-cell response ($r_s = 0.68$, $P$ value = 0.009).

**Conclusions:** Analysis 15 markers and use of K-means clustering algorithm, shows prominent inter-tumoral (but not intra-tumoral) heterogeneity in DCIS. Furthermore, epithelial cell specific clusters (high HER2 or EGFR) were associated with distinct B or T cell infiltration by TILs. Additional ongoing studies will determine the clinical significance of the clusters with respect to recurrence of DCIS and development of invasive carcinomas.
Title: Serial evolution of hormone receptor status and mutational profile among patients with metastatic breast cancer

Body: Introduction: Tumor heterogeneity presents a significant impediment to identifying appropriate treatments for patients. Genetic mutations and hormone receptors are frequently used as a guide for selecting appropriate targeted or hormonal therapies, however it is possible that these markers may change over time, leading to reduced effectiveness of these treatments. In this study, we review the results of serial and paired biopsies to identify receptor switch in estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2) status as well as to identify changes in clinically relevant mutations, including spatial and temporal heterogeneity.

Methods: We identified a total of 237 patients initially presenting with ER+/HER2 negative breast cancer and who had multiple biopsies during the course of their treatment, including at least one in the metastatic setting. ER, PR, and HER2 status for each of these serial biopsies was gathered from chart reviews. HER2 results by both IHC and FISH were collected. PIK3CA mutations were also assessed by Snapshot utilizing multiplexed PCR of common hotspot mutations using DNA derived from formalin-fixed, paraffin-embedded (FFPE) tissue.

Results: From a total of 213 patients with known ER status for multiple serial biopsies, we identified 9.4% (N=20) who had at least one change in ER status over time. From a total of 198 patients who had documented PR status for multiple biopsies, 40.4% (N=80) had at least one change in PR status. Changes in HER2 status were similarly assessed, with 6.7% of patients having at least one change by IHC and 4.4% of patients having at least one change by FISH. Of those patients exhibiting changes in ER status, 6 were noted to have multiple changes over time. Of those with changes in PR status, 18 had multiple changes over time. Changes in hormone receptor status were also noted to occur between serial biopsies in the metastatic setting. A total of 128 patients had ER results available for multiple metastatic specimens, of which 8.6% (N=11) had at least one change in ER status. A total of 116 patients had PR results available for multiple metastatic biopsies, of which 38.8% (N=45) had at least one change in PR status. Changes were also noted in the metastatic setting in HER2 (IHC) with a frequency of 8.7% and in HER2 (FISH) with a frequency of 4.7%. A subset of 108 patients were identified as harboring a mutation in PIK3CA. Within this population, 9.6% of patients had at least one change in ER status over time and 34.1% had at least one change in PR status. 9.0% exhibited at least one change in HER2 (IHC) and 6.5% in HER2 (FISH). Serial changes in genotype, from pre- and post-treatment biopsies, were also detected using NGS based Foundation Medicine platform, including acquired alterations in the ESR1 and PI3K pathway.

Conclusion: Serial changes in hormone receptor status and mutation profile are not uncommon among patients initially diagnosed with ER+/HER2 negative breast cancer, and some patients have been noted to have multiple changes over time. Further studies are needed to understand the mechanistic underpinnings governing the emergence of these alterations and their relationship to therapeutic resistance in breast cancer.
Title: Molecular characterisation, subtype concordance and prognostic group assignment between patient-matched primary breast tumours and axillary lymph node metastases

Body: Introduction
Currently the primary breast tumour is used for prognostic profiling and as a monitor of response to therapy but how often does the molecular profile of the primary cancer reflect the molecular profile of nodal metastases? No previous study has investigated in detail the genomic profile of matched primary breast cancer (P) and nodal metastases (N) and correlated these with outcome. The aim of this study was to investigate whether the mRNA profiles of matched P and N differ significantly.

Methods
RNA was extracted from core biopsies from primary breast tumours and paired metastatic axillary lymph node samples from both FFPE blocks and fresh frozen samples. RNA was labelled and hybridised to Illumina HT-12 BeadChips to create a dataset consisting of one primary and one or two matched nodal metastasis, totalling 68 samples from 31 patients. Data was processed and corrected for batch effects, then analysed using the statistical programming language R. Clinical data on progression free and overall survival was collected from electronic and medical case note review.

Results
Unsupervised hierarchical clustering of the 500 most variable genes in each sample grouped only 12 of 31 P&Ns (39%) together, meaning in the majority of patients their P or N more resembled a cancer from another patient than its own paired P or N.

The number of genes with greater than 2 fold change (>2FC) between P&N was used to categorise paired samples into 'least changed' (<130 genes with >2 FC) and 'most changed' (>370 genes with >2FC) groups. Multidimensional scaling of the 500 most variable genes in the most changed group (n-=10) showed consistently that nodal metastases differed molecularly from the primary cancer.
When categorised by Sorlie centroid, 12 of 31 patients (39%) had a different molecular subtype in N compared with P. N tended to be a poorer prognostic subtype than P. 50% had luminal A primaries paired with luminal B nodes. The remaining 50% changed in other non-consistent patterns.

6 patients had 2 N samples to analyse alongside P. 4 of these (67%) had the same subtype in all 3 samples, and a further 1 the same 2Ns (luminal B) which differed from P (luminal A). The final had luminal A P paired with 1 luminal A and 1 luminal B Ns.
There was no evident correlation between the least changed and most changed groups and progression free and overall survival. This may however reflect the short term follow up.

Discordance between P and N in expression of ESR1 was 32%; PGR 19% and ERBB2 16%.

Conclusions
This study of gene expression change in matched primary breast cancers and synchronous metastatic paired axillary lymph nodes shows that molecular subtype differs in 39%. 50% of nodes had a poorer prognostic subtype than their primary. Expression of ESR, PGR and ERBB2 differs in up to 32%
Classifying cancer molecular phenotype and estimating prognosis based only on the primary cancer misclassifies significant numbers of patients. Classification of prognosis, and treatment based on the nodal metastasis may provide better information on which to base treatment.
Breast cancer organoid cultures preserve intra-tumor heterogeneity and reveal intrinsically resistant phenotypes to standard chemotherapies

Sowder ME E, Ludwik KA A, Pasic L, Brenin DR R, Stricker TP P, Macara IG G and Lannigan DA A. Vanderbilt University, Nashville, TN and University of Virginia, Charlottesville, VA.

Breast cancer intra-tumor heterogeneity contributes to chemotherapy resistance and decreased patient survival, yet no reliable in vitro models exist to study this phenomenon. To address this need we developed an in vitro 3D organoid culture system using primary human breast cancer tissue. A major difficulty in the development of such models is to identify robust in vitro conditions that preserve the breast cancer phenotypes observed in situ. To address this challenge we used quantitative immunofluorescence imaging to compare the cellular phenotypes in the starting tumor tissue with those observed in the tumor organoids cultured in 3D. We utilized a clustering algorithm and utility function to quantitatively assess whether tumor organoids generated in vitro faithfully recapitulated intra- and inter-tumor heterogeneity of the tumor tissue in situ. This approach generated a normalized score that reflects tissue-organoid similarity. To test the sensitivity of our method to overall changes in tissue phenotype we focused on three distinct breast cancer subtypes distinguished by expression of estrogen receptor (ER), progesterone receptor (PR) and amplification of ERBB2/HER2 (HER2). Using our approach, we successfully recapitulated the tumor phenotypes present in ER+, ER+/HER2+ and triple negative breast cancer. We discovered that EGF preserves the TNBC phenotype, whereas AREG is required for recapitulating the phenotype of ER+ and ER+/HER2+ breast cancers. Additionally, our data demonstrate that HER1 ligands drive inter- and intra-tumor heterogeneity. To investigate how intra-tumor heterogeneity contributes to therapy responses we treated organoids with standard agents used clinically to treat each of the distinct subtypes. For all tumor subtypes we observed differential vulnerabilities between patients to drug treatments. Importantly, our analysis identified divergent cellular phenotypes that have various sensitivities to chemotherapies. Taken together, our methodology provides an unprecedented view of intra-tumor heterogeneity and allows for the investigation of chemo-resistance mechanisms. Further, this approach will provide a powerful tool, which will enhance the identification of novel therapies and facilitate personalized medicine.
Title: Evidence for tumor heterogeneity and clonal evolution during invasive progression of breast cancer

Ding Y, Marks JR R, King LM M, Hall AH H, Mardis ER R, Rodrigo AG G, Maley CC C and Hwang E-S. Duke, Durham, NC; ANU, Acton, ACT, Australia; ASU, Tempe, AZ and WashU, St. Louis, MO.

Purpose: Intratumoral heterogeneity is well recognized to be an important driver of treatment resistance and metastasis. We undertook this N of one study to measure the degree of heterogeneity in a single large preinvasive lesion with an invasive component to determine the relationship between tumor heterogeneity, spatial distribution, clonal evolution, and invasive progression.

Methods: We identified a patient with extensive DCIS measuring 7.5 cm, associated with 1.5 cm of an invasive component. We segregated the tumor sample into 32 unique blocks with precise geospatial localization; invasive cancer was identified in 3 of 32 blocks. NGS libraries were made from FFPE derived DNA (20-40ng) for full exome sequencing and hybridization to a 4.8 million element SNP array. All data were analyzed and a phylogentic tree was constructed.

Results: The sequence data was analyzed with Platypus[1] and 3922 somatic mutation sites were found in total. These sites were concatenated into one sequence for each sample. Then a Neighbor-Joining tree was built with a Jukes-Cantor model and 1000 bootstrap replicates using FastME 2.0[2], to assess the reliability of the tree (Figure 1). Phylogenetic analysis revealed that invasive cancer evolved twice, independently. Dense sampling allowed reconstruction of the temporal order of mutations that accumulated in the cell lineage of the invasive cancers. Furthermore, the phylogeny revealed that distant regions may be closely genetically related, the oldest parts of the tumor were in the interior of the tumor, and that the invasive tumors evolved near the oldest parts of the tumor, rather than at the expanding front.

Conclusions: Extensive sampling and sequencing of a single tumor yields important insights about tumor heterogeneity and tumor progression for DCIS to invasive cancer. Foci of invasion were geospatially associated with preinvasive regions of progressively higher mutational load.

Body: Background: Intra-tumor heterogeneity (ITH) plays a pivotal role in driving breast cancer progression and therapeutic resistance. Emerging evidence has indicated that the extent of genetic heterogeneity may serve as a clinically useful biomarker. While several studies have suggested the prognostic value of ITH in several cancer types, the clinical significance of genetic ITH and molecular portraits that correlated with different ITH levels were poorly understood in breast cancer. The establishment of algorithms estimating genetic ITH based on sequencing of bulk tumor DNA offered us an opportunity to explore the clinical implication of ITH in large breast cancer cohorts and, for the first time, to use integrative genomic analyses to reveal molecular portraits related to intra-tumor genetic heterogeneity.

Methods: We assessed 916 female breast cancer patients from The Cancer Genome Atlas. Mutant-allele tumor heterogeneity (MATH) values were calculated from whole-exome sequencing data. We used integers nearest to the tertiles of the MATH values as cutoff points to divide the patients into three groups nearly equal in size. The association between MATH value and clinical characteristics was evaluated, followed by survival analyses in these different MATH groups. We then compared the rates of total non-silent somatic mutations among the different MATH groups, and further determined the mutations independently associated with high MATH by logistic regression adjusting for T classification and clinical subtypes. Similar methods, superadding somatic copy number alteration (SCNA) burden in logistic model, were used to evaluate SCNA events that were significantly associated with high MATH level. Gene enrichment between the high and rest MATH groups was analyzed using Gene Set Enrichment Analysis.

Results: The patients were divided into low (MATH value lower than 33), intermediate (MATH between 33 and 46) and high (MATH higher than 46) MATH groups. High T stage, African American race, and triple-negative or basal-like subtype were associated with a higher MATH level (all P<0.001). In hormone receptor-positive and human epidermal growth factor receptor-negative patients, the high MATH group showed a tendency toward a worse overall survival (P=0.052); however, while in triple-negative breast cancer, both high and low MATH indicated a worse outcome (P=0.032). Furthermore, the TP53 mutation rate increased as MATH was elevated (P<0.001), whereas CDH1 mutations were correlated with a lower level of MATH (P=0.002). Several focal and arm-level SCNA events were more common in the high MATH group, including Chr8q24 with only the MYC gene in the “peak” region. Similarly, high MATH was associated with gene set enrichment related to the MYC pathway and proliferation.

Conclusion: Our study extended the knowledge concerning the clinical role of ITH in breast cancer, especially the distinct pattern of prognostic values in different clinical subtypes, which may help promote the clinical utilization of genetic ITH. Our attempt at exploring the molecular features related to ITH might provide clues for the source and consequences of ITH, inspiring subsequent experiments investigating the laws underlying tumor heterogeneity.

Title: Abstract Withdrawn
Title: Relationships between breast cancer subtypes and expression of autophagy related genes

Feugeras J-P, Belmiloudi S, Boyer-Guitaut M, Peixoto P and Hervouet E. University Hospital, Besançon, France, Metropolitan and Laboratory of Biochemistry, EA3922, University of Franche-Comté, Besançon, France, Metropolitan.

Body: Background:
Breast cancer (BC) is a heterogeneous disease and can be classified according to the expression of four genes: estrogen receptor (ER), progesterone receptor (PGR), human epidermal growth factor receptor 2 (HER2) and marker of proliferation KI67. Four groups of BC have been described: Luminal A (ER+ or PGR+, KI67 HER2), Luminal B (ER+ or PGR+, KI67+ or HER2+), HER2 (ER- HER2+) and triple negative (ER- PGR- HER2-). Autophagy is a lysosomal degradation pathway which plays a crucial dual role in tumorigenesis, producing pro-survival or pro-death activity. Altered autophagy has been observed in BC but no study has described transcript level variations of "autophagy genes" according to sub-groups. In order to further explore those alterations, we analyzed gene expression of 40 "autophagy genes" in normal and tumor cells using public transcriptomic data.

Samples and Methods:
5497 transcriptomes were obtained from raw data downloaded from public databases. Two distinct Affymetrix series were built after GC-RMA normalization: one from HG-U133A arrays (n=2806) and one from HG-U133 plus2 arrays (n=2691). Each series was standardized with the Aroma R package that was designed to normalize multicenter extremely large Affymetrix data sets. The same computations were performed in the two data set in order to cross-validate the results. Samples were classified with a reduced number of genes (such as for St Gallen classification) and with classifiers using 50 or more than 300 genes (PAM50, CIT and IntClust centroids).

Results:
In each of the two series, there were about 500 Basal, 300 HER2, 1800 Luminal tumors and 100 normal epithelial breast cells. Positivity or negativity of four genes (ER, PGR, KI67, HER2) produced robust classifications concordant with PAM50 classification based upon centroids. Within the 40 "autophagy genes" studied, at least 10 genes were significantly correlated with one or two sub-groups: ATG3 and ATG9A were associated with ER- tumors including basal group; ATG2B, BECN1 and ULK2 were positively correlated with ER expression and luminal subtypes; ULK1 and RAB24 were associated with ER+HER2+ tumors and MAP1LC3B and ATG5 with ER-HER2+ subgroup; GABARAPL1 was more expressed in normal breast tissue than in cancer cells.

Discussion:
Exploring autophagy in large-scale transcriptome data, we confirmed a previous result showing that GABARAPL1 expression is reduced in breast cancer cells compared with the normal epithelial cells. Interestingly, transcript levels of "autophagy genes"were not evenly distributed among the different tumor subtypes. For instance, some genes were preferentially expressed in ER+ subtypes and others in ER- tumors, suggesting that autophagy might play different roles in the different subgroups, providing different potential targets for therapy.
Title: Next generation sequencing (NGS) reveals high mutation rates in all established breast cancer subtypes with subtype-specific patterns

Bemanian V, Sauer T, Joel T, Katja V, Vessela K, Ida B and Jürgen G. Gene Technology; Pathology; Breast and Endocrine Surgery; EPiGEN; Oncology; Akershus University Hospital, Lørenskog, Norway and University of Oslo, Institute of Clinical Medicine, Campus AHUS, Oslo, Norway.

Body: Introduction. Next-generation sequencing (NGS) technologies offer the possibility for assessment of multiple genes for their somatic mutations and may elucidate the driver genetic variations involved in carcinogenesis and disease progression. Among the various subtypes of breast cancer (BC), the triple-negative subgroup (TNBC) is characterized by poor prognosis and a lack of reliable tumor markers when compared to the luminal-A/B and HER-2 positive subtypes. The aim of this study was to characterize genetic variations in primary BC obtained from a cohort of 159 Norwegian patients using a NGS panel consisting of 44 BC relevant genes. Our goal was to compare the genetic variations between BC subtypes in general with special emphasis on the TNBC subtype (over 40% of the patients).

Methods. Genomic DNA was extracted from paraffin embedded formalin fixed (FFPE) tissue obtained from 160 consecutive patients diagnosed with a primary BC at our hospital. The DNA samples were analyzed by next-generation sequencing (NGS) using Human Breast Cancer GeneRead DNAseq Targeted Panel V2 (Qiagen). The panel consists of a collection of PCR primers for targeted enrichment of the coding region of 44 genes commonly mutated in BC. Target enrichment and library construction was performed according to the GeneReader workflow (Qiagen) and paired end sequencing was performed on a NextSeq 500 sequencer (Illumina) running 2 x 150 bp chemistry Version 2. Data analysis including alignment to the reference genome hg19 and variant calling was performed using Qiagen's online Ingenuity Variant analysis.

Results. The Ingenuity variant analysis classified the genetic mutations according to their clinical significance into four groups: pathogenic, likely pathogenic, benign and likely benign. We present only mutations in genes that are characterized as pathogenic or likely pathogenic, where the term "likely pathogenic" indicates greater than 90% certainty of the mutation being pathogenic (as defined by the American College of Medical Genetics and Genomics). Genetic variations were mostly observed in a subset of 44 genes included in the breast cancer panel. The tumor suppressor genes TP53 as well as BRCA1 and BRCA2 represented the highest mutation rates (>5%) among all BC samples. Interestingly, additional genes potentially playing a pivotal role in BC biology like EP300 were also found to be mutated at a high rate in TNBC. The biological significance of the EP300 gene remains unknown. Additionally, comparing the mutation rates of several genes like TP53, PIK3CA, BRCA2, ATM, RET and EGFR between established BC subtypes showed significant differences.

Conclusion. Next generation sequencing of samples obtained from primary breast cancer tumors confirmed a high level of pathogenic or likely pathogenic mutations in a subtype-specific pattern involving genes like TP53, BRCA1/2, ATM, EGFR, RB1 and PIK3CA.
Title: A targetable EGFR-driven tumor-initiating program in breast cancer

Savage P, Saleh SMI MI, Wang Y-C, Revil T, Badescu D, Liu L, Iacucci E, Zuo D, Bertos N, Munoz-Ramos V, Asselah J, Meterissian S, Omeroglu A, Hébert S, Kleinman C, Park M and Ragoussis J. Goodman Cancer Research Centre, McGill University, Montreal, QC, Canada; Genome Québec Innovation Centre, McGill University, Montreal, QC, Canada; McGill University Health Centre, Montreal, QC, Canada and Lady Davis Institute, Jewish General Hospital, Montreal, QC, Canada.

Body: Background: Inter- and intra-tumour heterogeneity underlies variability in therapeutic response. Although targeting of the epidermal growth factor receptor (EGFR) in breast cancer has failed to demonstrate clinical efficacy at the population level, complete and durable responses have been reported at low frequencies. The molecular determinants of these responses are unknown, but of importance in the era of precision medicine. Results: We performed a patient-derived xenograft (PDX) clinical trial with gefitinib in a breast cancer PDX cohort. Consistent with clinical trial data, gefitinib exhibited limited efficacy across most models. One PDX, however, demonstrated a complete and durable (>6 months) clinical response, and was subject to deep molecular profiling to identify determinants of response. Exome sequencing revealed no single nucleotide variants or copy number alterations in EGFR pathway members. EGFR was differentially expressed between the two major cellular subpopulations identified by single-cell RNAseq and this cellular heterogeneity in EGFR expression was validated immunohistochemically. Fluorescence-activated cell sorting of the EGFR\textsuperscript{hi} subpopulation revealed cells with enhanced stem-like properties, including ALDH activity, sphere-forming capacity in vitro, ability to form tumours in vivo and seeding lung micrometastases from orthotopically transplanted tumours. Tumourspheres derived from EGFR\textsuperscript{hi} cells developed into mixed EGFR\textsuperscript{hi} and EGFR\textsuperscript{lo} subpopulations, as did macrometastases, supporting that EGFR\textsuperscript{hi} subpopulation can self-renew and re-populate. Analysis of expressed SNVs in the single-cell RNAseq data, filtered by variants identified from exome sequencing, showed no clonal segregation, supporting a non-clonal origin of the functionally distinct EGFR\textsuperscript{hi} and EGFR\textsuperscript{lo} subpopulations. This EGFR-driven tumour initiating cell program was observed in independent PDX models, some which showed growth inhibition in response to gefitinib. Conclusions: Using bulk and single-cell genomic profiling, we identified and functionally validated an EGFR-driven tumour-initiating program in a subset of aggressive breast tumours, which may be predictive of gefitinib sensitivity. This contradicts traditional beliefs that good therapeutic targets are homogenously expressed, in that we show that a target displaying intra-tumour heterogeneity can be effective so long that it is expressed in the tumour-initiating population.
Title: A pan-cancer perspective of functional proteomics provides novel information content for uncommon breast cancer subtypes

Zhao W, Li J, Lu Y, Akbani R, Liang H and Mills GB B. The University of Texas MD Anderson Cancer Center, Houston, TX.

Body: Cancer cell lines (CCLs) serve as models to study the functional consequences of the genomic lesions in patients and as screening platforms for prediction of drug response. While genomic and transcriptomic data have proven to be useful predictors, the ability of these omics platforms to predict protein level and function is limited. Furthermore, since proteins are the targets of the majority of the targeted therapies, protein levels and importantly protein function would be expected to provide more powerful predictions than DNA or RNA data. While large scale genomic and transcriptomic data linked to drug sensitivity are available for over a thousand CCLs, proteomic data is available for only a small subset of lines. Here we performed proteomic profiling of 736 cell lines using reverse-phase protein arrays (RPPAs) with approximately 300 antibodies providing an unbiased sparse representation of the majority of signaling pathways.

The functional proteomic analysis revealed 10 protein-based clusters across all cell lines. Similar to human tumors, the breast cell lines fell into three major clusters representing basal-like, luminal/Her2-amplified and claudin-low breast cancer subtypes. The basal-like and claudin-low clusters contained all of the representative breast cancer cell lines as well as a much larger number of other CCLs. For example, the 6 claudin-low breast cancers analyzed reside in an EMT cluster, in which only 8/126 are breast cell lines. However, the complete cluster including multiple non-breast cancer cell lines recapitulated mRNA and protein features of claudin-low breast tumors, including a high EMT signature and low level of hormone receptor pathway activity. We thus explored whether we could gain power for linking the limited number of basal and claudin-low breast cancer cell lines to therapeutic sensitivity by assessing patterns of drug sensitivity in each cluster for both the breast and non-breast cancer cell lines in the cluster. We explored drug sensitivity of 481 therapeutic compounds from the Cancer Therapeutic Response Portal (CTRP v2) and demonstrated that the non-breast cancer and breast cancer cell lines in each cluster provided similar patterns of drug sensitivity. For example, Claudin-low/EMT cell lines of both breast cancer and non-breast cancer origin showed decreased sensitivity to PI3K/mTOR inhibitors compared to luminal breast cancers (p<0.05 for 4 mTOR inhibitors) and drugs targeting EGFR family compared to basal cell lines (p<0.05 for 7 EGFR/ERBB2 inhibitors). Thus it is possible to gain information by characterizing cell lines with similar patterns of protein expression and provide important information related to drug sensitivity of uncommon breast cancer lineages. The functional proteomic analysis provides a wealth of information that complements the genomic and transcriptomic studies of cancer cell lines, and demonstrates the opportunity to leverage cell line ‘pan-cancer’ proteomic patterns to improve characterization of specific breast cancer subtypes. To facilitate broad access to these data, we developed a user-friendly data portal, the MD Anderson Cell Lines Project (MCLP), that provides both data analysis and download (http://ibl.mdanderson.org/mclp/).

**Title:** Chemotherapy (CT) decision in patients (pts) with node-positive (N+), ER+, early breast cancer (EBC) in the wake of new ASCO guideline – A different take on the evidence for the 21-gene recurrence score (RS) assay

Mamounas E, Goldstein L, Penault-Llorca F, Roche H, Gluz O, Harbeck N, Nitz U, O'Shaughnessy J and Albain K. UF Health Cancer Center at Orlando Health, Orlando, FL; Fox Chase Cancer Center, Philadelphia, PA; Centre Jean Perrin, Clermont-Ferrand, France; Institut Claudius Régaud, Institut Universitaire du Cancer Toulouse-Oncopole, Toulouse, France; Evangelical Hospital Bethesda, Moenchengladbach, Germany; University of Munich, Munich, Germany; Baylor University Medical Center, Texas Oncology, US Oncology, Dallas, TX and Loyola University Medical Center, Maywood, IL.

**Body:** Background: The use of molecular tools for prognosis and prediction of CT benefit in EBC has increased the complexity of decision making. The 21-gene RS (Oncotype DX) is included in the ASCO (2007) and NCCN guidelines (2006) for prognosis (risk of distant recurrence [DR]) and prediction of CT benefit in N0, ER+ EBC. In 2015, the NCCN added that the RS assay could be considered for select patients with 1-3 N+, ER+ EBC. Recently the ASCO BC biomarker/guideline group (J Clin Oncol 2016) advised that the “clinician should not use the 21-gene RS to guide decisions” and called the evidence quality “intermediate” and the recommendation “moderate” based on review of 2 N+ studies. It also advised no change in N+ clinical practice until the prospective SWOG S1007 study (RxPONDER) matures in several years. These discordant recommendations have led to major confusion among physicians, pts and payers. To address this controversy we herein report a comprehensive analysis of the body of evidence regarding the clinical utility of the RS in N+, ER+ EBC.

Methods: All published studies involving N+, ER+ EBC with RS data were analyzed by type of study design and category of trial (validation, supportive, decision impact, cost-effectiveness, and prospective outcomes).

Results: 30 studies provided clinical evidence supporting the value and utility of the RS in N+, ER+ pts. 7 studies employed a prospective-retrospective design or were prospective outcomes with clinical utility in >8000 N+ pts (Table). 23 additional studies assessed the impact of RS on CT decisions or cost-effectiveness.

</tbody>
</table>

Conclusions: The 21-gene RS has now been studied in >10,000 N+, ER+ EBC pts across 30 studies worldwide, including 2
prospective outcomes studies in >5000 pts, confirming that the RS consistently identifies low risk 1-3 N+ pts in whom CT can effectively and safely be avoided. This evidence suggests that ER+ pts with few N+ and low RS should have a discussion of the pros and cons of adjuvant CT until the results of RxPONDER provide a definitive answer in several years.
Mesenchymal subtype negatively associates with the presence of immune infiltrates within a triple negative breast cancer classifier

Introduction: Lehmann and colleagues (Lehmann et al., 2011) devised a gene expression classification system for triple negative breast cancer (TNBC) consisting of seven subtypes—IM, BL1, BL2, LAR, M, MSL, and UNS (unselected). We (Ring et al., 2016) recently modified this original algorithm of 2188 gene subtyping into a 101-gene algorithm. In addition to a reduction of genes, the 101-gene algorithm has two methodological differences: first, the immunomodulatory (IM) signature was treated not as a subtype but rather as a binary feature of one of the other subtypes (e.g. BL1/IM+, LAR/IM-); second, when tumors—by a predefined correlation coefficient—showed traits of more than one subtype, both subtypes were reported as “dual subtypes.”

Aim: Our aim was to apply the 101-gene algorithm for TNBC subtyping and to establish the relation of TNBC subtypes with their IM-status across several independent data sets.

Methods: 951 patients from four independent TNBC cohorts with available gene expression data were analyzed by the 101-gene algorithm. Of these 848 were classified with at least one subtype.

Results: The distribution of the 5 TNBC subtypes in both single and dual subtypes was 47%,10%,15%,18%,11%, for BL1, BL2, LAR, M, and MSL respectively. The majority of cases gave only one subtype (572, 67%) with M (Mesenchymal) being 9% (n=54) of these. Given this frequency of 9% of M as a baseline, in the remaining 276 (33%) cases with dual subtypes, the expectation that M would be one of the two is 11% (64 subtype calls). However, M is one of the two of the dual subtypes at a much higher frequency of 40% (222 subtype calls, Chi-Squared, P<0.0001). IM+ is a common feature across these cohorts (n=310 or 37%). When examining the IM feature within the patients exhibiting the M subtype as either a single subtype or one of the two dual subtypes (n=276, 33%), IM positive tumors are never of the M phenotype (Chi-Squared, p<0.0001).

Conclusions: We further have confirmed with the 101-gene algorithm that the IM signature inversely associates with the M subtype as it has been observed with the 2188 gene algorithm (Lehmann et al., 2016). Moreover, the M signature is occasionally a confounder of other subtypes however still identifies those tumors negative for immune infiltrates. This raises important opportunities to understand the relationships between intrinsic tumor biology reflected in TNBC subtypes and their interaction with variable immune cell stroma which are the subject of ongoing analyses.
Unique overlapping subtypes of triple-negative breast and ovarian cancers and sensitivity of “mesenchymal-like” cancers to HSP90 inhibition is revealed by integrated gene expression and drug sensitivity profiling

Shee K, Ung MH H, Cheng C and Miller TW W. Geisel School of Medicine at Dartmouth, Lebanon, NH.

Body: Next-generation sequencing and gene expression signature analysis of primary tumors from The Cancer Genome Atlas (TCGA) revealed striking similarities between triple-negative breast cancer (TNBC) and ovarian cancer (OVCA). We hypothesized that these similarities may reveal transcriptionally-identifiable subgroups within a mix of TNBC and OVCA that are uniquely sensitive to certain drugs.

To test this hypothesis, gene expression profiles for TNBC and OVCA cell lines in the Cancer Cell Line Encyclopedia were analyzed by unsupervised hierarchical clustering, which revealed two major unique subgroups containing both TNBC and OVCA cell lines that clustered according to the previously defined Mesenchymal and Basal subclasses of TNBC. Differential gene expression between “Mesenchymal-like” and “Basal-like” TNBC/OVCA cell lines was used to generate a gene signature that was subsequently validated using gene expression data in the Genomics of Drug Sensitivity in Cancer (GDSC) database. Drug sensitivity data from GDSC was then utilized to profile differential sensitivity of “Mesenchymal-like” and “Basal-like” cell lines to the 99 anti-cancer drugs with coverage of >50 breast and ovarian cell lines. Mesenchymal-like TNBC/OVCA cells were uniquely sensitive to HSP90 inhibition compared to Basal-like TNBC/OVCA cells for both HSP90 inhibitors in GDSC: CCT018159 (p<0.001) and 17-AAG (p=0.012). Strikingly, Mesenchymal-like TNBC/OVCA cells were most sensitive to HSP90 inhibition among all 33 solid tumor cancer lineages in GDSC, as well as other subgroups of breast and ovarian cancers.

Differential sensitivity of Mesenchymal-like and Basal-like TNBC/OVCA cells to HSP90 inhibition with 4 agents (CCT018159, 17-AAG, AT13387, PU-H71) was validated using growth assays for 12 cell lines (6 of each subgroup) previously characterized in GDSC. To further validate the predictive value of our gene signature, gene expression data for 6 TNBC/OVCA cell lines with uncharacterized drug sensitivity was used to classify cell lines as “Mesenchymal-like” (n=4) or “Basal-like” (n=2). Our gene signature successfully predicted differential sensitivity to HSP90 inhibition, with the 4 Mesenchymal-like cell lines displaying greater sensitivity to HSP90 inhibition. The gene signature has been used to select PDX models with predicted differential sensitivity to HSP90 inhibition, and treatment studies are ongoing.

In summary, we developed a novel approach to generate a gene expression signature that robustly predicts sensitivity to HSP90 inhibitors in preclinical models of TNBC and OVCA. HSP90 thus represents a therapeutic opportunity in an overlapping subpopulation of TNBC and OVCA. Our approach to identify novel combinations of drugs and histology/lineage-independent cancer subgroups may be used to discover new therapeutic opportunities in other cancer types.
Title: Integrated transcriptional analysis of the triple negative 'proliferation paradox': High proliferation, chemosensitivity, and poor prognosis

Stover DG G, Selfors LM M, Winer EP P, Partridge AH H and Barry WT T. Dana-Farber Cancer Institute, Boston, MA and Harvard Medical School, Boston, MA.

Body: Background: In triple-negative breast cancers (TNBC), high proliferation is associated with greater chemosensitivity but, paradoxically, also associated with poor prognosis. We hypothesized that this subset of TNBC has distinct transcriptional features that contribute to poor prognosis.

Approach: To evaluate transcriptional signatures associated with this 'proliferation paradox,' we identified 17 study cohorts of TNBC treated with neoadjuvant chemotherapy (NAC) that reported receptor status, pathologic response, and had expression data from biopsies obtained prior to NAC (n=446). In 6 studies, distant metastasis-free survival (DMFS) data was available for 235 patients with a median follow-up of 31.2 months. We calculated scores for 135 published gene expression signatures for each tumor and evaluated the association with response to chemotherapy and DMFS.

Results: Using recursive partitioning to develop a model of response using a training set (n=340), six of the 135 expression signatures stratify primary tumors into four groups based on signatures of proliferation, BRCA1 mutation, immune, luminal, Ras, and PI3K phenotypes (Table 1.). Response to NAC ranged from 11% to 61% pCR/RCB-I and results were highly concordant when applied to a validation set (n = 106, p = 0.006). The group that was highly proliferative but chemoresistant ('resistant' group) had a distinct transcriptional profile, including lower 'BRCA-ness' and DNA damage expression signatures with higher Ras and stem cell signatures. The 'resistant' group had the poorest DMFS (HR 2.48 [1.52-4.06]; log-rank p=0.002) and this poor survival was validated among chemotherapy-treated TNBCs in a separate dataset, METABRIC. Analyses of only patients with residual disease after NAC demonstrated that the 'resistant' group remained poorest prognosis, with median DMFS of only 31 months from diagnosis.

Conclusions: Using a novel approach to categorize primary TNBC tumors based on six signatures, we can effectively distinguish subgroups with higher versus lower pCR rates. One specific group demonstrated high proliferation but low response to chemotherapy and particularly poor survival. This group demonstrates expression signatures implicating DNA damage repair, stemness, and Ras pathway activity as potential mediators of the phenotype. We identify specific molecular characteristics for investigation in patients within a poor prognosis subgroup of TNBC.

Title: Immune signatures define and affect prognosis in triple-negative breast cancer subtypes

Bottai G, Balazs G, Nagy A, Pusztai L, Szallasi Z, Reis-Filho JS S and Santarpia L. Humanitas Clinical and Research Center, Milan, Italy; MTA TTK Momentum Cancer Biomarker Research Group, Budapest, Hungary; Yale Cancer Center, New Haven; Boston Children's Hospital, Boston and Memorial Sloan-Kettering Cancer Center, New York.

Body: Background: The tumor immune microenvironment is formed by many distinct and interacting cell populations, and its composition may predict patient's prognosis and response to therapies. Triple negative breast cancer (TNBC) is a heterogeneous disease in which different genomic subgroups have been described (Lehmann, et al. J Clin Invest.2011). Our aim was to integrate the composition of the tumor immune microenvironment with the molecular TNBC subtypes.

Methods: We retrospectively analyzed the composition and the functional orientation of the immune microenvironment of 963 TNBC tumors clustered in 4 main TNBC subgroups (Basal-Like [BL1/2], Immunomodulatory [IM], Mesenchymal/Mesenchymal Stem-Like [MS], Androgen Receptor [AR]) from independent cohorts using transcriptomic profiling. TNBC were stratified based on 9 different immune signatures (Natural Killer [NK], Dendritic Cells [DC], T-Cells [TC], B-Cells [BC], T-Cytotoxic [TC], Interferon [IF], Nuclear Factor-kB [NF-kB], anti-tumor Macrophages [M1] and pro-tumor Macrophages [M2]. We validated our findings using immunohistochemistry.

Results: We report that TNBC molecular subgroups and specific microenvironmental immune signatures are highly correlated. The IM was enriched of almost all the immune modules. On overall TNBC population, the TC (P = 0.01), IF (P = 0.007) and M1 (P = 0.001) signatures were associated with good prognosis. The BL subgroup with a good prognosis was characterized by overexpression of genes specific to M1-macrophages (P = 0.004) and TC-lymphocytes (P = 0.01). In contrast, the poor-prognosis MS expresses markers of cells of monocytic origin and significantly associated with the M2 signature (P = 0.01). The MS subgroup also displays an inflammatory and immunosuppressive signature. Pathological examination revealed that the MS subtype is characterized by a high density of pro-tumor macrophages that likely produce chemokines and cytokines which favor tumor-associated inflammation, resulting in a poor prognosis. In contrast, the AR exhibits low immune and inflammatory signatures.

Conclusions: The distinct immune orientations of the TNBC molecular subtypes pave the way for tailored immunotherapies.
Gene expression signatures and immunohistochemical subtypes add prognostic value to each other

Lundberg A, Lindström LS, Falato C, Carlson JW, Foukakis T, Czene K, Bergh J and Tobin NP. Karolinska Institutet and University Hospital, Stockholm, Sweden; Karolinska Institutet and University Hospital, Stockholm, Sweden; Karolinska Institutet and University Hospital, Stockholm, Sweden and Karolinska Institutet and University Hospital, Stockholm, Sweden.

Body: Background: We have previously demonstrated that gene expression signatures and Ki67 stratify the same breast tumour into opposing good/poor prognosis groups in approximately 20% of cases. Given this, we hypothesized that the combination of a clinically relevant gene signature and IHC markers may provide more prognostic information than either classifier alone. We tested this hypothesis in a large independent cohort of Swedish breast cancer patients with long-term follow-up data.

Methods: We assessed Ki67, ER, PR, HER2 and the research versions of the Genomic Grade Index (GGI), Mammaprint, cell-cycle score (CCS), Recurrence Score (RS) and PAM50 gene expression classifiers on matching TMA and microarray data in a Swedish breast cancer cohort of 623 patients. Change in likelihood-ratio (Δ LR-χ2) was used to first determine the additional prognostic information provided by gene expression signatures beyond that provided by 1) Ki67 alone and 2) Ki67 plus ER, PR and HER2, grouped to form the IHC molecular subtypes. Secondly and conversely, we then determined the additional prognostic information provided by Ki67/IHC subtypes beyond gene expression signatures.

Results: Representative images from Ki67/gene signature contrast groups show tumours with high levels of Ki67 expression that are classified as good prognosis by gene signatures and conversely, tumours with low Ki67 that are classified into poor prognosis groups by gene signatures. In all patients (n=623), the majority of signatures provided statistically significant information beyond that of Ki67 alone, however only RS and PAM50 remained significant in the presence of the IHC subtypes (Δ LR-χ2 RS= 11.7 and PAM50 = 15.4; P = 0.002 and 0.004, respectively). Conversely, IHC subtypes added prognostic information beyond gene signatures whilst Ki67 alone did not, a notable exception to this was PAM50.

Conclusions: In general, a combination of the IHC subtypes with gene signatures provides more prognostic information than either classifier alone when considering all breast cancer patients. Subsequent analyses will focus on patient subgroups including ER positive, node positive and ER positive, node negative groups, along with validation of our work in a second dataset of 253 patients.

Title: Mixed ductal-lobular carcinomas of the breast: Abrogated cell adhesion in the clonal evolution from ductal to lobular morphology

McCart Reed AE, Kutasovic JR, Nones K, da Silva L, Melville L, Jayanthan J, Vargas AC, Reid LE, Saunus JM, Cummings MM, Porter A, Evans E, Waddell N, Lakhani SR and Simpson PT. The University of Queensland, UQ Centre for Clinical Research, Brisbane, QLD, Australia; QIMR Clive Berghofer Medical Research Institute, Brisbane, QLD, Australia; Pathology Queensland, The Royal Brisbane and Women's Hospital, Brisbane, QLD, Australia; The University of Queensland, School of Medicine, Brisbane, QLD, Australia and The Wesley Breast Clinic, The Wesley Hospital, Brisbane, QLD, Australia.

Body: Mixed ductal-lobular carcinomas (MDL) display both ductal and lobular morphology, and are a clear example of intratumour morphological heterogeneity. The evolution of MDL carcinomas is not well understood. There is a paucity of data surrounding the genetic origin of the different morphological compartments and it remains to be seen whether the coincident presentation of these distinct morphological entities represents two independent tumours that have collided (so called 'collision tumours'), or whether they arise from a common clone. We propose that clonal progression during the evolution of these tumours is associated with a change in phenotype. To address this, a cohort of 82 MDLs was studied for clinical, morphological and molecular features. Key findings include: i) MDLs more frequently co-exist with ductal carcinoma in situ (DCIS) than lobular carcinoma in situ (LCIS); ii) the E-cadherin-catenin complex was recurrently normal in the ductal component but aberrantly localised in the lobular component of the same tumour; iii) E-cadherin deregulation in the lobular component was almost always aberrantly located to the cytoplasm, conversely classic ILCs are typically completely negative for this molecule; iv) epithelial to mesenchymal transition marker expression was not associated with E-cadherin deregulation. Comparative Genomic Hybridsation (CGH) and exome sequencing was performed to investigate clonal relationships between the different intratumour morphologies and identify mechanisms underlying the change in phenotype. Our analysis revealed that i) all morphological components within a case are clonally related; ii) divergence of the morphological components may occur early during tumour evolution (where both DCIS and LCIS are present) or later during tumour progression (cases with only DCIS detectible); and iii) mutations were identified in genes such as CDH1 and ESR1, and other breast cancer driver genes. Together, these data strongly support the concept that the disparate morphological components of these mixed tumours are clonally related, and are not the result of a collision event. Furthermore, we show that lobular morphology can arise via a 'ductal' pathway of tumour progression. The mechanisms driving the change in phenotype are yet to be fully elucidated, but there is significant intertumour heterogeneity and each case may utilise a unique molecular mechanism.
A multi-OMIC analysis to explore the impact of “actionable” genomic alterations on protein pathway activation: Clinical implication for precision medicine in metastatic breast cancer

Pierobon M, Wong S, Reeded A, Anthony S, Robert N, Northfelt DW W, Jahanzeb M, Vocila L, Wulfkuhle J, Dunetz B, Aldrich J, Byron S, Craig D, Liotta L, Carpten J and Petricoin EF F. George Mason University, Manassas, VA; Translational Genomics Research Institut, Pheonix, AZ; Virginia Cancer Specialists/US Oncology, Fairfax, VA; Mayo Clinic Arizona, Scottsdale, AZ; University of Miami, Deerfield Beach, FL; TD2 Translational Drug Development, Scottsdale, AZ; The Side Out Foundation, Fairfax, VA; Keck School of Medicine, Los Angeles, CA and Arizona Oncology, Sedona, AZ.

Body: Background: While genomic alterations are central players in tumor progression, proteins are the targets for precision therapy. The degree by which “actionable” genomic alterations translate into activated/altered proteins and pathway is still under investigation. Using a multi-OMIC approach from the SideOut 2 metastatic breast cancer (MBC) trial, this study explored the concordance between selected “actionable” genomic alterations and protein expression/activation.

Methods: Snap frozen biopsies from 29 MBC patients enrolled in a prospective phase II trial were used for this analysis. Exome WES and RNASeq data was processed using an in-house developed pipeline and identified amplification of CCND1 (6/29), FGFR1 (4/29), and FGF 3, 4, 5, and 19 (4/29) as some of most frequent “actionable” genomic alterations in our MBC cohort. Signaling analysis of the 29 cases was performed using Reverse Phase Protein Microarray coupled with Laser Capture Microdissection. Protein expression/phosphorylation was measured in a continuous scale and classified based on quartile distribution. Concordance between CCND1 amplification and Cyclin D1 expression, along with the activation of FOXM1 T600 and Rb S780, was explored. Amplification of the FGFR1 locus or its ligands was correlated with the level of activation/phosphorylation of FGFR1 Y653/654.

Results: While Cyclin D1 protein expression was greater than the population mean for 4/6 (67%) patients with CCND1 amplification, only 2/6 (33%) patients with CCND1 amplification had Cyclin D1 level within the top quartile of the population (n=29). FOXM1 T600 activation was independent from CCND1 amplification, with high levels of FOXM1 T600 predominantly in the CCND1 wild-type population. Only 1/6 (17%) patients with CCND1 amplification had FOXM1 T600 level similar to the top quartile of the population while a second patient was above the population median. Activation of Rb S780 was above the population median, but below the top quartile, in 2/6 (33%) CCND1 amplified patients. Similarly, none of the patients with activation of FGFR Y653/654 equal to the top quartile harbored an FGFR1 amplification. Only 1/4 (25%) patients carrying an FGFR1 amplification had an activation of FGFR Y653/654 above the population median. Similarly, 1/4 (25%) patients with FGF ligand amplification showed FGFR Y653/654 level within the top quartile while three patients had FGFR Y653/654 activation below the population median. No significant results were found between proteomic (below/above the median) and genomic characteristics by Fisher test (p>0.05).

Conclusion: Molecular genotyping of “actionable” cancer targets alone may be insufficient in predicting whether the actual drug target protein is expressed and/or activated in any given patient's tumor. Although these results need further validation, the combination of genomic and proteomic data may represent a more informative approach for identifying real molecular drivers of individual lesions as well as “actionable” protein/phosphoprotein targets in the absence of genomic events. Multi-OMIC approaches may lead to more effective stratification in precision medicine trials.
Title: Prediction of 10yr distant recurrence (DR) using the Prosigna® (PAM50) assay in histological subgroups of a Danish breast cancer group (DBCG) cohort of postmenopausal Danish women with hormone receptor-positive (HR+) early breast cancer (EBC) allocated to 5yr of endocrine therapy (ET) alone

Laenkholm A-V, Jensen M-B, Buckingham W, Schaper C, Knoop A, Eriksen JO Ole, Rasmussen BB Bruun, Ferree S, Haffner T, Kiboel T and Ejlertsen B. Zealand University Hospital, Slagelse, Denmark; DBCG Secretariat, Danish Breast Cancer Group, Rigshospitalet, Copenhagen, Denmark; NanoString Technologies, Seattle, WA; NanoString Technologies, Seattle, WA; Rigshospitalet, Copenhagen, Denmark; Zealand University Hospital, Slagelse, Denmark; Herlev Hospital, Herlev, Denmark; NanoString Technologies, Seattle, WA; NanoString Technologies, Seattle, WA; Zealand University Hospital, Slagelse, Denmark and DBCG Secretariat, Danish Breast Cancer Group, Rigshospitalet, Copenhagen, Denmark.

Body: Background: The Prosigna (PAM50) risk of recurrence (ROR) score predicts 10yr DR in early breast cancer patients treated with ET alone (level 1 evidence). Invasive lobular breast cancer (ILBC) accounts for 10-15% of all breast cancer histological subtypes. Sporadic ILBC is characterized by somatic CDH1 mutations with loss of E-cadherin and a majority of low proliferative ER positive/HER2 negative tumors consistent with Luminal A subtype. Here we examine the ability of PAM50/ROR to predict 10yr DR in postmenopausal women who following a diagnosis of HR+ early ILBC were allocated to 5yr of ET alone.

Methods: Using the population based clinical DBCG database FFPE primary tumor blocks, treatment, and follow-up data were collected from all patients diagnosed from 2000-2003 with HR+, postmenopausal EBC (N0-N1) who by nationwide guidelines were allocated to 5yr of ET alone, N=2,722 (1256 N0, 1466 N1). PAM50 intrinsic subtype classification (Luminal A, Luminal B, HER2-enriched, Basal-like) was conducted using the NanoString nCounter® Analysis System. Univariate and multivariate analyses tested the ability of PAM50 to predict DR. Patients were categorized as Low or High Risk based upon pre-specified ROR cutoff value of 40. HER2 positive tumors by immunohistochemistry were excluded from analysis.

Results: Median follow-up was 9.25 years. Risk of 10yr DR by ROR and PAM50 (Luminal A and Luminal B) is shown in the table by ILBC as compared to invasive ductal breast cancer (IDBC) type.

Cumulative incidence for 10 yr distant recurrence (DR)

</tr>
</tbody>
</table>

In this specific cohort the ILBC subgroup had a worse 10yr DR of 16.4% [12.2-21.1] as compared to IDBC of 12.1% [10.6-13.7] (Gray’s test, p = 0.046). A significant difference regarding the distribution of ILBC into both High and Low Risk Group and intrinsic subtypes as compared to IDBC was identified (p < 0.0001). Molecular intrinsic subtype analysis for ILBC by Prosigna (PAM50) showed DR 12.7 [8.6-17.8] for Luminal A vs 24.1 [14.5-35.1] for Luminal B. The difference between ILBC subtypes was not significant (p = 0.09). Adding ROR to a Fine and Gray’s proportional sub-hazards model containing clinical and pathological variables significantly improved the model for ILBC, (likelihood ratio: p = 0.0001); HR for a 20-point change in ROR = 1.84 [1.37-2.48] notable with DR 9.7 [5.5-15.4] for the Low Risk Group.

Conclusions: Following 5-yr of endocrine treatment alone patients with ILBC in this large population-based study had an inferior DR as compared to patients with IDBC and the apparent difference between ILBC and IDBC must be interpreted with caution.
Title: Tumor genomic profiling of triple negative breast cancer during neoadjuvant chemotherapy: Results from a prospective trial of carboplatin and docetaxel

Ademuyiwa FO O, Miller CA A, Li T, Sanati S, Ma CX X, Weilbaecher K, Ellis MJ J and Mardis ER R. Washington Uni Sch of Medcn, St. Louis, MO and  Baylor College of Medicine, Houston, TX.

Body: Background-The clonal evolution and effect of neoadjuvant chemotherapy on the mutational landscape of triple negative breast cancer (TNBC) is unknown. Inability to eradicate TNBC may be due to clonal progression and selection of cells fundamentally resistant to chemotherapy. In this study, we sought to decipher the genomic architecture of TNBC serially during neoadjuvant chemotherapy to distinguish pre- versus post-chemotherapy genotypes.

Methods-Tumor specimens were obtained from patients with stages II and III TNBC enrolled on an ongoing prospective neoadjuvant co-clinical trial (NCT02124902). Patients have a research biopsy at baseline, cycle 1 day 3 (optional), and at definitive surgery for those with residual disease. Patients are treated with docetaxel 75mg/m^2 and carboplatin AUC6 cycled every 3 weeks X six cycles. Definitive surgery is 3-5 weeks after chemotherapy. The primary endpoint is pathologic complete response rate. Correlative studies include development of patient derived xenografts, evaluation of genomic signatures of resistance and response, and comparison of chemotherapy responses between xenografts and host patients. Five patients’ serial tumor samples and germline DNA were studied by exome and transcriptome sequencing. Three of these patients had an additional on-treatment sample at cycle 1 day 3. Two patients lacked residual disease samples- one was not banked and the other could not be accurately genotyped due to low cellularity. The median sequencing depth was 90.13x. Sequencing was performed on either fresh frozen or formalin-fixed paraffin-embedded samples with high cellularity (≥50%). After identifying somatic mutations in each tumor series, we evaluated whether each mutation was persistent, emergent, or cleared by comparing pre- and post-treatment (and when possible, on-treatment) samples.

Results-All five patients had response to neoadjuvant chemotherapy based on caliper-based and pathologic (residual cancer burden I or II) measurements. All residual disease remained TNBC by standard immunohistochemistry and all samples were basal-like from PAM50 gene expression analysis. We identified 908 somatic mutations, including the expected variants in TP53 which persisted in all post-treatment samples. Non-silent somatic variants were identified in other breast cancer-related genes, including GATA1, FBXO11, PIK3R1, AXIN2, ARID1B, BRCA2, and RBCC1. In spite of the clinico-pathologic evidence of response, we observed little change in clonal architecture, as derived from the purity-corrected variant allele fractions between baseline, cycle 1 day 3, and post-chemotherapy samples. Copy number alterations were likewise stable and transcriptional-based assessment indicated that patterns of mutant allele expression in driver genes were retained throughout the course of treatment.

Conclusion-In TNBC patients undergoing neoadjuvant platinum-based chemotherapy, there were no apparent shifts in the prevalence of known breast cancer specific somatic variants during or after chemotherapy. Despite pathologic response, core genomic features appear to be preserved in TNBC patients with residual disease following chemotherapy, likely accounting for high rates of relapse in these patients.
An exploratory correlative biomarker analysis of NSABP FB-7, a phase II randomized trial evaluating neoadjuvant therapy with weekly paclitaxel (P) plus neratinib (N) or trastuzumab (T) or neratinib and trastuzumab (N+T) followed by doxorubicin and cyclophosphamide (AC) with postoperative T in women with locally advanced HER2-positive breast cancer

The NSABP FB-7 trial enrolled HER2-positive breast cancer patients (pts) with locally advanced disease who were randomly assigned to trastuzumab (T) or neratinib (N) or the combination (T+N) with weekly paclitaxel (P) followed by standard AC. A total of 126 pts were randomized to Arm 1 (T+P→AC), Arm 2 (N+P→AC), or Arm 3 (N+T+P→AC). Eligibility criteria included women >18 years of age, ECOG PS 0-1, stage IIB-IIIC invasive breast cancer, HER2-positivity by IHC 3+, FISH, or CISH as determined by local laboratories, hormone receptor positive or negative, LVEF ≥50%, and adequate laboratory parameters . The primary endpoint was pathologic complete response (pCR) in breast and nodes and was reported at SABCS 2015 (Jacobs et al, abstract # PD5-04). Dual anti-HER2 therapy yielded greater pCR rates than single targeted therapies in the overall cohort, and the magnitude of pCR was highest in HR-negative patients. Since this initial report, an in depth correlative biomarker analysis with clinical outcome has been performed and will be presented.

Methods: In an effort to discover candidate predictive markers of response to study drugs, pre-treatment core biopsy samples (n=59) and post treatment surgical samples (n=17) were obtained from a subset of patients. Samples were collected prospectively from 2011-2014 and stored prior to batch analysis. Retrospective correlation with clinical outcome was performed after datalock of 1st Sept. 2015. Expression and activation of HER family RTKs, including truncated HER2, as well as downstream components of PI3K/AKT and MAPK pathways, were quantified using the multiplexed microarray CEER™platform (Collaborative Enzyme-Enhanced Reactive immuno-assay). pCR data were available in n=51 pts from the biomarker cohort. After excluding low tumor content non-evaluable samples, correlative biomarker analysis was performed in n=42 patients. Breast cancer subtypes were assessed with RNA-Seq to assess changes in gene expression and subtypes before and after treatment and association of pathways with pCR. The distribution, in our study population, of MammaPrint and BluePrint scores (Agendia) and their association with pCR will be presented. Results from a custom AmpliSeq (Thermo-Fisher) gene-panel used to assess the variant status of 117 genes potentially relevant to the development of resistance to anti-HER2 therapies, will be presented.

Conclusions: Different patterns of baseline expression and activation levels of several key drivers, such as p95HER2, HER2, HER3, and PI3K, were observed between pCR in Arm1 (T+P→AC) and Arm 2 (N+P→AC). In particular, Arm 2 pCR displayed higher baseline levels of truncated HER2 compared to non-pCR. This exploratory marker analysis generates the hypothesis that high p95HER2 levels as measured by CEER™ may predict the likelihood of response to a neratinib containing regimen in the neoadjuvant setting in locally advanced breast cancer. Other correlatives will be discussed.

**Title:** The mutation detection and a high throughput screening of driver mutations in PI3K/AKT pathway based on next generation sequencing

Chen L, Yang L, Yao L, Hu X and Shao Z. Fudan University Shanghai Cancer Center, Shanghai, China; Cancer Institute, Fudan University Shanghai Cancer Center, Shanghai, China and Shanghai Medical College, Fudan University, Shanghai, China.

**Body:**

**Background**

The deregulation of the PI3K/AKT signaling pathway is essential to malignant cellular processes of breast cancer, including proliferation, apoptosis, and drug response. Oncogenic activating somatic mutations in the PI3K/AKT pathway are pervasive. However, it remains difficult to discriminate between driver and passenger mutations. This study was conducted to identify the landscape of genetic mutations in the PI3K/AKT pathway using Amplicon Sequencing in a Chinese population. Notably, we developed a Gateway-based mutation barcoding (GaMB) library which enables a high-throughput mutation-phenotype screen for specific vulnerable mutations that contribute to the cancer development and drug resistance.

**Method**

We collected 149 breast cancer specimens in a Chinese population and performed Ion Torrent Amplicon Sequencing for the key genes in PI3K/AKT pathway: PIK3CA, PIK3R1, AKT1, AKT2, AKT3, PTEN, PDK1, and the canonical tumor suppressor gene TP53, at 1000× coverage. Next, we established a high-throughput GaMB library that contained all of the PIK3CA mutations, either newly identified in Chinese population or reported in TCGA and COSMIC database, and tagged each mutations with a specific barcode. We then applied this library to functional screening processes using proliferation and drug response selection (doxorubicin or BKM-120) assays through which we screened the functional mutations with specific characteristics. The genomic DNA of the pooled surviving cells from the library, as well as the original cells before the screenings, was extracted and used for PCR amplification of the barcode regions, and then detected using Illumina Miseq sequencing to analyze the functional mutations. We then validated the cellular 2D- & 3D- proliferation abilities and the status of PI3K/AKT pathway activation in presence of identified mutations, respectively.

**Result**

Mutations in the PIK3CA (44%), PIK3R1 (37%), AKT3 (15%) and PTEN (12%) genes were the most prevalent. Mutations in PIK3CA were present in 65 samples (43.6%) which is similar to that reported in TCGA database. PIK3R1 (37%) was found significantly mutated, with a novel recurrent mutation, N595S, being identified in 24 patients. Similarly, AKT1 (10.1%), AKT2 (10.1%), and AKT3 (14.8%) mutations were present at a higher frequency in our population than has been reported in the TCGA and COSMIC database.

In the PIK3CA-GaMB library, our highest-ranking mutations included the previously validated deleterious mutations H1047R and E545K and several mutations of uncertain significance, including E39K, G1049R, N345I, N345K, M1043V, and H1047T. In the validation assays, we found a high phenotype-consistency of these identified mutations using these functional validation techniques. The breast cancer cells harboring identified mutations exhibit a relatively higher proliferation ability and tolerance to chemotherapy and pathway inhibitors.

**Conclusion**

This study identified the landscape of genetic mutations in the PI3K/AKT pathway using Amplicon Sequencing in a Chinese population. A novel developed GaMB screening platform may allow the rapid identification of significant mutations that dominate breast cancer development and drug responses during treatment.

Title: Rates of immune infiltration in patients with triple-negative breast cancers by molecular subtype and in patients with inflammatory and non-inflammatory breast cancers

Body: Background

In patients with triple-negative breast cancer (TNBC), tumor-infiltrating lymphocytes (TILs) have been reported to be associated with improved survival. Lehmann et al. identified 6 molecular subtypes of TNBC [basal-like (BL) 1, BL2, mesenchymal (M), mesenchymal stem like (MSL), immunomodulatory (IM), and luminal androgen receptor (LAR)], and we previously reported that TNBC subtype is a predictor of pathologic complete response (pCR). Recently, the IM gene expression signature has been shown to be indicative of the presence of TILs and has been incorporated into TNBC subtyping as a modifier of the other groups rather than a separate subtype. However, the association between TNBC subtype and the presence of TILs is not known. We hypothesized that the BL2 and LAR subtypes, which have low pCR rates, have low rates of immune infiltration. Inflammatory breast cancer (IBC) is an aggressive cancer that is frequently triple-negative. The association between IBC and the presence of TILs also is not known. In this study, we analyzed the association between TNBC molecular subtype and the IM signature and determined whether the IM signature differed between patients with IBC and non-IBC.

Methods

We retrospectively analyzed 88 patients with TNBC from the World IBC Consortium dataset for whom IBC status was known (IBC, n=39; non-IBC, n=49) and tumor gene expression data were available. TNBC specimens were classified using the TNBCtype algorithm (Insight Genetics, Inc., TN, USA), which uses a 101-gene signature. For each tumor, the TNBCtype algorithm reports the TNBC molecular subtype (BL1, BL2, M, MSL, or LAR) and the IM status, which is described as positive (IM+) or negative (IM-). Recently, Fisher's exact test was used to analyze differences in subtype distribution between the IM+ and IM- tumors.

Results

The subtype distribution differed significantly between the IM+ and IM- tumors

<table>

(p=0.0087). The majority of IM+ cases occurred in the BL1 and MSL subtypes. No IM+ cases were observed in the BL2 or M subtypes, and only 1 was observed in the LAR subtype. IM+ cases occurred at roughly the same frequency in patients with IBC (33%) and non-IBC (37%, p=0.73).

Conclusions

TNBC molecular subtypes differ in their degree of immune infiltration, and most IM+ TNBCs are of the BL1 and MSL subtypes. Our finding that the proportion of IM+ cases was not different between IBC and non-IBC indicates that TILs are recruited to the
tumor microenvironment similarly in IBC and non-IBC tumors. Further, Pietenpol et al recently showed that the MSL signature represents normal stromal cells rather than tumor cells by performing laser-capture microdissection of TNBC specimen. Validation studies are needed to corroborate and further expand upon our findings.

**Title:** Detection of molecular alterations in breast cancer through next generation sequencing of both tumor tissue and circulating tumor DNA: The UC San Diego Moores Cancer Center experience

**Body:**

**Background:** Next generation sequencing (NGS) analysis of actionable molecular alterations has the potential to guide cancer treatment, especially for patients with advanced cancer who have progressed on standard treatment. In this study, we analyzed tumor biopsies and peripheral blood from 62 patients with advanced breast cancer by two different NGS clinical-grade assays for molecular alterations in tumor tissue or in circulating tumor DNA (ctDNA). We used these results to determine if these specimens have potentially “actionable” alterations that could guide cancer therapy.

**Methods:** From 2014 to 2016, 62 patients with advanced breast cancer had plasma sent for ctDNA analysis (Guardant360 assay; 54 to 70 genes) Thirty-eight of these patients (61%) also had tumor biopsies evaluated by NGS (FoundationOne®; 182 to 315 genes). Alterations were defined as mutations, insertions, deletions, truncations, or rearrangements or amplifications/copy number variations. Patients that harbored multiple alterations in the same gene were not counted as having separate alterations; however, if a gene amplification and an alteration were found in the same gene these were counted as separate events. Variants of unknown significance (VUS) and synonymous mutations were excluded from both assays. Data were collected and analyzed according to a UCSD Institutional Review Board approved protocol.

**Results:** The median age of our patients at the time of ctDNA analysis was 55 years (range, 44 to 84 years); the median age at the time of tissue biopsy for NGS was 52 years (range, 39 to 82 years). One patient was male. The most common receptor status was estrogen receptor (ER) and progesterone receptor (PR) positive, human epidermal growth factor receptor 2 (HER2) non-amplified or negative (neg)(N=44; 71%), followed by triple negative breast cancer (ERnegPRnegHer2neg) (N=10, 16%), triple positive (N=6, 1%) and finally ERnegPRnegHER2positive (N=2, 0.03%). One patient of 38 (2%) had no tumor alteration detected and 19 of 62 had no ctDNA alterations (31%). In 38 breast cancer patients with tumor NGS results, alterations were detected in 79 unique genes, with the most frequent being TP53 (37% of patients), PIK3CA (24%) and GATA3 (24%) genes. In the 62 patients with ctDNA analysis, 31 unique genes had at least one alteration, with the most frequent being TP53 (36% of patients) and PIK3CA (23%) and EGFR amplification (11%) (GATA3 was not analyzed in the ctDNA assay). Both assays had a high rate of detection for potentially actionable mutations: 41 out of 62 patients (66%) by ctDNA and 34 out of 38 (89%) by tumor NGS. No two patients harbored identical genomic profiles by either tumor NGS or plasma ctDNA analysis except for 1 patient who had no alterations detected by either assay.

**Conclusions:** Plasma and tissue NGS analysis appear to be complementary assays that yield a high percentage of potentially actionable alterations in patients with advanced breast cancer. Studies of the clinical impact of NGS-guided therapy in breast cancer are warranted.
Title: Multi-level gene expression signatures provide significant prognostic information in metastatic breast cancer patients

Tobin NP P, Lundberg A, Lindström LS S, Harrell JC C, Egyhazi Brage S, Frostvik Stolt M, Einbeigi Z, Loman N, Malmberg M, Perou CM M, Bergh J and Hatschek T. Karolinska Institutet and University Hospital, Stockholm, Sweden; Karolinska Institutet and University Hospital, Stockholm, Sweden; Virginia Commonwealth University, Richmond; Sahlgrenska University Hospital, Gothenburg, Sweden; Skåne University Hospital, Lund, Sweden; Skåne University Hospital, Helsingborg, Sweden and Lineberger Comprehensive Cancer Center, University of North Carolina-Chapel Hill, Chapel Hill.

Body: Background: We have previously demonstrated how transcriptional pathway activity and the molecular subtypes of breast cancer metastases significantly influence patient post-relapse survival. Here we extend our analysis to determine whether the prognostic information provided by gene expression signatures in primary breast tumours is also relevant in the metastatic setting. Specifically, we test the research versions of the Genomic Grade Index (GGI), Mammaprint, Recurrence score (RS) and PAM50 gene signatures along with our own cell-cycle based classifier (CCS).

Methods: 287 patients with morphologically confirmed loco-regional or distant breast cancer relapse were enrolled in the Swedish multicenter TEX trial from December 2002 until June 2007. Of these, sufficient tumour RNA for gene expression profiling was obtained from metastatic tissue by fine needle aspiration from 111 patients (totalling 120 relapse biopsies). Gene signatures were applied as described in the original research articles and their relationship to short (1.5 year) and long-term (5 year) post-relapse survival was assessed using likelihood ratio, Kaplan-Meier and Cox regression analysis.

Results: As anticipated from an aggressive metastatic cohort, the majority of samples (> 70%) were classified into intermediate or high risk groups by all signatures. In both short and long-term survival analysis only PAM50 provided statistically significant prognostic information (short: LR$\chi^2 = 14.7$, p = 0.005 and long: LR$\chi^2 = 13.2$, p = 0.010), with the cell cycle score signature displaying a prognostic trend in long-term survival only (LR$\chi^2 = 5.2$, p = 0.074). Kaplan-Meier curves and Cox regression analysis suggest that the strength of both signatures resides in their ability to select a group of low-risk patients with better long-term survival.

Conclusions: Our findings demonstrate the prognostic utility of the multi-level PAM50 and to a lesser extent, cell cycle score signatures in predicting survival of patients with metastatic breast cancer. Simpler binary gene expression signatures (GGI and Mammaprint) do not appear to capture the same prognostic information and as such may have limited utility in a metastatic setting.

Title: The SCAN-B study: 5-year summary of a large-scale population-based prospective breast cancer translational genomics platform covering a wide geography of Sweden (NCT02306096)

Saal LH H, Hegardt C, Vallon-Chistersson J, Häkkinen J, Ehinger A, Manjer J, Larsson C, Loman N, Rydén L, Malmberg M and Borg Å. Lund University, Lund, Sweden; Blekinge Country Hospital, Karlskrona, Sweden; Skåne University Hospital, Malmö, Sweden; Lund University, Lund, Sweden; Skåne University Hospital, Lund, Sweden and Skåne University Hospital, Lund, Sweden.

Body: Background:
Breast cancer exhibits significant molecular, pathological, and clinical heterogeneity. Current clinicopathological evaluation is imperfect for predicting outcome, which results in overtreatment for many patients, and for others, leads to death from recurrent disease. Therefore, additional criteria are needed to better personalize care and maximize treatment effectiveness and survival. To address these challenges, large-scale population-based studies are needed to develop and evaluate new predictive biomarker tests under real-world conditions.

Methods:
In 2010 we initiated the Sweden Cancerome Analysis Network - Breast (SCAN-B) multicenter prospective study (ClinicalTrials.gov identifier NCT02306096) with longsighted aims to 1) analyze breast cancers with next-generation genomic technologies for translational research in a population-based manner and integrated with healthcare; 2) decipher fundamental tumor biology from these analyses; 3) utilize genomic data to develop and validate new clinically-actionable biomarker assays; and 4) establish real-time clinical implementation of molecular diagnostic and treatment-predictive tests. Eligibility criteria are suspicion or confirmed diagnosis of primary breast cancer. Eligibility will be extended to recurrent breast cancer in late 2016. For all patients, tumor biopsy and/or surgical tumor specimen and baseline blood samples are collected, as well as follow-up blood samples at defined intervals, and clinical data are obtained from regional and national databases. From all samples, DNA, RNA, and protein fractions are isolated, and tissue arrays are constructed. In the first phase, we focus on molecular profiling of tumor tissue by next-generation RNA-sequencing.

Results:
From August 2010 through May 2016, we have consented and enrolled 8,669 patients with primary breast cancer at 9 hospital sites in Sweden, representing approximately 85% of eligible patients in the catchment area. Preoperative blood samples have been collected for 8,288 (96%) patients and primary fresh-frozen tumor specimens collected for 6,129 (71%) patients. All tumors have been RNA-sequenced, and newly enrolled cases are analyzed in “real-time” within an average of 7 days after biopsy/surgery. Herein we describe the study infrastructure and protocols and present initial proof of concept results from prospective RNA-sequencing including tumor molecular subtyping, detection of driver gene mutations, and determination of ER, PgR, HER2, Ki67, and tumor grade from RNA-seq data. Prospective patient enrollment is ongoing and pilot clinical reports are being evaluated at multidisciplinary breast cancer conferences.

Conclusions:
We demonstrate that population-based collection and real-time RNA-sequencing analysis of breast cancer is feasible at large-scale. The SCAN-B Study should significantly reduce the time to discovery, validation, and clinical implementation of novel molecular diagnostic and predictive tests. We welcome the participation of additional comprehensive cancer treatment centers.
Title: Regulation of estrogen receptor-α by NF1

Body: Background. Although great strides have been made in targeting the ER pathway for treating ER+ breast cancer, relapse and death is common and is closely linked to resistance to ER-targeting agents. As a result, the majority of deaths from breast cancer still come from ER+ tumors. To discover drivers for endocrine resistance, we have sequenced tumor DNAs from a cohort of >600 patients treated with 5-year tamoxifen (Tam) monotherapy with a median 10.4 years follow up. Our preliminary data show that the worst outcome mutations (Hazard Ratio of ∼3 for relapse) were mostly those of the Neurofibromatosis type 1 (NF1) gene (encoding Neurofibromin), with nonsense/frame shift mutations creating early stop codons.

Germline NF1 mutations cause neurofibromatosis type 1, a common inherited disorder that predisposes individuals to both benign and malignant tumors of the nervous system, as well as an increased risk for breast cancer. Analysis of DNA sequencing data has also shown that the NF1 gene is mutated in a wide range of common cancers (e.g., melanoma, lymphoma, and cancers of the lung, breast, and colon). Thus, NF1-deficiency underlies the formation and/or progression of a large number of cancers, so that the development of therapies targeted to NF1-deficient malignancies would have broad impact.

These observations support the hypothesis that NF1 gene inactivation is associated with aggressive tumor behaviors, such as endocrine therapy resistance in breast cancer. The key focus of this study is to define how the NF1 protein neurofibromin, regulates endocrine therapy resistance. Although neurofibromin is best known as a negative regulator for Ras, our data show that it may have other functions.

Method. Our data suggest that many of the identified nonsense/frame shift create a NF1 null state; thus, we have used gene-silencing to recapitulate the effects of such NF1 mutations on the activities of ER+ breast cancer cells. NF1+ and NF1– ER+ breast cancer cells were grown in defined media to measure how estradiol (E2) and Tam impact their growth, transforming activities, and gene expression. The binding between neurofibromin and components of the ER transcriptional pathway was measured biochemically and using the mammalian two-hybrid system.

Results. Our data showed that NF1-silenced cells use Tam as an agonist and can grow with very little E2, and these activities are driven by enhanced recruitment of ER to the ERE, leading to efficient expression of many classic ER-responsive genes. Expressing the NF1-GAP domain does not restore normal responses to Tam and E2 in NF1-silenced cells, suggesting that neurofibromin can regulate ER activity in a Ras-independent manner. To investigate the possibility that neurofibromin can directly regulate ER, we found that it can bind ER; furthermore, neurofibromin was more strongly recruited to the ERE by Tam than by E2.

Conclusion. Our data support a model whereby neurofibromin acts like a co-repressor for ER. As such, NF1 loss may result in more aggressive tumor behaviors by activating, not only the Ras pathways, but also the ER transcriptional pathways. Simultaneous activation of two powerful oncogenic pathways by the loss of a single tumor suppressor may explain why neurofibromin is such a potent tumor suppressor lost in a wide range of cancers.

Title: Mutant GATA3 actively promotes the growth of normal and malignant mammary cells

Kenny PA A, Chandiramani N and Lofgren KA A. Gundersen Medical Foundation, La Crosse, WI and Albert Einstein College of Medicine, Bronx, NY.

Body: GATA3 is a transcription factor expressed in luminal breast epithelial cells and is required for mammary gland development. Analysis of TCGA data reveals that somatic heterozygous mutations in GATA3 occur in up to 15% of estrogen receptor positive breast tumors, and that these tumors are diagnosed a median of eight years earlier than other estrogen receptor positive tumors, suggesting a more aggressive phenotype. These mutants have been proposed to be null alleles resulting in haploinsufficiency, however the mutation spectrum of GATA3 in breast cancer is in sharp contrast to that found in HDR syndrome, a true GATA3 haploinsufficiency disease. Based on this disparity, we propose that there is a selective pressure to mutate and retain a portion of the GATA3 in breast cancer. Here we focus on the GATA3 mutants which lack the second zinc finger which is responsible for GATA motif binding. Expression of these mutants accelerated xenograft tumor growth by ZR751 cells, and transgenic expression in mouse mammary glands promoted precocious lobuloalveolar development. We have used integrated gene expression and ChIP-Seq profiling to demonstrate that these zinc-finger deleted proteins retain the ability to associate with the genome by tethering to complexes associated with FOXA1 and AP-2gamma recognition motifs, where they modulate the expression of adjacent genes. These data support a model in which the GATA3 mutations recently observed in breast cancer encode for active transcription factors which elicit proliferative phenotypes in normal mammary epithelium and promote the growth of estrogen receptor positive breast cancer cell lines.

Title: Identification and characterization of a novel endoxifen substrate, PKCβ1, and its interaction with the estrogen receptor

Body: Background: The primary mechanism by which tamoxifen (Tam) and its metabolites exert their biologic effects is through estrogen receptor (ER) binding and inhibition of ER signaling. We and others demonstrated that endoxifen (Endx) has greater antitumor activity in vitro and in vivo compared to Tam and the first-in-human Endx phase I study demonstrated its antitumor activity in patients with prior progression on Tam (Goetz SABC 2015). PKCs are a family of serine/threonine-specific protein kinases that regulate signaling pathways involved in cell proliferation and tumorigenic transformation. Our prior protein docking studies suggested endoxifen may be a substrate for PKCs. Here we report the effects of Tam and Endx on PKCβ1 binding, kinase activity, as well as interactions between PKCβ1 and ERα.

Methods: Surface Plasmon Resonance (SPR, Biacore T200, GE Healthcare) was used to evaluate binding of Tam, N-desmethyl Tam (NDMT), 4-HT, and Endx to PKCβ1 and PKCβ2. The effects of Tam and Endx on PKCβ1 kinase activity were determined. Proliferation and colony formation in MCF7 parental and PKCβ1 overexpressing cells were evaluated. siRNA silencing was used to knockdown PKCβ1 expression in the following cells: MCF7 aromatase expressing cells that were either sensitive (MCF7/AC1) or resistant to letrozole (MCF7/AC1 L-resistant); T47D; and MDA-MB-361. Coimmunoprecipitation assay and DUOlink in situ proximity ligation were used to investigate the interaction between PKCβ1 and ERα.

Results: Endx more potently inhibited PKCβ1 kinase activity compared to Tam (IC50 350 nM vs 47.8 µM) with Kd's for PKCβ1 binding as follows: Endx (100 nM), Tam (2 µM), 4-HT (2 µM) and NDMT (> 7 µM). None of the SERMs exhibited PKCβ2 binding. In the MCF7/AC1 and MCF7/AC1 L-resistant cells, PKCβ1 knockdown resulted in ERα degradation and potently inhibited cell proliferation. These results were confirmed in T47D and MDA-MB-361 cells. Notably, PKCβ1 knockdown in MCF7/AC1 cells resulted in significantly greater E2 induced proliferation comparing siRNA knockdown vs. control. To further explore these effects, we evaluated the effects of PKCβ1 overexpression in MCF7 cells and demonstrated that PKCβ1 overexpression reduced cell proliferation and colony formation compared to parental MCF-7 cells without affecting ERα protein stability. Coimmunoprecipitation assays in transient transfected MCF-7 cells with exogenous PKCβ1 as well as PKCβ1 expressing MDA-MB-231 cells transiently or stably transfected with ERα demonstrated PKCβ1 and ERα interaction, with confirmation by Duolink assay that this interaction occurs in the cytoplasm.

Conclusions: Our findings demonstrated that endoxifen binds and inhibits PKCβ1 at relevant concentrations achieved in the endoxifen clinical trial studies. PKCβ1 interacts with cytoplasmic ERα and PKCβ1 knockdown inhibits cell proliferation and enhances ERα turnover. However, in PKCβ1 overexpressing cells, PKCβ1 may exhibit tumor suppressive effects. These data suggest a complex interaction between PKCβ1 and ERα and that endoxifen's effects on PKCβ1 may alter drug response of endocrine therapy. Further studies are ongoing to characterize the role of PKCβ1 and its role in ER biology and response to endoxifen.
Title: SOX9 is a critical regulator of triple-negative breast cancer cell growth and invasion

Ma Y, Shepherd J, Mazumdar A, Zhao D, Bollu L, Hill J, Zhang Y and Brown P. UT MD Anderson Cancer Center, Houston, TX.

Body: Background: SRY (Sex Determining Region Y)-related HMG-box (SOX) genes belong to a super-family of genes, which is characterized by a homologous sequence called the HMG-box residing on the Y-chromosome. There are 20 SOX genes present in humans and mice. We performed a siRNA screen of SOX transcription factors, and found that SOX9 was essential for breast cancer cell growth. The SOX9 protein recognizes the sequence CCTTGAG along with other members of the HMG-box class DNA-binding proteins and has been shown to be required for development, differentiation and lineage commitment. Moreover, SOX9 is expressed in adenocarcinomas, and is highly expressed in the most aggressive cancers. Our previous data shows SOX9 is highly expressed in “triple negative breast cancer” (TNBC) than in non-TNBC. Thus, we hypothesized that the SOX9 transcription factor acts as an essential molecule regulating TNBC growth and invasion. To test the hypothesis, we used SOX9-overexpressed, or SOX9-knockdown/knockout breast cancer cell models to determine whether SOX9 is necessary and/or sufficient to regulate TNBC cell proliferation, migration and invasion.

Methods: We measured the cell growth using an automated cell counting assay. Cell migration and invasion were detected by transwell migration & invasion assays in ER-positive (MCF7 and ZR75-1) and ER-negative (MDA231 and MDA468) breast cancer cells. DOX-inducible SOX9-knockout cell lines were established in MDA231, MDA468, and LM2 cell lines using an inducible Cas9-CRISPR system. A SOX9 expressing lentivirus was used to overexpress SOX9, and siRNAs was used to knockdown SOXs in the different breast cancer cells. Protein and mRNA levels of SOX9 in TNBC, non-TNBC, immortalized human breast epithelial cell lines were examined by western blotting and qRT-PCR assay.

Results: Knockdown of SOXs by siRNA caused decreased cell proliferation of MDA231 by ≥50% and of MDA468 by 30%-50% in siSOX4, siSOX6, siSOX9, siSOX10 and siSOX11 treatment groups (but not in siSOX8 and siSOX17 treatment groups). However, in MCF7 and T47D cell lines, treatment with siRNA to these SOX factors did not cause significant cell growth reduction. We demonstrated that SOX9 is more highly expressed in TNBC cells at both the mRNA and protein levels. Knockdown of SOX9 decreased cell migration and invasion of MDA231 to 25% and 50% respectively. The same effect also was observed in MDA468 cells, with approximately a 50% decline in migration and invasion. In SOX9-knockout MDA231, MDA468, and LM2 cells, cell proliferation, migration, and invasion were significantly reduced. In contrast, overexpression of SOX9 in MCF7 and ZR75-1 cells increased cell migration and invasion. We are now conducting in vivo studies to determine the effect of SOX9 on breast cancer cell metastasis.

Conclusion: SOX9 is a critical regulator of TNBC cell proliferation, migration and invasion. These studies suggest that regulating SOX9 transcription factor and its signaling pathway will be a promising therapeutic strategy to treat TNBC and prevent metastasis.

Title: Discovering drug targets for aggressive breast cancer with TP53 missense mutations by a genome-wide screen

Pal A, Park J, Gonzalez-Malerva L, Eaton S and LaBaer J. The Biodesign Institute, ASU, Tempe, AZ.

Body: Breast cancer is a heterogeneous disease and has subtypes with distinct phenotypic and molecular characteristics. Genetically, 30% of all breast tumors and 80% of the basal-like breast cancer (BLBC) subtype harbor mutations in TP53 and numerous sporadic somatic mutations in other genes. This molecular heterogeneity has posed a challenge in developing safe and effective therapeutic regimens to treat a broad spectrum of breast cancer patients, and discovery of intra-subtype along with inter-subtype heterogeneity has added another layer of complexity for targeted therapies. Based on the analysis of somatic mutation profiles in the BLBC subtype, we identified a wide variety of TP53 missense mutations and thousands of co-existing mutations, which led us to hypothesize that intra-subtype heterogeneity is derived from combinatorial effects of neo-morphic (gain-of-function) activities of different types of missense mutant p53 proteins and complex interplay between specific driver mutations in TP53 and a distinct subset of functionally important co-mutations (or “co-drivers”). We ectopically overexpressed the ten most prevalent missense mutations in TP53 found in breast cancer tumors in non-transformed mammary epithelial cells and examined their cellular functions associated with the hallmarks of cancer. The results showed widely different spectrums of phenotypic changes in cell proliferation, resistance to apoptosis, cell invasion, anoikis resistance and cell polarity. As a proof of concept for the ‘co-drivers’, we knocked-out PTEN in a non-invasive TP53 mutant cell using the CRISPR and shRNA systems. Inactivation of PTEN in non-invasive TP53-mutant cell increased its invasiveness. TP53 mutations and PTEN deletions are frequent in BLBC patients, who have significantly higher rates of metastasis, recurrence and a lower survival rate than the other subtypes. The absence of three signaling hormone receptors, which can be targeted by specific inhibitors, significantly limits available therapies for the majority of BLBC patients to surgery and cytotoxic chemo/radiotherapies. Combination therapies targeting the driver and co-driver gene associated pathways could be quite promising solutions to treat aggressive breast cancer cases. To address this, we have developed a genome-wide CRISPR based gene knock-out screening approach to test the effect of loss-of-function of individual human genes in clinically important TP53 mutant backgrounds that can promote cancer-like behaviors and identify the combinations of ‘TP53 mutation and co-driver pathways’ that can be targeted by specific inhibitors.
Title: BC200 IncRNA is involved in the progression of triple negative breast cancer

Barton M, Santucci-Pereira J, Su Y and Russo J. Temple University School of Medicine, Philadelphia, PA and Fox Chase Cancer Center, Philadelphia, PA.

Body: Long non coding RNAs (lncRNAs) have been identified as regulators of the cell cycle, apoptosis, and DNA damage among other processes that if deregulated, may lead to cancer by acting as proto-oncogenes, tumor suppressor genes, and drivers of metastatic transformation. Using RNA sequencing we have identified 42 differentially expressed lncRNAs from a healthy cohort of parous vs. nulliparous women. After bioinformatics and RT-qPCR analysis, we have focused on a vaguely studied lncRNA called BC200 that is highly expressed in the nulliparous postmenopausal breast tissue. It is known that BC200 lncRNA is overexpressed in invasive and pre-invasive breast cancer; however, its functional role in the initiation and progression of breast cancer is poorly understood. In the present work we provide insight on the role of BC200 in the context of luminal and triple negative breast cancer (TNBC). We have confirmed that BC200 is highly expressed in breast cancer tissue and in widely used breast cancer cell lines such as MCF7, T47D, MDAMB231, and Hs578T. Using a lentiviral system we successfully obtained cell lines which stably express BC200. Overexpression of BC200 increases proliferation, migration, and invasion potential in vitro in the cell lines tested, specifically luminal T47D and TNBC MDAMB231. Xenograft studies performed in the mammary fat pad of female SCID mice confirm the role of BC200 as a tumor promoter. Tumors in mice injected with MDAMB231 cells overexpressing BC200 were 4.5 times bigger than tumors in the control group in only 6 weeks when injecting 1 million cells. Moreover, we have determined, using reverse transcriptase PCR targeting genes less than 200 kb from the start site of BC200, that when BC200 is overexpressed, CALM2 is downregulated in both T47D and MDAMB231 cell lines. CALM2 or Calmodulin is a calcium binding protein that plays a role in signaling pathways, cell cycle progression, proliferation, and apoptosis. Mutations in CALM2 are associated with increased risk of breast cancer. Our positive results on Cis regulation are being expanded using chromatin isolation by RNA immunoprecipitation to determine BC200’s genome wide regulation. These results demonstrate the participation of BC200 IncRNA in the progression of breast cancer. Notably, BC200 regulates nearby genes that have an implication in cancer progression. BC200, identified in the normal breast tissue of nulliparous women, not only plays a key role in breast cancer progression but also provides a new insight in the preventive role of pregnancy by the downregulation of the expression of this IncRNA in the normal parous breast. Title: Assessing the impact of loss of NF1 protein on endocrine therapy resistance

Cakar B, Chan D, Yan P, Zheng Z, Singh P, Lei JT Thomas, Haricharan S, Ellis M and Chang E. Baylor College of Medicine, Houston, TX.

Body: Background: The vast majority of breast cancers belong to the luminal subtype, which expresses the estrogen receptor-α (ER). Although great strides have been made in targeting the ER pathway for treating the ER+ tumors, relapse and death is common and ongoing. In order to identify the cause for treatment resistance, we have conducted a retrospective analyses on the tumor genomes of >600 patients treated by tamoxifen monotherapy in the adjuvant setting with a median follow-up of 10.4 years. Our data have revealed that NF1 (Neurofibromatosis type 1) gene loss of function mutations were greatly associated with poor prognosis. NF1 is a tumor suppressor acting mostly as a GAP (GTPase activating protein) to switch off activated Ras. We aim to define the impact of loss of NF1 protein on patient outcome in ER+ breast cancer patients by establishing an immunohistochemistry (IHC) protocol to detect NF1.

Method and results: We have first surveyed commercially available antibodies by Western blot and found one that could efficiently detect endogenous NF1. We then use this to validate inducible shRNA clones against NF1, as well as a breast cancer cell line that is NF1-null. This antibody has high background. We have thus partially purified a commercially available NF1 antibody by preclearing using NF1-null cell lysate. We then performed immunostaining using NF1-silenced and null cells as control and found that NF1 is mostly cytoplasmic and nuclear. To get antibody of high quality, we have decided to make our own antibody by expressing a C-terminal fragment of NF1 as a GST-tagged protein (GST-NF1c). Production of polyclonal and monoclonal antibody is in progress.

Conclusion: Our clinical profiling data suggest that loss of NF1 protein, a very common event in a wide range of other cancers, promotes endocrine therapy resistance. An efficient IHC protocol will enable us to firmly validate whether loss of the NF1 protein indeed correlates with poor patient outcome. This method will ultimately enable us to identify high risk NF1 deficient patients and to properly treat them.
Identification of tumor-promoting and tumor-inhibiting genes with age dependent expression in breast cancer patients

Gu X, Zhu H and Sun L. University of Texas Health Science Center, San Antonio, TX.

Age is the number one risk factor for breast cancer development. The breast cancer incidence rate increases with age, following beta distribution, which is approximately linear in range from 30 to 70 years old [1]. Transcriptome alterations have been shown to promote tumorigenesis for many types of cancers. Therefore, we hypothesize that the genes with altered expression during aging may promote breast cancer development and/or progression. Using The Cancer Genome Atlas data, we extracted whole transcriptome profiling data of matched normal tissues from 82 female patients with age at diagnosis and menopausal status available. First, we applied simple linear regression to study the association between gene expression level and age at diagnosis on all the 82 patients. 258 upregulated and 240 downregulated genes are identified, which are associated with age. Secondly, 493 upregulated and 254 downregulated genes are identified that are altered by menopause by comparing post-menopausal to pre-menopausal patients (FDR < 0.05). Exclusion of these menopause affected genes from those genes affected by age (258 upregulated and 240 downregulated) results in 148 upregulated and 189 downregulated genes during aging. Thirdly, by comparing matched tumor and adjacent normal samples, 3356 upregulated and 3124 downregulated genes are found to be associated with tumorigenesis. Overlapping of tumorigenesis associated genes with age dependent genes result in 14 upregulated and 24 downregulated genes that are both age and tumorigenesis associated. This discovery is being validated with normal breast tissues from donors in GTEx cohort. Experimental manipulation of the upregulated genes in seven breast cancer cell lines, representing five subtypes of breast cancer, demonstrated their essential role in promoting tumor malignancy, suggesting the upregulation is not merely passenger event. In a large mixed cohort, this panel of genes have significant predictive value in relapse free survival of breast cancer patients.

**Title:** Aurora kinase-A protein stability is negatively regulated by eEF1α2 and PTEN in breast cancer: Prognostic and therapeutic implications

Treekitkarnmongkol W, Kai K, Katayama H, Tian W, Rodriguez-Canales J, Sahin AA A and Sen S. The University of Texas M.D. Anderson Cancer Center, Houston, TX and Okayama University, Okayama, Japan.

**Body:**

**Background:** The AURKA gene encoding Aurora kinase-A (Aurora-A) protein is localized on chromosome 20q13 that is frequently amplified and overexpressed across multiple cancer types correlating with patient prognosis. Aurora-A plays a pivotal role in faithful segregation of chromosomes and normal progression of mitosis, peaking at G2/M followed by degradation at the end of mitosis by APC/C (Cdh1). However, regulation of Aurora-A protein stability in human cancer cells is not well elucidated. Here, we show that Aurora-A is targeted for ubiquitination and degradation by SCF complex involving eEF1α2 and PTEN in human breast cancer cells. **Methods:** Using a panel of breast cancer cell lines, as in vitro models, the eEF1α2 was knocked down or ectopically expressed to test the stability of Aurora-A protein. For in vivo models, tissue micro arrays of human breast cancer were immunostained for Aurora-A and eEF1α2 expression and categorized values were statistically tested by Chi-squared test. In addition, the public breast cancer dataset (Transbig) was used to predict breast cancer prognosis by Kaplan-Meier survival analysis. **Results:** In breast cancer cell lines and patient samples, an eEF1α2 non-expressing group showed a trend of higher Aurora-A expression than eEF1α2 expressing group, whose trend was significant in patient samples (P<0.05). Knocking down of eEF1α2 enhanced Aurora-A protein stability. In contrast, ectopic expression of eEF1α2 dramatically decreased Aurora-A protein stability. Inhibition of proteasome activity by MG132 could restore the Aurora-A protein in eEF1α2 expressing cells. Biochemical assays showed the direct binding between eEF1α2 and Aurora-A, and eEF1α2 dependent ubiquitination of Aurora-A. Inverse correlation of the expression levels of the two proteins was also observed throughout the cell cycle, with eEF1α2 levels being high from G1 through G2 phases while Aurora-A expression peaked from G2/M phase through cytokinesis. Taken together, these findings highlight eEF1α2 as a novel negative regulator destabilizing Aurora-A through ubiquitin-proteasome proteolytic pathway. Further, mechanistic studies revealed that eEF1α2 enhanced the interaction of SCF E3 ubiquitin ligase complex protein; FBXW7 and Cul1, with Aurora-A. In line with this scenario, knocking down of Cul1 increased Aurora-A level. Since PTEN loss was reported to stabilize Aurora-A through inhibiting SCF complex, we tested the significance of PTEN loss in our model. Knocking down of PTEN further stabilized Aurora-A suggesting an independent role of PTEN from eEF1α2 in destabilizing Aurora-A. When eEF1α2 expressing cells were treated with AKT inhibitor, Aurora-A was destabilized with enhanced bindings between Aurora-A and FBXW7/Cul1. Lastly, low PTEN expression correlated with poor prognosis of Aurora-A over expressing breast cancer patients (P<0.01). **Conclusions:** Aurora-A overexpression in human breast cancer cells may be associated with loss of eEF1α2 and PTEN due to reduced interaction of SCF with Aurora-A. Findings indicate significant prognostic and therapeutic implications of altered expression of eEF1α2/PTEN/Aurora-A pathways among Aurora-A subset of breast cancer patients.
Title: Introduction of H1047R oncogenic mutation of PI3K p110alpha subunit in HER2-overexpressing mammary epithelial cells confers a "stem-like" phenotype and acute sensitivity to HSP90 inhibition

Surendran S, Bhola N, Arteaga CL L, Chakraborty K and Chakrabarty A. Shiv Nadar University, Greater Noida, UP, India; University of California-San Francisco, San Francisco, CA; Vanderbilt University, Nashville, TN and CSIR Institute of Genomics and Integrative Biology, Delhi, India.

Body: The Human Epidermal Growth Factor Receptor 2 (HER2) oncogene is amplified in one-fifth of breast cancers (BC). However, development of resistance against standard anti-HER2 therapies poses a major clinical challenge. Anti-tumor efficacy of HER2-targeting agents depends on inhibition of the downstream phosphatidylinositol-3 kinase (PI3K) signaling cascade. Gain-of-function somatic mutations in the gene encoding the PI3K catalytic subunit p110alpha (PIK3CA), co-expressed in about 40% of HER2+ BC, have been implicated in conferring resistance to HER2 monoclonal antibody herceptin. The single amino acid alteration H1047R within the kinase domain of PIK3CA is one of three hot spot mutations prevalent in BC. Previously, we demonstrated that introduction of H1047R mutation in HER2-overexpressing MCF10A mammary epithelial cells enhances cellular transformation and decreases herceptin sensitivity by inducing secretion of endogenous ErbB ligand heregulin. However, genetic ablation of HER3, the major co-receptor for HER2 and the solitary receptor for heregulin, was insufficient for complete inhibition of cell growth, indicating the existence of additional mechanism/s responsible for the heightened aggressiveness and decreased drug sensitivity of HER2/H1047RPI3K cells. In the current study, we looked further into the molecular changes within these cells that might be responsible for these phenomena.

When compared with the HER2/WTPI3K cells, the HER2/H1047RPI3K cells revealed a significant increase in CD44<sup>high</sup>/CD24<sup>low/negative</sup> populations, common markers of BC stem cells, as well as molecular and phenotypic changes associated with epithelial-to-mesenchymal transition. These observations are in agreement with previously published report on mouse model of HER2/H1047RPI3K BC. Further analyses demonstrated additional stem cell-associated characteristics in HER2/H1047RPI3K cells, such as expression of angiogenic and inflammatory cytokines, ability to induce chemotaxis and invasion, activation of TGFb and NFKb signaling pathways. Connectivity map (CMap) analysis of the gene expression signatures from HER2/H1047RPI3K cells revealed a negative association with those from BC cells treated with 17AAG, an inhibitor of the heat shock protein 90 (HSP90). In line with this, HER2/H1047RPI3K-expressing cells are found to be more sensitive to HSP90 inhibition compared to the pan-ErbB inhibitor lapatinib.

Cancer stem cells are implicated in drug resistance and tumor recurrence. Enrichment of cell population expressing high levels of stem cell markers and stem cell-related features could be one of major mechanisms by which BC cells co-expressing HER2 and H1047RPI3K adapt to anti-HER2 therapeutic agents. Acute dependence on molecular chaperone HSP90 provides a unique, yet practical opportunity to effectively inhibit tumors harboring both molecular alterations, since HSP90 inhibitors have already shown encouraging clinical activity in herceptin-resistant setting.
Title: UHRF1 promotes breast cancer progression via suppressing KLF17 expression

Gao S-P, Sun H-F, Li L-D and Jin W. Key Laboratory of Breast Cancer in Shanghai, Collaborative Innovation Center of Cancer Medicine, Fudan University Shanghai Cancer Center, Shanghai, China and Shanghai Medical College, Fudan University, Shanghai, China.

Body: Background: UHRF1, also termed as ICBP90 or Np95, is reported to be an epigenetic regulator of DNA methylation and histone modifications, which takes pivotal functions in cell differentiation and tumorigenesis. Here, we show that UHRF1 is markedly increased in breast cancer tissues and cell lines. And patients with high UHRF1 expression have a poor prognosis compared with those in low UHRF1 expression as showed by Kaplan Meier plotter analysis. However, the underlying mechanisms of UHRF1 in breast cancer remain largely unknown. Thus, the aim of this study is to validate potential mechanisms of UHRF1 in breast cancer cells.

Methods: The stable cell lines were constructed using interference and overexpression methods and the efficiency was confirmed by western blot. Then cell proliferation and migration were evaluated by CCK8 and transwell assay. The MDA-MB-231 pCDH and pCDH-UHRF1 cells were inoculate into mouse left flank to further testify UHRF1 function in vivo. Furthermore, microarray and ChiP-seq were implemented to detect potential mechanisms and the candidate genes were assessed by ChiP and qPCR. The BSP or MSP primers were designed by the methprimer database. Genomic DNA was prepared from breast cancer cells and then the genomic DNA was bisulfite modified using EZ DNA Methylation-Gold Kit. The methylation PCR products were cloned into pMD-18T and ten positive clones were sequenced. The data were analyzed using the QUMA analyzer software.

Results: We found that UHRF1 was indeed increased in breast cancer tissues and cells. And patients with high levels of UHRF1 were likely to have a shorter disease-free survival than patients with low levels. UHRF1 overexpression can promote cell proliferation and migration while UHRF1 downregulation have inverse functions. In vivo, UHRF1 also accelerate tumor growth on mice. Mechanistic studies revealed that 9 candidate genes were obtained by analysis from ChiP-seq and microarray databases. The further verification showed that Krüppel-like factor 17 (KLF17) is the most significantly upregulated one when UHRF1 gene was depleted, with rich CpG islands on its promoter region. We also observed that an inverse relationship between the expression of UHRF1 and KLF17 both in breast cancer cell lines and tissues. What's more, cells proliferation and migration which were inhibited by UHRF1-depletion can be rescued by KLF17 silence, suggesting UHRF1 promote breast cancer proliferation and migration through downregulating KLF17 expression. Moreover, overexpression of UHRF1 increases the methylation of CpG nucleotides and reduces the expression of KLF17 while depletion of UHRF1 decreases the methylation of CpG nucleotides with elevating expression of KLF17.

Conclusion: Our results demonstrate that increased UHRF1 can promote breast cancer cell proliferation and migration by epigenetic silencing of KLF17 expression through CpG islands methylation in its promoter region. These results provide insight into the breast cancer progression process and suggest that making changes in this mechanism represent new therapeutic approaches to block breast cancer development.
Title: p53 status and 17q21.3 amplicon formation in HER2-positive breast cancer

Tan G, Seeliger M and Cohen J. Stony Brook University, Stony Brook, NY.

Body: Breast cancers that overexpress HER2/neu are associated with poor clinical outcome. Treatment of HER2-positive breast cancers with trastuzumab, a monoclonal antibody that antagonizes HER2 receptor signaling, increases patient overall and disease-free survival. While targeted therapy is reasonably effective, resistance to trastuzumab remains a problem, particularly in the case of metastatic disease. Tumor suppressor p53 is the most commonly mutated gene in human cancer and mutations that lead to the stabilization and accumulation of p53 in HER2-positive breast cancers are associated with worse clinical outcome. Another feature of HER2-enriched breast cancers are amplifications of the HER2 locus on chromosome 17q21.3.

Table 1: Among 58 cases, Her2-positive tumors with mutated p53 (n=37, 63.9%) occurred at a 4.9-fold higher frequency than amplification of the 17q21.3 gene set (n=8, 13.1%), with significant mutual exclusivity (p=0.005). The patient genomic data set was obtained from the Breast Invasive Carcinoma Study conducted by the TCGA Network (Nature, 2012) and visualized using cBioPortal (MSKCC), Copy alterations of genes were assessed using GISTIC2.0 (Broad Institute) via cBioPortal.

We studied the genomic profiles of 58 HER2-positive breast tumor samples using cBioPortal to determine p53 mutation status. 74.1% of samples expressed mutant p53 and a large fraction of mutations occurred in the key DNA binding domain. We assessed the amplification status of 24 genes within the chromosome 17q21.3 locus as an indicator of amplicon formation, and found that 21.8% of breast tumors demonstrated copy number amplification (Table 2). Mutant p53 tumors with no amplicon formation occurred 5 times more frequently than tumors with only 17q21.3 amplicon formation. These alterations tended to occur exclusive of one another (p=0.005, Table 1). Separately, using gene expression data from Kaplan-Meier Plotter, we observed that alterations in gene expression within the 17q21.3 amplicon can have differential effects on the survival of HER2-positive breast cancer patients (Table 2).

Table 2: List of relevant genes within the chromosome 17q21.3 amplicon. Genes in this amplicon can influence both beneficial and hazardous survival outcomes in HER2-positive breast cancer patients (n=208). Hazard ratios (HR) were determined from gene expression data available through Kaplan-Meier Plotter (Gyorffy, 2010).
Our data shows that HER2-positive breast cancers can be divided into p53 mutant and non-mutant subsets with p53 mutations relatively exclusive to 17q21.3 gene amplification. However, p53 mutation status and 17q21.3 copy number have a variety of effects on patient outcome. We are interested in understanding the interaction between these two genetic alterations and whether subdividing HER2-positive breast cancer into these subtypes will improve our ability to provide effective therapy to patients.
The clinical importance of nuclear wild-type p53-induced phosphatase 1 (Wip1) expression in breast cancer patients

Inoue Y, Yamashita N, Tokunaga E, Kitao H, Tanaka K, Saeki H, Oki E and Maehara Y. Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan and 2) National Hospital Organization Kyushu Cancer Center, Fukuoka, Japan.

Body: Backgrounds; The wild-type p53-induced phosphatase 1 (Wip1) is a member of the serine/threonine protein phosphatases, and plays an important role in the nucleus as one of the key components in the DNA damage response network. Wip1 is encoded by the protein phosphatase magnesium dependent 1 delta (PPM1D), sited on locus 17q23. PPM1D gene amplification and/or Wip1 expression have been observed in numerous tumors, including breast cancer. PPM1D is referred to as oncogene, as Wip1 inhibits phosphorylation of p53 and work as a negative regulator in cell death. Inhibition of Wip1 may have an important therapeutic role in suppressing tumor growth and evolution.

Aims; We evaluated the expression of Wip1 mRNA, Wip1 protein and PPM1D DNA copy number to clarify the relationship between Wip1 expression and the clinicopathological features and prognosis to determine the biological significance of Wip1.

Materials and Methods; Breast cancer cell lines (MCF7, T47D, MDA-MB231, HCC1937, HS578T, BT20 and SKBr3) were used for Wip1 expression analysis and copy number analysis. The specimens were obtained from Japanese breast cancer patients who underwent surgery without neoadjuvant chemotherapy or endocrine therapy in our department. Wip1 mRNA expression was evaluated in 140 cases by quantitative RT-PCR and Wip1 protein expression was evaluated in 192 cases by immunohistochemistry (IHC). The PPM1D DNA copy number was analyzed by genomic PCR in 33 breast cancer cases and by SNP-CGH array (Illumina, Human Omni 2.5-8) in 12 cases. The effects on the cell growth of the Wip1 inhibitor (GSK2830371) were analyzed by the viability assay in MCF7.

Results; Wip1 mRNA expression was significantly higher in MCF7, luminal type cell line. There was no significant correlation between Wip1 mRNA expression and prognosis. In IHC, positive nuclear Wip1 protein expression was detected in 21 cases (10.9%). There was no significant correlation between Wip1 mRNA expression and Wip1 protein expression. There was no significant association between the Wip1 protein expression levels and the clinicopathological factors and the prognosis. PPM1D DNA copy number significantly correlated with Wip1 protein expression (p=0.0035). Copy number gain at 17q23 was detected in 6 cases by SNP-CGH array, and all of these six cases showed positive nuclear Wip1 expression. PPM1D copy number gain was not observed in Wip1 negative cases. In the cell viability assay, the MCF7 cell growth was suppressed by Wip1 inhibitor administration.

Conclusions; Wip1 protein expression in nucleus is important as oncogene, and its expression may be regulated by PPM1D copy number gain. Wip1 is considered to be the new therapeutic target for breast cancer patients.
**Title:** Impact of MAF gene amplification on disease recurrence and effects of adjuvant zoledronic acid in early breast cancer

Coleman R, Hall A, Bell R, Cameron D, Marshall H, Jean-Mairet J, Tercero J, Rojo F, Albanell J and Gomis R. University of Sheffield, Sheffield, United Kingdom; University of Leeds, Leeds, United Kingdom; Andrew Love Cancer Centre, Geelong, Australia; University of Edinburgh, Edinburgh, United Kingdom; Inbiomotion SL, Barcelona, Spain; Fundación Jiménez Díaz, Madrid, Spain; Hospital del Mar, Barcelona, Spain and Institute for Research in Biomedicine (IRB Barcelona) and Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.

**Body:**

**Background:** Meta-analysis of clinical trials has shown that adjuvant bisphosphonates reduce bone metastases and improve survival in postmenopausal (PM) pts\(^1\). However, we are unable to select pts most likely to benefit. To address this, the recently identified early breast cancer bone relapse biomarker, 16q23(\textit{MAF}) gain (\textit{MAF}+)\(^2\), was tested retrospectively in the large prospectively randomized AZURE trial\(^3\) of standard adjuvant therapy +/- zoledronic acid (ZOL) to determine the prognostic value of MAF and its potential to predict the effects of ZOL on disease outcomes.

**Materials and methods:** All analyses were performed with ethics approval and consent. The biomarker analysis was completed on TMAs from primary tumors. Quadruplicate cores of breast tumor tissue were arrayed across replicate TMAs. MAF+ was detected using a validated (\textit{MAF}/\textit{D16Z3}) FISH test (Inbiomotion SL, Barcelona, Spain). A central laboratory (Targos, Kassel, Germany) validated the assay for analytic and diagnostic performance, established acceptance criteria, included appropriate quality controls for each assay, and performed the analyses in a blinded fashion. A copy number cut-off $\geq 2.5$ was preset for MAF+. Invasive disease free (IDFS), overall (OS) survival and time to bone metastases multivariate analyses were performed in control and ZOL pts separately. Subsequently, interactions between MAF+ and effects of ZOL on disease outcomes by menopausal status were evaluated.

**Results:** 1769 of the 3360 AZURE pts donated primary tumor samples. Median follow-up was 84 months. 865 pts (49%) had 2 FISH evaluable cores and were included in the analysis of which 184 (21%) had MAF+ tumors. Tumors that were MAF+ were more likely to be of higher grade, ER-ve and Her2+.

In control pts, MAF was not prognostic for IDFS or OS although there were differences in IDFS by menopause (HR for MAF-/MAF+ in PM=0.47 [95%CI 0.25-0.88]; HR in non-PM=1.58 [0.82-3.03], test for interaction (TFI) by menopause $P=0.007$). In ZOL pts, MAF was prognostic for IDFS (HR=0.52 [0.36-0.75] and OS (HR=0.48 [0.31-0.75]). There were insufficient bone events (19 MAF+, 73 MAF-) in this sample set to reliably assess the impact of MAF+ on relapse in bone.

In pts with MAF- tumors, ZOL was associated with improved IDFS (HR=0.74 [0.56-0.98]) and OS (HR=0.78 [0.55-1.10]). However, the effects of ZOL in MAF+ were profoundly influenced by menopausal status with possibly better outcomes in PM women (HR for IDFS=0.74 [0.35-1.58]) but clearly worse IDFS and OS outcomes in ZOL treated MAF+ pts who were non-PM (HR for IDFS 2.46 [1.23-4.92], TFI by treatment $P=0.002$ and HR for OS=2.27 [1.04-4.93], TFI by treatment $P=0.032$). The interactions between disease outcomes, ZOL use and menopause were driven largely by an association between MAF+ and an increased risk of extra-skeletal recurrence with the use of ZOL in women who were not PM.

**Conclusions:** Absence of MAF amplification is associated with improved disease outcomes with adjuvant ZOL. However, the use of adjuvant ZOL in women with MAF+ tumors who are not PM at the start of treatment is associated with extraskeletal spread and worse DFS and OS.

Title: Homologous repair deficiency (HRD) as measure to predict the effect of carboplatin on survival in the neoadjuvant phase II trial GeparSixto in triple-negative early breast cancer

Body: Introduction

Addition of carboplatin to anthracycline/taxane-based neoadjuvant chemotherapy has shown to improve pathological complete response (pCR; ypT0 ypN0) rates in patients with triple-negative breast cancer (TNBC) in two large phase II studies (GeparSixto: von Minckwitz et al, Lancet Oncol 2014, CALGB 40603: Sikov WM, J Clin Oncol 2015). Participants of the GeparSixto study showed an improvement of pCR rate from 36.9 to 53.2% (p=0.005) and DFS by absolute 9% (HR 0.56 95% CI 0.33-0.96] p=0.035) with the addition of carboplatin in the TNBC subgroup. No effect was observed in the HER2-positive subgroup. We here report results on homologous repair deficiency (HRD) status in relation to pCR and DFS in the TNBC subgroup.

Patients and Methods

In the GeparSixto trial (NCT01426880), patients were treated for 18 weeks with paclitaxel 80mg/m² q1w and non-pegylated-liposomal doxorubicin (NPLD) 20mg/m² q1w. Patients with TNBC (N=315) received concurrently bevacizumab 15mg/kg i.v. q2w until surgery. All patients were randomized 1:1 to receive concurrently carboplatin AUC 1.5-2 q1w vs no carboplatin. Carboplatin dose was reduced from AUC 2.0 to 1.5 by an amendment after 330 patients. Primary objective is pCR rate (ypT0 ypN0). Event free survival (EFS), and overall survival (OS) were secondary objectives. HR Deficiency status was assessed on FFPE material from pretherapeutic core biopsies. HR Deficiency was defined as either HRD score high or a BRCA mutation.

Results

HRD status was measurable in 193 of 315 TNBC patients. 101 patients of them were randomly assigned to receive carboplatin and 92 to no additional carboplatin. After median follow-up of 34.3 months 43 event free survival (EFS) events have been reported.

HR deficiency was detected in 136 (70.5%) tumors of which 79 (58.1%) showed high HRD score with intact tBRCA. HR deficiency independently predicted pCR (ypT0is ypN0) (odds ratio (OR) 2.506, CI 1.243-5.051, p=0.009). Adding carboplatin to PM significantly increased the pCR rate from 36.6% to 63.2% in HR deficient tumors with intact tBRCA (p=0.018), only marginally from 61.9% to 72.7% in BRCA mutated tumors (p=0.406), and moderately from 20.0% to 40.7% in HR non-deficient tumors (p=0.086). In general, patients with HRD deficient tumors had a better EFS than non HRD deficient ones (HR 1.805 (0.985-3.309); p=0.0526). Patients with high HRD score had an insignificant trend towards an improved EFS compared to those with low HRD score (HR 1.546 (0.764-3.127) p=0.2223). HRD deficiency did not predict carboplatin effect in patients without BRCA mutation (HR 0.8617). In multivariable analysis, only therapy, clinical nodal status before treatment, and lymphocyte predominant breast cancer were significant prognostic on EFS.

Conclusion

Within the GeparSixto study HR deficiency (either HRD score high or BRCA mutation) was associated with a higher pCR in general and an improved EFS. The effect of carboplatin could not be predicted by HR deficiency in this relatively small study. However, the results will help to understand the role of HR deficiency and the value of the HRD score in TNBC especially in patients without BRCA mutation.
Title: Relative radioresistance in triple negative tumors in the SweBCG91-RT randomized clinical trial

Sjöström M, Lundstedt D, Hartman L, Holmberg E, Kovács A, Malmström P, Niméus E, Werner Rönnerman E, Fernö M and Karlsson P. Lund University, Clinical Sciences Lund, Oncology and Pathology, Lund, Sweden; Sahlgrenska University Hospital, Gothenburg, Sweden; Regional Cancer Center WT, Gothenburg, Sweden; Sahlgrenska University Hospital, Gothenburg, Sweden; Lund University, Clinical Sciences Lund, Surgery, Lund, Sweden and University of Gothenburg, Sahlgrenska Academy, Institute of Clinical Sciences, Gothenburg, Sweden.

Body: Introduction: Breast-conserving surgery (BCS) with adjuvant whole breast radiation therapy (WBRT) is the standard treatment for a majority of early breast cancer patients. No predictive biomarkers for RT are in use and most patients are cured by surgery alone, and are thus over-treated. Further, some patients suffer a relapse despite WBRT, and may have benefited from mastectomy or more aggressive postoperative treatment. Gene expression tests can be used to predict risk of distant recurrence and effect of adjuvant systemic therapy, and can reveal the intrinsic subtype of the tumor. A surrogate method of determining intrinsic subtype based on high quality centralized immunohistochemistry (IHC) has been proposed with criteria set up by the St Gallen consensus conference 2013. The intrinsic subtypes provide prognostic information and are treatment predictive for chemotherapy, but the predictive potential for WBRT has not been conclusively determined.

Aim: To evaluate the effect of WBRT on ipsilateral breast tumor recurrence (IBTR), in patients with tumors of different intrinsic subtypes.

Methods: Tumor tissue from FFPE blocks were collected from 1003 breast cancer patients with node negative, stage I-II disease, randomized to BCS with or without WBRT, in the randomized SweBCG RT-91 trial between 1991-1997. Systemic adjuvant treatment was administered according to regional guidelines, but was sparsely used. Median follow-up was 15.2 years. Tissue microarrays were constructed and stained for estrogen receptor (ER), progesterone receptor (PgR), human epidermal growth factor receptor 2 (HER2) and Ki-67. Centralized evaluation was performed by two pathologists subspecialized in breast pathology. Endpoint IBTR within 10 years was considered with a cumulative incidence and competing risks approach. P-values were calculated with the cause-specific logrank test and hazard ratios (HR) with cause specific Cox regression. Multivariate models, with or without an interaction term between subtype and WBRT, were compared to formally test if the effect of RT differs between subtypes.

Results: We were able to stain and score 963 out of 1003 tumors. These were classified as Luminal A-like (n=537), Luminal B-like (Her2-negative, n=261), triple negative (n=95) and HER2-positive (any ER status, n=70). WBRT reduced the frequency of IBTR for Luminal A-like tumors (19% vs 9%, HR 0.45 (0.28-0.73), p<0.001), Luminal B-like tumors (23% vs 6%, HR 0.23 (0.11-0.51), p<0.001) and non-significantly for HER2-positive tumors (24% vs 16%, HR 0.59 (0.20-1.75), p=0.33), but not for triple negative tumors (18% vs 16%, HR 0.86 (0.32-2.31), p=0.76). However, the overall difference in WBRT effect between subtypes was not formally statistically validated (p=0.20).

Conclusions: We found that WBRT reduced IBTRs among the Luminal A-like and B-like subgroups, and to a lesser extent in the HER2-positive subgroup, but not in the triple negative subgroup. Thus, intrinsic subtyping by IHC may give important information on how tumors respond to adjuvant WBRT, and patients with triple negative tumors may need more aggressive local treatment. Additional studies are required and it remains to study the effect on breast cancer specific survival.
Title: Proliferation and p21 refine risk of relapse in residual disease after HER2-directed therapies

Bianchini G, Pienkowski T, Im Y-H, Bianchi GV V, Tseng L-M, Liu M-C, Lluch A, de la Haba-Rodríguez J, Semiglazov V, Oh D-Y, Poirier B, Pedrini JL L, Valagussa P and Gianni L. IRCCS Ospedale San Raffaele, Milan, Italy; Centrum Onkologii, Warsaw, Poland; Samsung Medical Center, Seoul, Republic of Korea; IRCCS Fondazione Istituto Nazionale dei Tumori, Milan, Italy; Taipei-Veterans General Hospital, National Yang-Ming University, Taipei, Taiwan; Koo Foundation Sun Yat-Sen Cancer Center, Taipei, Taiwan; Hospital Clínico Universitario, INCLIVA Biomedical Research Institute, Valencia, Spain; Hospital Reina Sofia, Córdoba, Spain; NN Petrov Research Institute of Oncology, St Petersburg, Russian Federation; Seoul National University Hospital Cancer Research Institute, Seoul, Republic of Korea; Hôpital du Saint-Sacrement, CHU de Québec, Québec, Canada; Hospital Ernesto Dornelles, Porto Alegre, Brazil and Fondazione Michelangelo, Milan, Italy.

Body: Background: Patients (pts) with residual disease (RD) after neoadjuvant therapy are at higher risk of relapse. We investigated whether biomarkers assessed at surgery in patients pts with RD in the NeoSphere study were informative for risk of distant event free survival (DEFS).

Methods: In NeoSphere 417 HER2+ pts were randomized to neoadjuvant TD, TPD, TP or PD (T=trastuzumab, P=pertuzumab, D=docetaxel), and received FAC/FEC and trastuzumab after surgery. 296 pts had RD. Affymetrix derived gene expression profiles (GEPs) were available at surgery for 201 pts (67.9%). 176 pts (60.1%) had paired samples before and after treatment with available GEPs. We investigated the prognostic value of proliferation evaluated by Mitosis Kinase Score (MKS) (Bianchini GCancer Res 2010), and performed a gene discovery for association between gene expression at surgery and DEFS.

Results: MKS as continuous marker was associated with significantly higher risk of relapse when assessed at surgery (HR 1.80 [1.23-2.65]; p=0.002), but not before treatment (HR 1.50 [0.80-2.78]; p=0.20). In paired samples, there was an average decrease (p=9.2E-11) of MKS after treatment, which was prominent in ER+ and chemotherapy-containing arms. In ER- and TP arm there were cases of increase and of decrease of MKS. In ER+ the 5 years DEFS was 94.3% in the Low/Int MKS tertiles group (pooled) vs 70.5% in the High MKS tertile group (HR 5.41 [1.87-15.6]; p=0.002). In ER-, the 5 years DEFS was 85.0% in the Low/Int vs 64.1% in the High group (HR 2.89 [1.08-7.76]; p=0.035). Notably, MKS at surgery after the two monoclonal alone was also prognostic.

In the gene discovery approach only the expression of CDKN1A (p21) at surgery was associated with DEFS after correction for false discovery rate (FDR=0.01). Pre-treatment p21 was not associated with DEFS. Paired comparison showed significant upregulation of p21 in all patients, treatment arms and ER groups. The Int/High p21 tertiles group (pooled) had lower risk of recurrence than the low tertile in ER+ (HR 4.31 [1.60-11.6]; p=0.004) and in ER- (HR 5.81 [1.87-18.1]; p=0.002) groups. p21 in TP arm was also prognostic. MKS and p21 expression provided independent prognostic information and remained significant after correction for clinico-pathological variables (nodes and T stage) and tumor-infiltrating lymphocytes. Combining the two markers, there was a group at very low risk (Low/Int MKS and Int/High p21) and one at high risk (High MKS and Low p21). The other tertiles combinations had intermediate risk. In ER+, the 5 yrs DEFS was 94.9% in the low risk group and 52.9% in the high risk (p=1.9E-05). In ER-, the 5 yrs DEFS was 96.5% in the low and 45.5% in the high risk group (p=0.001). The markers’ combination was also prognostic in the two monoclonal only arm.

Conclusions: Proliferation (MKS) and p21 expression are modulated by trastuzumab and/or pertuzumab regimens. Tumors with high MKS and low p21 in RD after neoadjuvant therapy defined a group at very high risk of relapse. Tumors with low/int proliferation and int/high p21 had low risk of recurrence similar to that of patients achieving pCR. Whether the pharmacodynamic modulation of p21 could be used as surrogate marker of long term benefit in patients with RD deserves additional investigation.
Title: The role of immune and apoptosis markers for prediction of pCR in the WSG-ADAPT HER2+/HR+ phase II trial evaluating 12-weeks of neoadjuvant TDM1 ± endocrine therapy (ET) versus T + ET in HER2-positive hormone-receptor-positive early breast cancer (EBC)

Body: Background: Immune and apoptosis biomarkers are potential prognostic/predictive markers in HER2+ EBC. High PD-L1 expression was shown to be predictive for lower pCR after chemotherapy+trastuzumab+-pertuzumab, particularly in HER2+, ER-, disease. Yet, HER2+ EBC co-expressing hormone receptors is a distinct entity. The ADAPT HER2+/HR+ phase II trial (n=376) compared 12 weeks of neoadjuvant T-DM1 + ET vs. trastuzumab (T)+ET and demonstrated pCR rates of about 41% in both (well tolerated) T-DM1 arms.

Methods: In order to identify potential early predictors for pCR (i.e. no invasive tumor in breast and lymph nodes), immune markers (PDL1 on infiltrating immune cells (IIC) and on tumor cells (TC); CD8 in invasive margin and in tumor center) and apoptosis markers (bcl-2; mcl-2) were determined by immunohistochemistry (IHC; H-scores) in core biopsy sections obtained at primary diagnosis and at cycle 2. For multivariate logistic regression, each biomarker (separately), clinical factors (Ki-67, cT, cN) and therapy were entered. All analyses were exploratory.

Results: Biomarkers were available in up to 326 patients (pts) at baseline and up to 170 pts at 3 weeks (due to low tumor content in 2nd core biopsy).

Baseline IIC-PDL1 was associated with pCR in the T-DM1 arm (OR 2.89; 95%CI: 1.11-7.51); IIC-PDL1 at cycle 2 was not associated with pCR. PD-L1 expression in TC was rare (2%); cycle-2 TC-PD-L1 was associated with pCR in all pts and in the pooled TDM-1 arms. High baseline CD8 in tumor center was associated with pCR in the whole cohort (OR 2.4; CI: 1.04 – 5.5) and in the T+ET arm (OR=10.1; CI: 1.12 - 91.6) and at cycle 2 in all pts (OR=9.52; CI: 2.17 – 41), in pooled TDM-1 arms (OR=15.7; CI: 2.49 – 99), and in TDM-1+ET (OR=25.05; CI: 2.12 – 295). Increases in this marker also predicted pCR in all pts, pooled T-DM1, and in TDM-1+ET. Association of cycle-2 CD8 in tumor center with pCR persisted in multivariate models.

Lower baseline CD8 in invasive margin was associated with non-pCR in all pts (OR=0.28, CI: 0.12 - 0.66), in the pooled TDM-1 arms (OR=0.216, CI: 0.08 - 0.61), and particularly in the T-DM1+ET arm (OR=0.14; CI: 0.03 - 0.71). This association persisted in multivariate analysis. At cycle 2, lower bcl-2 had OR=0.16 (CI: 0.03 - 0.96) in the pooled TDM-1 arms. No association with efficacy was seen for mcl-1.

Conclusions: The WSG-ADAPT HER2+/HR+ phase II trial is the first international trial to focus on HER2+/HR+ EBC alone and the first to show substantial pCR rates of > 40% after only 12 weeks of T-DM1 -- without standard chemotherapy. Expression of bcl-2 may affect resistance to T-DM1. High immune activity at baseline and/or cycle 2 seems to be associated with...
pCR. The association of CD8 expression and its changes with therapy efficacy is complex and could depend on ET. Further biomarker analyses are ongoing and will be presented at the meeting.
Title: Prognostic and predictive relevance of cell cycle progression (CCP) score in ductal carcinoma in situ: Results from the UK/ANZ DCIS trial

Thorat MA A, Wagner S, Jones LJ J, Levey PM M, Bulka K, Hoff R, Sangale Z, Flake II DD D, Bunded NJ J, Fentiman IS S, Forbes JF F, Lanchbury JS S and Cuzick J. Centre for Cancer Prevention, Wolfson Institute of Preventive Medicine, Queen Mary University of London, London, United Kingdom; Centre for Tumour Biology, Barts Cancer Institute, Queen Mary University of London, London, United Kingdom; Blizard Institute Core Pathology, Blizard Institute of Cell and Molecular Science, Queen Mary University of London, London, United Kingdom; School of Medicine and Public Health, The University of Newcastle, Callaghan, New South Wales, Australia; Institute of Cancer Sciences, The University of Manchester, Manchester, United Kingdom; Guy's Hospital, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom and Myriad Genetics, Inc., Salt Lake City, UT.

Body: Background: The prognostic abilities of most gene expression signatures in breast cancer are often due to detection of proliferative activity measured from expression of genes regulated as a function of cell cycle progression. Cell Cycle Progression (CCP) score is an important prognostic factor in prostate cancer, and has shown promising results for renal and lung cancer; its role in ductal carcinoma in situ (DCIS) has not been explored. We investigated the prognostic and predictive relevance of CCP Score in DCIS using material from UK/ANZ DCIS trial.

Methods: Formalin-fixed paraffin embedded tissues were collected from patients enrolled in the UK/ANZ DCIS trial, a randomised 2X2 factorial design trial investigating role of tamoxifen, radiotherapy (RT) or both as adjuvant treatment in DCIS. mRNA expression of 25 S- and M-phase CCP genes was evaluated by reverse transcription followed by PCR on customized Taqman low-density arrays. CCP score is an un-weighted average of the expression values of CCP genes after normalisation with 14 housekeeping genes. CCP score was analysed as a continuous variable and also as an ordinal variable using tertile-based cut-offs. Exploratory analyses with subgroups defined by HER2 status by immunohistochemistry were performed.

Results: CCP scores were evaluable in 521 (134 recurrence events) of 704 available samples (DCIS absent or insufficient RNA in 51, assay failure in 132). Increase in CCP score (median 1.15; IQR 0.71-1.74) was associated with increased risk of ipsilateral breast event (IBE) [Hazard ratio (HR) = 1.28; 95% Confidence Interval (95%CI) 1.08-1.51; p = 0.0049]. CCP score however was not an independent predictor in multivariate analyses [HR = 1.16; 95%CI 0.95-1.42; p = 0.14]. CCP scores were categorised as CCP low (<0.87), CCP intermediate (/>= 0.87 to < 1.52) and CCP high (/>= 1.52) by tertiles. The benefit of RT in reducing IBE was significant when CCP score was low [HR = 0.35; 95%CI 0.14-0.87; p = 0.024] or intermediate [HR = 0.23; 95%CI 0.09-0.59; p = 0.0023], however, those with high CCP score did not derive significant RT benefit [HR = 0.59; 95%CI 0.31-1.13; p = 0.11].

In exploratory subgroup analyses, HER2 negative DCIS with high CCP score (20.9% of all DCIS cases) did not derive RT benefit and the largest RT benefit was seen for DCIS that expressed HER2 and did not have a high CCP score (23.2% of all DCIS cases).

Conclusions: CCP score is not independently associated with the risk of IBE but appears to be a predictor of RT benefit. Exploratory analyses suggest that combined with HER2 status, it may help in identifying a large DCIS subgroup where RT is
highly indicated and another large subgroup where mastectomy may be merited.
Title: Predictive effect of cytotoxic tumor infiltrating lymphocytes in HER2-positive metastatic breast cancer: A correlative study with CCTG MA.31

Background and Objectives: The presence of tumor infiltrating lymphocytes (TILs), particularly CD8+ cytotoxic T-cells, has been associated with improved prognosis in patients with HER2+ breast cancer. Increasing levels of TILs also appear to predict response to adjuvant trastuzumab in early breast cancer, although they did not predict benefit of combined trastuzumab-lapatinib neoadjuvant dual therapy over monotherapy in NeoALLTO. CCTG MA.31 randomized 652 women with HER2+ metastatic breast cancer to treatment with trastuzumab (T) vs. lapatinib (L), in combination with taxane (Tax) chemotherapy for 24 weeks, followed by the same HER2-targeted monotherapy. Final results from MA.31 found trastuzumab was superior to lapatinib for the primary endpoint of progression free survival (PFS): the hazard ratio (HR) for lapatinib to trastuzumab was 1.37 (95% CI, 1.13-1.65). Although both agents block HER2 signaling, trastuzumab has additional mechanisms of action via the immune system. We hypothesized that TIL levels may predict response to HER2-targeted therapy (trastuzumab vs. lapatinib).

Methods: MA.31 included HER2+ metastatic breast cancer patients, median age 55 years, and median follow-up 21.5 months. Overall TILs were counted per published guidelines on the original H&E stained sections used for pathology review at study entry. Immunohistochemistry (IHC) was performed on unstained sections from tissue microarrays or individual formalin-fixed paraffin-embedded blocks to test expression of lymphocyte biomarkers CD8, FOXP3, CD56 and PD-1 on stromal and intra-tumoral TILs (sTILs, iTILs). Statistical analysis was conducted by CCTG for a total of 9 prespecified biomarker tests. Associations of TILs with PFS were evaluated by univariate stratified log-rank test with graphical Kaplan-Meier curves, and by stratified multivariate Cox proportional hazards regression analysis. Predictive effect was examined with a test of interaction between treatment allocation and biomarker classification (high vs. low, using pre-established cutpoints).

Results: Of the 652 cases, 614 had slides for overall TIL assessment and 427 for IHC biomarker assessments. In this correlative study set, superiority of trastuzumab over lapatinib for PFS was confirmed in multivariate analysis (LTax/T vs. TTax/L: HR = 2.55, 95% CI = 1.43-4.55, p = 0.001). TIL counts by H&E were neither prognostic nor predictive in this set of metastatic HER2+ breast cancers. Lymphocyte IHC markers were not prognostic. However, prespecified stratified univariate analysis detected a significantly higher risk for lapatinib over trastuzumab (HR = 2.94, 95% CI = 1.40-6.17, p = 0.003) in patients with low CD8+ sTIL (<3) than was observed among those with high CD8+ sTIL (HR = 1.36, 95% CI = 1.05-1.75, p = 0.019). This differential effect was confirmed in multivariate analysis (interaction test p = 0.042). The other tested biomarkers did not demonstrate significant predictive effects.

Conclusions: In this correlative study of metastatic HER2+ breast cancer, a low level of pre-existing stromal cytotoxic T cell infiltration predicts women who benefit most from trastuzumab over lapatinib. Overall TIL counts were neither prognostic nor predictive.
Title: Efficacy and gene expression results from SOLTI1007 NEOERIBULIN phase II clinical trial in HER2-negative early breast cancer

Prat A, Ortega V, Villagrassa P, Paré L, Galván P, Oliveira M, Nuciforo P, Lluch A, Morales S, Amillano K, Lopez R, Gonzalez R, Manso L, Martinez J, Llombart A, De la Peña L, Di Cosimo S, Rubio I T, Harbeck N, Baselga J and Cortés J. Body: Background: Eribulin is the only cancer agent that has demonstrated a significant prolongation in overall survival on previously treated breast cancer patients. To date, no biomarker exists to prospectively select patients who will derive the maximum benefit from this chemotherapeutic. In the SOLTI1007-NeoEribulin study, we explored, in a prospective clinical trial, the efficacy and the association of pre-treatment expression of RNA in patients with HER2-negative breast cancer treated with neoadjuvant eribulin.

Methods: SOLTI1007 is a phase II, open-label, single-arm, exploratory pharmacogenomic study of single agent eribulin as neoadjuvant treatment for stage I-II HER2-negative breast cancer (planned n=100 hormonal receptor-positive [HR+] and n=100 HR-negative). Patients received 1.4 mg/m2 of eribulin intravenously on Days 1 and 8 every 21-day cycle, for 4 cycles. Baseline and post-treatment (surgical) formalin-fixed, paraffin-embedded tissue samples were collected and gene expression profiled. PAM50 intrinsic subtype and the Risk of Relapse based on subtype and proliferation (ROR-P) were evaluated in each time-point. The association of each PAM50 signature and pathological complete response in the breast (pCRB) was evaluated using univariate logistic regression models.

Results: Between September 2012 and October 2015, one hundred and seventy-four patients (TNBC n=73 and HR+ n=101) were recruited. Mean age (55.5), stage II (90%), negative axilla (78% and 67%), grade 3 (62% and 26%), mean tumor size (3 cm and 3.6 cm) and mean Ki-67 (61% and 31%). Completion of 4 cycles of eribulin was achieved by 85% of the patients. Grade 3-4 toxicities were observed in 19.54%, mostly due to neutropenia (5.1%) and alopecia (4.02%). The overall pCRB was 5.4%. No significant differences were observed between HR+ and TNBC disease. Distribution of the PAM50 intrinsic subtypes was as follows: Luminal A (n=43, 27.7%), Luminal B (n=42, 27.1%), Basal-like (n=63, 40.6%) and HER2-enriched (n=7, 4.5%). pCRB rates by subtype were the following: HER2-enriched (28.6%, 2/7), Luminal B (7.1%, 3/42), Basal-like (4.8%, 3/63), Luminal A (2.3%, 1/43). pCRB rates significantly (p=0.047) differed when HER2-enriched was compared to the other subtypes (odds ratio = 8.06, 95% CI 1.32-49.1). pCRB rate differed significantly by ROR-P (p=0.006): ROR-P high (17.1%, 6/35), ROR-P med (2.7%, 2/75), ROR-P low (2.2%, 1/45). Ki67 % by IHC did not predict pCRB (p=0.918). Subtype change at surgery occurred in 60% (3/5) HER2-enriched, 44.1% (15/34) of Luminal Bs, 10.3% (4/39) of Luminal A and 5.4% (2/37) of Basal-like tumors. 100% of subtype changes in Luminal B disease were to Luminal A.

Conclusions: From a response and biological perspective, patients with HER2-enriched and Luminal B disease may benefit the most from eribulin therapy. Mechanistically, our gene expression data further supports previous preclinical evidence suggesting that eribulin triggers a phenotypic conversion.
Title: Pathological complete response to neoadjuvant trastuzumab is dependent on HER2/CEP17 ratio in HER2-amplified early breast cancer

Singer CF F, Tan YY Y, Fitzal F, Steger GG G, Egle D, Reiner A, Rudas M, Gruber C, Bartsch R, Fridrik M, Seifert M, Exner R, Balic M, Bago-Horvath Z, Filipits M, Gniant M and For the Austrian Breast and Colorectal Cancer Study Group. Medical University Vienna, Vienna, Austria; Cancer Comprehensive Center, Medical University Vienna, Vienna, Austria; Cancer Comprehensive Center, Medical University Vienna, Vienna, Austria; Medical University of Innsbruck, Innsbruck, Austria; Institute of Pathology, Sozialmedizinisches Zentrum Ost, Vienna, Austria; Institute of Pathology, Medical University of Vienna, Vienna, Austria; Institute for Clinical Pathology, Barmherzige Schwestern Hospital, Linz, Austria; Allgemeines Krankenhaus Linz, Linz, Austria; Medical University of Graz, Graz, Austria and Institute of Cancer Research, Medical University of Vienna, Vienna, Austria.

Body: Purpose To evaluate whether pathological complete response to neoadjuvant trastuzumab is dependent on the level of HER2 amplification.

Patients and Methods 114 women with HER2-overexpressing early breast cancer who had received neo-adjuvant trastuzumab in the prospective ABCSG-24 and ABCSG-32 trials, and for whom the HER2/CEP17 ratio was available, were included in this analysis. The ratio was correlated with tumor response as measured by the three most commonly used definitions of pathological complete response: ypT0 ypN0, ypT0/is ypN0, and ypT0/is.

Results In trastuzumab-treated patients, ypT0 pN0 was achieved in 69.0% of patients with a HER2/CEP17 ratio of >6, but only in 30.4% of tumors with a ratio of ≤6 (p=0.001, Chi Square test). When pCR was defined by ypT0/is pN0 or by ypTis, 75.9% and 82.8% of tumors with a high ratio had a complete remission, while only 39.1%, and 38.3% with a low ratio achieved a pCR (p=0.002 and p<0.001, respectively). Logistic regression revealed that tumors with a higher HER2/CEP17 ratio had a significantly higher probability to achieve ypT0 ypN0 (OR: 5.08, 95% CI 1.86-13.90; p=0.002) than tumors with a low ratio, while none of the other clinicopathological parameters was predictive of pCR. The association between high HER2 amplification and pCR was almost exclusively confined to HR positive tumors (62.5% vs. 24.0%, 75.0% vs. 28.0%, and 87.5% vs. 28.0%, for ypT0 ypN0, ypT0/is ypN0, and ypT0/is; p=0.014, p=0.005, and p<0.001), and was largely absent in HR negative tumors.

Conclusion A HER2/CEP17 ratio of >6 in the pre-therapeutic tumor biopsy is associated with a significantly higher pCR rate particularly in HER2 / HR co-positive tumors, and can be used to predict outcome before neoadjuvant trastuzumab is initiated.

Title: Outcome after neoadjuvant chemotherapy in progesterone receptor negative breast cancer patients – A pooled analysis of individual patient data from ten prospectively randomized controlled neoadjuvant trials

Body: Background

The estrogen receptor (ER) as a nuclear transcription factor alters the transcription of estrogen sensitive genes to which the progesterone receptor gene belongs. The ER has also been described to exert non genomic effects by interacting with several cell signalling pathways that do not initially involve increases in gene transcription. These different patterns of action of the ER lead to the assumption that in tumors that utilize the non-genomic ER activity in order to stimulate tumorigenesis and proliferation progesterone receptor (PgR) expression would be decreased or absent. Therefore lack of PgR expression could be a surrogate marker of altered growth factor signalling. The aim of this study was to investigate if PgR expression may act as a predictive factor for response to neoadjuvant chemotherapy and long-term outcome in breast cancer patients.

Methods

5613 patients with primary breast cancer, follow-up, positive ER expression; HER2+ and HER2- from overall 10 (n=9785) German neoadjuvant trials receiving an anthracycline and taxane based chemotherapy were included. The pathologic complete response (pCR)(ypT0, ypN0), long term survival data (disease free survival (DFS), distant disease free survival (DDFS), overall survival (OS) and local recurrence free survival (LRFS)) and early relapse, defined as DFS <37 months, were compared according to their PgR expression, overall and in subgroups defined by HER2.

Results

Tumors lacking PgR expression (1172 patients) were more often of grade 3 (38.4% v 26.3%; p<0.001), tended to have an advanced clinical nodal involvement (6.8% v 4.7%; p=0.004) and were more likely to demonstrate HER2 positivity (36.2% v 22.3%; p<0.001). pCR rates were significantly higher in PgR negative patients in the entire cohort (13.8% v 7.5%; p<0.001) as well as in the HER2 negative subgroup (11.2% v 5.8%; p<0.001) whereas there was no significant difference in the HER2 positive (22.1% v 18%; p=0.117). After adjusting for known predictive factors in the multivariable logistic regression analysis PgR negativity was an independent predictive factor for pCR overall (OR 1.76; p<0.001) and in the HER2 negative patients (OR 1.99; p<0.001). PgR negativity was also significantly associated with an early relapse overall (32.8% v 25.7%; p<0.001) and in the subgroups defined by HER2 (HER2- 32.2% v 24.9%; p<0.001 and HER2+ 39.9%v 30.5%; p=0.002).

Patients with PgR negative disease had a significantly worse DFS, OS, DDFS and LRFS (p<0.001, respectively). Multivariable Cox regression analysis revealed that PgR was an independent prognostic factor. This was also observed in the HER2+ and- subgroups. Interestingly, in the PgR negative tumors HER2 status did not influence long-term outcome.

Conclusion

This analysis demonstrates that ER positive and PgR negative tumors represent a specific subset in primary breast cancer patients associated with higher response but also worse long term outcome after neoadjuvant chemotherapy. Interestingly, PgR negativity served as an independent predictive factor for achieving a pCR after neoadjuvant chemotherapy and therefore its status should be considered when deciding on systemic treatment.
Title: Dose dense adjuvant chemotherapy in patients with early breast cancer: Differential treatment effects according to composite index of benefit

Body: Background In patients with node-positive early breast cancer (EBC), dose-dense adjuvant chemotherapy improves disease-free survival (DFS) compared with standard interval chemotherapy. The GIM2 trial supports the value of dose-dense chemotherapy and suggests that the benefit is present in patients with hormone receptor-negative or hormone receptor-positive tumours (Del Mastro et al. Lancet 2015). In order to individualize decision making, there is a need to examine the absolute treatment effects of dose dense chemotherapy according to patient and tumor characteristics.

Patients and Methods The randomized phase III GIM2 trial enrolled 2091 patients. The primary endpoint was DFS. A continuous, composite measure of treatment benefit for each patient was determined from a Cox model incorporating potential predictive factors (age: 25-40/41-55/56-71; histological grade: 1+2/3; hormonal receptor status: positive/negative). Subpopulation treatment effect pattern plot methodology was used to reveal differential treatment effects on DFS according to composite index. The study focused on patients with HER2–negative disease (N=1287).

Results On average, the magnitude of benefit with dose dense chemotherapy versus standard chemotherapy ranged widely across different subpopulations, as quantified by the composite measure of relevant variables. The highest benefit was observed in patients with high grade, hormone receptor-negative disease (hazard ratio for DFS 0.44, 95% CI 0.23-0.83). Of note, a relevant benefit was observed also in patients with high grade, hormone receptor-positive disease (hazard ratio for DFS 0.74, 95% CI 0.50-1.09).

Conclusion The absolute improvement in DFS with dose dense adjuvant chemotherapy is substantial in some patients with node-positive HER2-negative breast cancer, particularly those regarded as having high index risk (hormone receptor-negative, high grade disease). Interestingly, a significant effect of dose dense chemotherapy was observed also in patients with hormone receptor-positive, high grade disease.
A RB-1 loss-of-function gene-signature (RBsig) predicts resistance to neoadjuvant chemotherapy in HER2+/ER+ breast cancer patients

Risi E, Grilli A, Migliaccio I, Biagioni C, Guarducci C, Bonechi M, Hart CD D, Biganzoli L, Bicciato S, Di Leo A and Malorni L. Hospital of Prato, Azienda USL Toscana Centro, Prato, Italy; Hospital of Prato, Azienda USL Toscana Centro, Prato, Italy and Center for Genome Research, Univeristy of Modena and Reggio Emilia, Modena, Italy.

Body: Background: HER2+ breast cancers (BC) are clinically and biologically heterogeneous, with approximately half being ER+. Compared to other BC subtypes, HER2+ ER+ tumors display among the lowest rates of pathological complete response (pCR) following neoadjuvant chemotherapy (NACT) +/- anti-HER2 agents (anti-HER2). Yet in spite of this, HER2+/ER+ patients (pts) are typically treated with NACT plus anti-HER2, with the subsequent related toxicity. Currently there is a lack of predictive biomarkers that identify which subgroups of pts will not respond to such therapy. Inactivation of the Retinoblastoma (Rb) signalling pathway is a frequent event in BC. Previously developed gene-signatures of Rb loss-of-function have shown strong prognostic value and prediction of response to NACT. However, none has been extensively studied in the context of HER2+/ER+ BC. We have recently developed a gene-signature of RB-1 loss-of-function (RBsig) that is prognostic in luminal A-like and luminal B-like BC. Here we report the results of a retrospective in-silico study aimed to determine whether low expression of the RBsig in HER2+/ER+ BC correlates with a low pCR rate following NACT +/- anti-HER2.

Methods: We performed a PubMed search for clinical trials of NACT +/- anti-HER2 (trastuzumab, lapatinib, or both) in HER2+ BC pts, and selected studies which had available gene expression data, hormone receptors status and pCR information. In-silico analyses of correlation between RBsig expression and pCR were performed using receiver-operating characteristic (ROC) curves and Fisher exact test to assess the prediction performance of the signature score. The threshold RBsig score was set at the 50th percentile of the score distribution.

Results: Out of 16 identified studies, 10 fulfilled the inclusion criteria and were included in the analysis (514 pts). Overall, of the 211 HER2+/ER+ BC pts, 49 achieved pCR (23%); the pCR rate following NACT +/- anti-HER2 of pts with RBsig low expression was significantly lower compared to pts with RBsig high expression (16% vs 30%, respectively; Fisher exact test p=0.0098). The area under the ROC curve (AUC) was 0.62 (95% confidence interval (CI) 0.54-0.7, p=0.005). Results were similar for pts receiving NACT alone (94 pts; pCR rate 13% vs 28% in RBsig low vs RBsig high, respectively; Fisher exact test p=0.06; AUC 0.62, 95% CI 0.5-0.74, p=0.043) or combined with anti-HER2 (117 pts; pCR rate 18% vs 33% in RBsig low vs RBsig high, respectively; Fisher exact test p=0.049; AUC 0.61, 95% CI 0.5-0.72, p=0.041). In 303 HER2+ ER- pts treated with NACT +/- anti-HER2, the pCR rate was 42%. No correlation was found between RBsig expression score and pCR rate in this group (pCR rate 42% vs 43% in RBsig low vs RBsig high, respectively; Fisher exact test p=0.53; AUC 0.5, 95% CI 0.43-0.56, p=0.973).

Conclusions: RBsig identifies a subset of HER2+/ER+ pts with a low pCR rate following NACT +/- anti-HER2. We hypothesize that this signature has the potential to identify pts for whom chemotherapy could be avoided in favour of combinations of endocrine therapy and target therapies. Further refinement and validation in an independent dataset is warranted.

Title: Breast carcinoma with 21-gene recurrence score lower than 18: Rate of distant metastases in a large series with clinical follow-up

Wen HY Y, Krystel-Whittemore M, Patil S, Pareja F, Bowser ZL L, Dickler M, Norton L, Morrow M, Hudis C and Brogi E. Memorial Sloan Kettering Cancer Center, New York, NY and University of Kansas Medical Center, Kansas City, KS.

Body: Background: The 21-gene recurrence score (RS) estimates the likelihood of distant recurrence and the benefit from chemotherapy in patients with early-stage node-negative, estrogen receptor (ER)-positive, HER2-negative breast carcinoma. The use of the assay resulted in a substantial reduction in adjuvant chemotherapy usage. In this study, we reviewed the outcome of patients with node-negative, ER+/HER2- breast cancer and low recurrence score treated at our center to further verify the prognostic value of the assay.

Design: We identified breast cancer patients treated at our center between 09/2008 and 08/2013 with ER-positive, HER2-negative breast cancer and known RS. We reviewed clinicopathological characteristics, RS, treatment and outcome data. The Institutional Review Board approved the study.

Results: We identified 1406 consecutive patients with early stage node negative ER+/HER2- breast cancer and low RS [RS 0-10: 510 (36%), RS 11-17: 896 (64%)] in the study period. The median age at breast cancer diagnosis was 56 years (range 22-90). Sixty-three (4%) patients were <40 years old at breast cancer diagnosis. A total of 1362 (97%) patients received endocrine therapy, and 170 (12%) received chemotherapy. The median follow up time was 46 months (range 1-85). Six (0.4%) of the 1406 patients developed biopsy proven distant metastases within 5 years of breast cancer diagnosis, 5 of which were in the RS 11-17 group (Table 1). Three of the 5 patients with RS 11-17 and distant metastases were younger than 40 years old at breast cancer diagnosis. In the RS 11-17 group, the absolute incidence of distant metastases among patients with breast cancer diagnosed at age younger than 40 years old is 7.1% (3/42), whereas the absolute incidence of distant metastases among patients ≥40 years is 0.2% (2/854).

Conclusion: Our results suggest that young age (<40 years old) might be a negative prognostic factor even in patients with low RS. Analysis of data from other studies is necessary to further validate this observation.

Title: Tumor and serum DNA methylation in women receiving preoperative chemotherapy (PST) with or without vorinostat in primary operable HER2-negative breast cancer in TBCRC008

Connolly RM M, Fackler MJ J, Zhang Z, Zhou XC C, Goetz MP P, Boughey JC C, Walsh B, Carpenter J, Storniolo AM M, Watkins S, Barielson E, Sukumar S and Stearns V.  Johns Hopkins School of Medicine, Baltimore, MD;  Mayo Clinic, Rochester, MN; University of Alabama, Birmingham, AL; Indiana University, Indianapolis, IN and Anne Arundel Medical Center, Annapolis, MD.

Body: Background:
DNA methylation is a promising prognostic and predictive biomarker of response to treatment in advanced breast cancer (Fackler MJ. Can Res 2014). We evaluated whether baseline and change in tissue and serum methylation would predict pathological complete response (pCR) in patients with HER2-negative early breast cancer treated with PST.

Methods:
TBCRC008 was a multicenter placebo-controlled trial that investigated pCR (no invasive cancer in breast/axilla) following 12 weeks of preoperative carboplatin and albumin-bound paclitaxel with or without the histone deacetylase (HDAC) inhibitor vorinostat in 62 patients with HER2-negative breast cancer. We performed an exploratory planned biomarker study correlating baseline and change (D15) in tumor tissue and serum methylation with pCR. Methylation was measured using cumulative methylation index (CMI) in quantitative multiplexed methylation-specific polymerase chain reaction (QM-MSP) assays; cMethDNA assay for serum (Fackler MJ. Can Res 2014) and QM-MSP for tissue (Fackler MJ. Can Res 2004). The analysis population included all patients with available methylation and pCR data. Association between CMI level (log transformed baseline, D15, change) and pCR was evaluated using univariate as well as multivariable logistic regression models controlling for treatment arm and estrogen receptor (ER) status. Additional subgroup analyses assessed association of CMI level with pCR stratified by ER status and treatment arms, respectively. Spearman's correlation coefficient was performed to evaluate the correlation between tissue and serum CMI.

Results:
pCR data were available for 61 of 62 patients. One patient with unknown response was treated as a non-responder. The pCR rate was similar in both arms (vorinostat 25.8%, placebo 29%). Both tissue and serum CMI data were available in 55 (baseline), 50 (D15) and 46 (change) patients. Elevated serum methylation based on a predefined threshold (6.9 units) was identified in 23/59 (39%) patients. In univariate analysis, one log unit increase in tissue CMI levels at D15 was associated with a 40% lower chance of obtaining a pCR (odds ratio, OR=0.60, 95% CI 0.37-0.97; p=0.037). The multivariable analysis did not show a statistically significant association of tissue or serum CMI with pCR, although a similar trend in magnitude towards association with pCR was observed for D15 and change in tumor tissue CMI (OR 0.67 and 0.57, p=0.129 and 0.147 respectively). Subgroup analyses suggested a significant association between tissue CMI levels at D15 and pCR in the group treated with vorinostat [tissue OR: 0.44 (0.20, 0.93), p=0.03; serum OR 0.37 (0.13, 1.07), p=0.07] but not in the placebo group. No significant correlation was observed between tissue and serum CMI.

Conclusion:
This is the first study to evaluate the predictive role of tissue and serum methylation (CMI) in patients with early breast cancer treated with PST ± an HDAC inhibitor. Methylation was detected more frequently in tissue than serum. Tissue CMI levels at D15 may predict poor response to this regimen. Further evaluation of the predictive role of methylation in early breast cancer is warranted.
Title: Randomized study of COX2 inhibition on systemic inflammation in obese and non-obese subjects

Brenner AJ, Lengfelder L, Quach DK, Cavazos DA, Ramirez RJ, Gruslova A, Kist K, Lathrup K, Kaklamani V, Beeram M and deGraffenried LA. CTRC at UT Health Science Center San Antonio, San Antonio, TX; UT Austin, Austin, TX and START Center for Cancer Care, San Antonio, TX.

Body: Introduction: Obesity is associated with poor breast cancer outcomes in postmenopausal women. Our prior retrospective studies have shown that use of nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with reduced recurrence in obese breast cancer patients and a doubling of time to recurrence. Because it was recently determined that CD163+ M2 macrophages were clinically associated with fast proliferation, poor differentiation, estrogen receptor negativity and histological duct type in human primary breast tumors, the mechanism proposed was a decrease in prostaglandin E2 (PGE2) and aromatase locally in the breast with a concomitant decrease in circulating M2-activated tumor associated macrophages (TAMs). Methods: Postmenopausal women of varying body habitus were recruited at the CTRC in San Antonio and underwent randomized assignment to 1 of 3 arms: Aspirin (ASA) at 81mg daily, 1500mg of docosahexaenoic acid (DHA) and 2500mg eicosapentaenoic acid (EPA) given daily, or combined ASA and DHA/EPA. Sera were collected prior to and following 28 days of exposure, and cytokines including prostaglandin E2 were assessed via enzyme −linked immunosorbent assay (ELISA). 28 circulating cytokines/chemokines were assessed by Luminex array using Millipore Milliplex MAP to look for associations between cytokine array profiles, PGE2 production and macrophage activation. Circulating class M-1 activated and M-2 activated macrophages were enumerated by flow cytometry to assess how PGE2 modulation influences macrophage phenotype and function. Investigators were blinded to randomization until analysis was complete. Results: A total of 122 patients were randomized with 2 drop outs and 115 completing the 28 days of intervention as planned. The median BMI was 31.4, with 12.8% normal (BMI <25.0), 27.3% overweight (25.0-29.9), and 59.9% obese (>29.9). Patients had a median age of 63 (47-76), 91% white, and 46.0 % Hispanic. A positive correlation was observed between BMI and baseline PGE2 levels. The most consistent impact on PGE2 was observed with ASA with 81% obtaining a decrease from baseline (median change -28%); by comparison 55.1% (-1%) and 65.6% (-22%) of subjects showed decrease in the DHA/EPA and combined groups respectively. As of today, full cytokine profiling was performed on a subset of 38 patients and revealed a positive correlation with change in PGE2 and cytokines: EGF, Eotaxin, GM-CSF, IL1Ra, IL5, IL8, MIP1b, and TNFa. Conclusion: Aspirin alone most consistently impacted patient circulating PGE2 levels, and will be used in planned studies as an adjunct to adjuvant endocrine therapy in obese hormone receptor positive post-menopausal patients. Full cytokine and macrophage activation status will be reported.
**Title:** EndoPredict multigene test in the prediction of response and outcome after neoadjuvant hormonal treatment with letrozole adn palbociclib (OOTR-N007)

Chow LWC WC and Toi M. Institute for Applied Research in Medicine and Health, Macau University of Science and Technology, Macau, SAR, China; Organization for Oncologya and Translational Research, Hong Kong SAR, Hong Kong; UNIMED Medical Institute, Hong Kong SAR, Hong Kong and Kyoto University Hospital, Kyoto, Japan.

**Body:** Background:
The EndoPredict [EP] is a multi-gene expression assay designed to predict the replapse-free survival of patients with estrogen receptor [ER] positive, HER2 negative breast cancer treated with adjuvant endocrine therapy alone. Relative expression levels of the eight prognostic genes [AZGP1, BIRC5, DHCR7, IL6ST, MGP, RBBP8, STC2, UBE2C] and 3 reference genes were analyzed by real-time PCR system. EP low-risk patients have a better RFS when treated with endocrine therapy. One study indicated that EP high-risk patients are more sensitive to anathracline-based neoadjuvant chemotherapy than low-risk patient.

Palbociclib is an orally active potent and highly selective reversible inhibitor of CDK4/6. N007 study aims to evaluate the efficacy of the pre-operative use of letrozole plus palbociclib for ER positive, HER2 negative post-menopausal breast cancer. Whether EP could predict for response and outcome to such treatment will be evaluated.

**Method:**
Twenty patients were treated. EP assays were intended to be tested for all patients. RNA were extracted from paired FFPE tumour blocks [core biopsies and corresponding surgical sections]. EP score were calculated for the first 7 paired samples. Also the EP Clin Score which integrate both mRNA of prognostic genes expression and their pathological parameters, including tumor size and nodal status, were also evaluated. The change in EP score were compared with that of Ki67 and also with the pathologic tumor response.

**Results:**
The results of the first 7 patients were presented. The overall pCR rate rate was 14.3%[1/7]. 85.7% [6/7] samples were classified as low risk group. Paired T-test showed EP score is significantly lower [P=0.0014] after neoadjuvant hormonal treatment [NHT]. The change of EP score before and after treatment corresponds to the change in Ki67. Both have a similar prediction of response.

. EP scores either remained high or showed minimal change for patients with stable disease [SD]. The subsequent EP Clin score was high for one of such patients, indicating high clinical risk. The corresponding Ki67 did not show any change and was low after treatment [Table1].

**Conclusion:**
pCR has been used as an endpoint for neoadjuvant chemotherapy trial. Our data suggest that the EP score can be reliably determined in core biopsy specimens and can be applied as endpoint on NHT trials. Changes in EP score correlated with that of Ki67 and also with response. However, changes in EP score may have a better prediction of response than Ki67. EP Clin score,
which integrates clinical parameters, may predict subsequent risk and clinical outcome after treatment. The data of all the 20 patients will be presented at the meeting.
A clinically validated DNA microarray for high-resolution HER2 testing defines a new genomic subtype in high-risk breast cancer with equivocal results by IHC and FISH

Gunn S, Yaziji H, Sims C, Govender S, Moore M, Cotter P and Jones S. Targeted Genomics, San Antonio, TX; Vitro Molecular Laboratories, Miami, FL; PacificDx, Irvine, CA and Oncology Insights, Scottsdale, AZ.

Body: Background: In all stages of breast cancer, the HER2 status of a patient's tumor is critically important as both a prognostic indicator, and for predicting response to targeted anti-HER2 therapies. CAP/ASCO 2013 guidelines recommend that newly diagnosed, recurrent, and metastatic breast tumors be evaluated for HER2 positivity by protein-based immunohistochemistry (IHC) and/or chromosome-based fluorescence in situ hybridization (FISH). In the majority of cases, these testing modalities provide a clearly actionable “positive” or “negative” answer. However, in an estimated 10- to 20% of breast cancers, both tests are reported as “equivocal” leaving the clinician with a treatment decision dilemma and no definitive alternative testing method. Here we report validation of an IHC-targeted DNA microarray comparative genomic hybridization (array CGH) assay for HER2 equivocal breast cancer, and definition of a new genomic subtype of HER2 status in high-risk breast cancer with equivocal IHC and FISH results.

Methods: IHC-targeted HER2 receptor “hot spot” DNA samples extracted from 25 formalin fixed paraffin embedded (FFPE) breast tumor tissue samples previously characterized by IHC and FISH, were analyzed by array CGH. Eight tumors were known to be highly HER2 positive, seven tumors had IHC scores of 0 with negative FISH, and ten tumors had HER2 receptor staining by IHC (1-2+) and equivocal results by FISH (4-6 HER2 gene copies.) Tumor DNA (test) and human genomic DNA (reference) were fluorescently labeled, and competitively hybridized to a custom-designed genomic DNA microarray with high-density probe coverage of the HER2 amplicon on chromosome 17 (Agilent Technologies, Santa Clara CA). The array design includes over 4,600 chromosome 17 probes representing the p arm, q arm, telomeric and centromeric regions with 66 tiling probes over the HER2 (ERBB2) gene. Following hybridization, average HER2 gene copy number was calculated for each tumor sample by converting mean log2 signal intensity ratio value into genomic region copy number adjusted for % clonal fraction and experimentally established log2 ratio compression of the assay. Results: 25/25 (100%) of samples yielded adequate DNA for analysis and all highly HER2 positive and HER2 negative results were confirmed by array CGH. In 10/10 IHC equivocal cases with HER2 gene copy number 4-6 by FISH, CGH results confirmed HER2-Low gene copy number.

Conclusions: High-resolution HER2 testing by IHC-targeted DNA microarray analysis accurately classifies HER2 status in breast cancer and better defines the HER2-Low genomic subtype most often called “equivocal” by standard IHC and FISH testing. This subcategory is characterized at the protein level by IHC evidence of anti-HER2 therapy target receptor expression on the surface of the cells, and at the genomic level by HER2 gene copy number < 6. Results of the NSABP-B47 clinical trial and further studies with larger numbers of HER2-Low patients are needed to determine if these patients benefit from anti-HER2 therapy.

Title: Tumor RNA disruption index as a tool to predict response to neoadjuvant chemotherapy in breast cancer: Optimizing timing of biopsy

Samkari A, Chung W, Parissenti A, Pritzker L, Trabulsi N, Basik M and Boileau J-F. Jewish General Hospital, Montreal, QC, Canada; Northeast Cancer Centre, Sudbury, ON, Canada; Kingston General Hospital, Kingston, ON, Canada and Rna Diagnostics Inc., Toronto, ON, Canada.

Body: BACKGROUND. Early detection of tumor response to neoadjuvant therapy (NAT) could be used to tailor therapy and lower toxicity from ineffective treatments. The CCTG MA.22 trial has shown that RNA disruption is associated with breast cancer response to NAT when measured by image guided core biopsy mid-treatment. The objectives of this study were: 1) to determine the optimal time to measure the tumor RNA Disruption Index (RDI) after initiation of NAT when assessed by fine needle aspiration (FNA) in an office setting and 2) to determine if RDI could predict response to a second chemotherapy agent in patients that had a suboptimal response.

METHODOLOGY. We performed a prospective pilot study including patients with palpable biopsy-proven breast cancer eligible for NAT. Chemotherapy and surgery were at the discretion of the treating physician. Two FNAs after cycles 1, 2, 3 and after initiation of a new chemotherapy agent were collected in RNA Protect Cell Reagent and sent to Rna Diagnostics Inc. to assess RDI. Prospectively recorded clinical tumor measurements and surgical pathology reports were obtained. Tumor pathological response (pR) after NAT was measured by pathological complete response (pCR: no invasive disease in breast) and residual cancer burden index (RCBI).

RESULTS. 30 patients were accrued to the study. One patient withdrew consent, one patient was found to have metastatic disease and did not undergo surgery, and one patient had bilateral breast cancer (n= 29 evaluable tumors). ER+HER2-: 38% (11/29), ER-Her2-: 28% (8/29) and HER2+: 34% (10/29). 89% (25/28) of patients received taxane and anthracycline containing regimens. All HER2+ received trastuzumab. Our pCR and RCBI 0-1 rates were 24% (7/29) & 38% (11/29) respectively. At cycles 1, 2 and 3, RDI could be evaluated in 72% (21/29), 73% (16/22) and 44% (7/16) of palpable tumors. After the switch to a new agent, RDI could only be evaluated in 30% (3/10) of patients with palpable tumors. After the switch to a new agent, RDI could only be evaluated in 30% (3/10) of patients with palpable tumors. Using a tumor RDA cutoff at 5 (non-responder RDI < 5 (NR) and responder RDI ≥ 5 (R)), responder status between cycle 1 and 2 was concordant in 73% (11/15). After 1 cycle, NR vs. R was associated with numerically lower pCR (13% (2/15) vs. 33% (2/6), p=0.54) and RCBI 0-1 at surgery (20% (3/15) vs. 33% (2/6), p=0.60). These findings were similar after cycle 2. Non-analyzable samples (NAS) because of absence of RNA were associated with high pR (pCR: 38% (3/8) and RCBI 0-1: 75% (6/8)). The 3 NR at cycle 1 that achieved a significant pR had either non-palpable tumors or NAS after switching to a new chemotherapy agent.

CONCLUSION. RDI can be measured by FNA in an office setting and could be helpful to identify early non-responders to NAT. The optimal time to perform RDI is after 1 or 2 cycles of treatment, which should be considered in ongoing and future trials. This study was underpowered to detect a statistically significant correlation between RDI and pR. NAS is associated with high pR and could represent responders to treatment. This early data suggests that RDI is unlikely to be helpful in assessing response to a second chemotherapy agent after receiving 4 cycles of standard chemotherapy. The use of RDI to tailor NAT needs to be evaluated in larger prospective trials.
Title: An optimized workflow to analyze ESR1 mutations in both circulating cell-free and circulating tumor cell DNA by digital PCR

Vitale SR R, Siewerts AM M, Helmijr J, Beije N, van der Vlugt – Daane M, Foekens JA A, Sleijfer S, Jansen MPHM PHM and Martens JWM WM. Erasmus MC Cancer Institute, Erasmus University Medical Center, Rotterdam, Netherlands; University of Catania, Catania, Italy and Cancer Genomics Netherlands, Rotterdam, Netherlands.

Body: Background
In metastatic breast cancer (MBC) patients ESR1 mutations (mESR1) in cell-free DNA (cfDNA) have been related to endocrine therapy (ET) resistance. Such mutations might also be detectable in circulating tumor cells (CTCs). Mutation detection in small amounts of cfDNA and in CTCs in a background of leukocytes is highly challenging. The current study evaluated how to reliably investigate mESR1 status in such minute amounts of cfDNA and in DNA from CellSearch-enriched CTCs.

Materials & Methods
Plasma (200 µL) and matched CellSearch-enriched CTC fractions of 7 healthy blood donors (HBD) and 29 MBC patients at baseline and after ET (≥ 5 CTC/7.5 mL) were evaluated. cfDNA was isolated from plasma with the QIAamp CNA kit and CTC-enriched DNA with the AllPrep kit (Qiagen). mESR1 status in both cfDNA and CTC-enriched DNA fractions was compared with or without whole genome amplification (repli-g WGA, Qiagen) or ESR1 target specific amplification. Quantitative PCR (qPCR) for wild type (WT) ESR1 was used to control the number of WT copies loaded into the chips for digital PCR (dPCR) analysis. The variant allele frequencies (VAF) of hotspot mutations for ESR1 (D538G, Y537S, Y537C and Y537N) were evaluated with mutation-specific Taqman assays by chip-based dPCR (QuantStudio 3D, Thermo Fischer Scientific).

Results
To allow inclusion of as many samples as possible, we successfully downscaled the volume of required plasma from 1 mL to 200 µL as this resulted in the same VAF. Sample-type specific thresholds for mESR1 presence were established (2% for the cell-free plasma samples, at which percentage all HBDs were negative, and 0.5% for the CTCs to allow identification of one mutated CTC-specific copy in a background of ~1,000 leukocytes).

WGA was unable to adequately amplify fragmented cfDNA, resulting in a too low DNA yield. However, locus-specific target pre-amplification of a 136 bp fragment covering all 4 different mutations followed by mutant specific dPCR performed well for both cfDNA and CTC DNA, but only if the loading of the pre-amplified product into the dPCR chips was optimized by qPCR for the number of WT ESR1 copies.

The most optimal results for dPCR data interpretation were obtained after: 1. including at least one positive sample in each dPCR session; 2. using a “safe loading window”, 3. loading and reading chips at least twice in QuantStudio 3D ; 4. critically evaluating the contribution by a non-specific “comet effect”; and 5. after loading the data in the software, performing at least two independent data analyses to exclude intra-observer variations.

Summary
Here we describe our workflow to assess mESR1 in a limited amount of plasma cfDNA or CellSearch enriched CTC DNA. This workflow has been successfully used to investigate the mESR1 VAF status in DNA from matched CTC DNA and cfDNA of MBC patients before start of 1st line endocrine therapy and at progression (see also abstract number 851017).
Title: Clinical evaluation of miR-100 as a predictor of endocrine-responsiveness in hormone-receptor positive breast cancer

Body: Background: Micro RNAs (miRNAs) are short, non-coding RNA molecules that act as negative regulators of gene-expression, mainly at the post-transcriptional level. Alterations in miRNA functions have been implicated in a variety of human diseases, including cancer.

We demonstrated that the ectopic expression of miR-100 in cancer stem cells (CSCs) derived from aggressive, basal-like BC (HRs and HER2 negative) caused loss of stemness and the acquisition of a hormone receptor positive and endocrine treatment sensitive phenotype (Petrelli et al, Oncotarget 6;2315-30, 2015). We therefore sought to study whether miR-100 is a determinant of the endocrine-responsive phenotype in HR-positive BC patients (pts).

Methods: Women with newly diagnosed, estrogen-receptor and/or progesterone-receptor positive, HER2 negative BC were eligible for this study. Treatment consisting of tamoxifen for pre-menopausal and letrozole for post-menopausal pts was administered daily for 21 days (+/- 3 days) before breast surgery. MiR-100 levels in pre-treatment tumor biopsies, measured as fold-change with respect to a reference RNA and transformed to the natural logarithms to normalize the data, were correlated with proliferative response to endocrine therapy, as measured by Ki67 expression in the final surgical specimen. The primary end-point was a complete proliferative response (CPR), defined as a post-treatment Ki67 ≤ 1%. Additionally, we considered a “post-hoc” composite endpoint where response was defined as a post treatment Ki67 <10% together with a Ki67 reduction ≥80% compared to pre-treatment values. The target accrual is 88 patients (pts). Here we report the results of the first interim analysis focusing on post-menopausal pts receiving letrozole.

Results: A total of 42 pts were evaluable for miR-100 levels and response to endocrine therapy. Median ER and PgR expression was 99% (58%-99%) and 96% (0-99%) respectively. Median pre-treatment Ki67 was 18% (5-76%). Thirty-one tumors were ductal carcinomas, 9 were lobular and 2 were “other” histotypes. The median (range) miR-100 values in pre-treatment specimens was 2.253 (0.460-3.750). After treatment, median Ki67 was 4% (1%-46%) and the median percentage variation with respect to baseline values was -74% (0% to -94%). A CPR was observed in 5/42 pts (12%, 95% C.I. 5%-25%). The median miR-100 levels in responders and non-responders were 3.058 and 2.198, respectively (p = 0.03). Logistic regression analysis showed that each unit increase in miR-100 was associated with a 7-fold increase in the likelihood of a CPR (OR 7.056, 95% C.I. 1.103-45.141, p = 0.04).

Considering the composite end-point, 17/42 pts (40%, 95% C.I. 27%-56%) were considered responders. Median miR-100 levels in responders and non-responders were 2.427 and 1.956, respectively (p = 0.05).

Conclusions: preliminary results of this prospective clinical trial suggest that miR-100 can be a modulator of the endocrine-responsive phenotype in post-m pts with HR-positive breast cancer. The study is completing its target accrual and an investigation of miR-100 targets is being conducted.

Title: Utilization and outcomes of post-mastectomy radiotherapy in women with 1-3 positive axillary nodes following neoadjuvant chemotherapy: A multiply-imputed, propensity-adjusted National cancer database analysis

Horne ZD D, Gebhardt BJ J, Balasubramani GK K and Beriwal S. University of Pittsburgh Cancer Institute, Pittsburgh, PA and University of Pittsburgh, Pittsburgh, PA.

Body: Background: Use of post-mastectomy radiotherapy (PMRT) following neoadjuvant chemotherapy (NAC) varies widely. The combined analysis of NSABP B1724 studies suggests a higher risk of locoregional recurrence for women with persistently positive lymph nodes following NAC. The impact of PMRT on survival in the subset of patients with 1 to 3 positive nodes after NAC is not clear and the goal of the current study is to evaluate practice patterns and the impact of PMRT on survival in this subset of patients.

Methods: The National Cancer Database was queried for women who underwent NAC followed by mastectomy and had 1-3 persistent axillary lymph nodes with or without adjuvant PMRT. A propensity score was generated to account for indication bias under two circumstances: one with the original dataset and one following a multiple imputation to complete the dataset to allow for a more accurate propensity score generation. Factors impacting utilization of PMRT were calculated with backwards-selection binary regression. Kaplan-Meier with log-rank test and Cox-regression analyses were used for survival.

Results: Within the queried cohort of 14,895 women from 2006-2012, 70% of women received PMRT following NAC with 1-3 positive axillary lymph nodes. One lymph node was positive in 56%, 2 in 25.9%, and 3 in 18.1%. PMRT was utilized in 67.3% of women with 1 node positive, 71.5% with 2 nodes positive, and 76.2% with 3 nodes positive. Factors associated with the usage of PMRT were: residence on the east coast in a highly populated region with proximity to the treatment center, later year of diagnosis (71% of women in 2012), younger age, non-African American race, non-Hispanic descent, private insurance, higher clinical stage, triple negative/high grade histology, pathologic T4, greater number of axillary node positive, positive margins or LVSI, greater number of nodes examined, and use of adjuvant hormonal therapy (all p<.05).

Median follow up was 40.1 months (range: 2.6-106.9 months). Prior to multiple imputation, a propensity score was generated which accounted for 28.7% of cases. PMRT did not have an impact on survival within the limited analysis. In a pooled propensity-adjusted Cox analysis following multiple imputation to complete the dataset, PMRT was found to have an OS HR of 0.878 (95%CI 0.806-0.957, p=.003). Five year overall survival rates with and without PMRT were 77.6% and 75.4% (p<.001). For 1-3 positive nodes respectively, 5-year overall survival rates with and without PMRT were: 79.7% vs. 79.1% (p=.041), 77.3% vs. 70.8% (p<.001), and 71.8% vs. 68.0% (p=.004).

Conclusions: In a population-based analysis of women who underwent neoadjuvant chemotherapy prior to mastectomy, post-mastectomy radiotherapy appears to confer a survival advantage in women with 1-3 residual axillary lymph nodes. There continues to be a wide variation in practice nation-wide with a significant number of women with persistently positive 1-3 axillary lymph nodes not receiving PMRT.
Title: A signature predictive of early vs. late recurrence after radiation treatment (RT) for breast cancer that may inform the biology of early, aggressive recurrences

Speers C, Chang L, Santola A, Liu M, Zhao SG, Chandler B, Olsen E, Bartelink H, Feng FY and Pierce LJ. University of Michigan Hospital and Health System, Ann Arbor, MI and Netherlands Cancer Institute, Amsterdam, Netherlands.

Body: Purpose: Unmet clinical needs in breast cancer (BC) management include the identification of patients (pts) at high risk to fail locally despite standard local therapy including RT and understanding the biology of these recurrences. We previously reported a RT response signature and here extend those studies to identify a signature predictive of timing of recurrence after completion of RT (before or after 3 years).

Methods: Two independent patient cohorts (treated with BCS) from non-randomized clinical trials were used for training and validation. The training cohort included 119 pts with in-breast tumor recurrence and the validation cohort had 25 pts with recurrences. Initial feature selection used Spearman's rank correlation correlating gene expression (14,806 genes) to recurrence time. Genes with sig. correlation (FDR <0.1) and large expression range (fold change >2) were used to train an elastic net penalized Poisson regression model. This model was locked and then applied to the validation dataset. Cox regression was used for both univariate and multivariable analyses (UVA and MVA). To identify biological-related concepts, Spearman's corr. coefficients of recurrence time to gene expression within the training cohort were used to generate a pre-ranked list upon which GSEA pathway analysis was performed.

Results: Spearman's correlation identified 485 genes whose expression was significantly associated with recurrence time (early vs. late). Feature reduction further refined the gene list to 41 genes, which were retained within the signature and locked for further validation. In the training dataset the Spearman's correlation of the continuous score to recurrence time was 0.852 with a P-value of 1.3x10^{-34} and an AUC of 0.92. Application of this early vs late signature to an independent BC validation set accurately identifies pts with early vs. late recurrences (Spearman's corr.=0.537, p-value<0.007, AUC=0.74, sensitivity=0.71, specificity=0.73, PPV=0.77, NPV=0.67). In UVA and MVA the early vs. late recurrence signature remained the most significant factor associated with recurrence time. Although independent of intrinsic subtype, GSEA analysis of the 41 genes retained within the signature identifies proliferation and EGFR concepts associated with early recurrences and luminal and ER-signaling pathways associated with late recurrences. Knockdown of genes associated with the early and late recurrences is currently underway to assess phenotypic changes (proliferation and clonogenic survival as a measure of early and durable RT response) associated with the early and late recurrence-associated genes.

Conclusion: In this study we derive a BC-specific RT signature predictive of early vs. late recurrence with biologic relevance and validate this signature for prediction of timing of recurrence in an independent clinical dataset. By identifying pts with tumors likely to recur sooner vs. later this signature has the potential to allow for a furthered understanding of the biology underlying early and late recurrences and has a potential to personalize RT, particularly in patients for whom treatment intensification is needed.

Title: A randomized trial of accelerated breast radiotherapy utilizing either 3-dimensional radiotherapy versus intensity modulated radiotherapy

Leonard CE E, Sobus RD D, Fryman S, Sedlacek S, Kercher J, Widner J, Asmar L, Wang Y, Howell K, Barke L and Carter D. Rocky Mountain Cancer Center, Denver, CO; Rocky Mountain Cancer Center, Aurora, CO; SurgOne, Littleton, CO; Linasmar Consulting, Houston, TX and Invision Sally Jobe Breast Network, Greenwood Village, CO.

METHODS AND MATERIALS: 656 patients (3D-CRT n=325; IMRT n=331) were prospectively randomized to either IMRT or 3D-CRT accelerated partial breast radiotherapy to 38.5 Gy in 10 BID 3.85 Gy fractions. Follow-up was: 1, 4, 8, 12, 16, 20, 24 months then yearly. At follow-up, patients completed a cosmesis/pain self-assessment form and physicians completed a cosmesis and disease-status form.

RESULTS: 636 patients completed treatment (3D-CRT n=316; IMRT n=320). Median age was 62. Mean tumor size was 1.1 cm. Mean margin was 7mm. Histology was: 74.5% IDCA, 7% ILCA, 17% DCIS, 0.5% Tubular, 1% Mucinous. 99% were ER+. HER2/neu status by IHC was 3+ in 16% of patients. Median follow-up is 2 years. Tables 1 and 2 show there is no significant difference in patient-assessed pain and cosmesis between the two treatment arms (p=0.14, 0.68 respectively). Decreasing pain and worsening cosmesis as reported by the patient were significantly related to time (p<0.01, 0.012 respectively). MD assessed cosmesis worsened significantly from baseline in the IMRT compared to 3D-CRT cohort (p=0.045). At 2 years Grade 3 and 4 toxicities were 1.5% and 3.9% respectively for 3D-CRT versus IMRT cohorts. Overall Survival at 2 years were 99.7% for both cohorts. There were 3/319 (0.9%) and 7/328 (2.1%) ipsilateral breast recurrences in the 3D-CRT and IMRT cohorts respectively.

Table 2.

Conclusion: There were no significant differences in patient-assessed pain and cosmesis between the two treatment arms (p=0.14, =0.68 respectively) and no significant increase in pain over time. However, MD assessed cosmesis showed worsening cosmesis in the IMRT cohort compared to the 3D-CRT cohort when compared to baseline.
Title: Accelerated partial breast irradiation versus whole breast irradiation: Health-related quality of life analysis from a phase 3 trial

Body: Background. Accelerated partial breast irradiation (APBI) represents a valid option for selected early breast cancer (BC); potential advantages of APBI include shorter treatment time, improved safety profile, and a cost reduction compared with standard fractionation.

We reported the final analysis of quality of life (QOL) results from a phase 3 randomized trial comparing standard adjuvant radiotherapy (50 Gy in 25 fractions, plus 10 Gy boost) to APBI using IMRT technique (30 Gy in 5 daily fractions). The 5-year results have been recently published showing equivalence in terms of local control (ClinicalTrials.gov, NCT02104895).

Methods. Overall 205 patients (105 APBI and 100 WBI) fully completed the given questionnaires at time 0 (RT start), time 1 (RT end), and time 2 (2-year follow up). Patients were asked to compile two specific questionnaires on QOL, the EORTC QLQ-C30 as a reliable and valid measure of the QOL of cancer patients in multicultural clinical research settings, and the BR23 module as a supplementary questionnaire for assessing QOL issues relevant to patients with BC. The statistical software SPSS (SPSS Inc, Chicago, IL, USA) for Windows (version 22), and STATA (StataCorp LP, College Station TX77845, USA) for Windows (version 12) were used. Chi-squared test or Mann Whitney U test were used to compare the individual characteristics of the patients between two arms. Mean and standard deviations (SD) were calculated for all QOL domains, and all scores were compared between APBI and WBI arms using the Mann Whitney test due to non-parametric distribution of data. The Kruskal-Wallis test was used to compare the scores between age groups.

Results. Mean values (and SD) of QLQ-C30 scores according to arm in the series of 205 BC patients at time 2 (time 0 vs time 2), showed significant improvement in favor of APBI in terms of global health status (mean 75.5 vs 59.5, SD range 13.3-22.0; p<0.0001), main functional (p<0.01), and symptom scales (p<0.01). Concerning the BR23 module, APBI showed significantly better outcome in terms of body image perception (mean 89 vs 72.1, SD 13.2-26.6; p<0.0001) and future perspective (84.8 vs 57, SD 23.1-28.5; p<0.0001) among functional scales; breast (6.1 vs 18.9, SD 6.6-18.2; p<0.0001) and arm symptoms (11.7 vs 19.6, SD 13.4-19; p=0.002) among symptom scales.

Conclusions. Women treated with APBI reported a significantly better QOL outcome as compared with women treated using WBI. QOL improvement was evidenced in terms of functional, symptoms, and global health status/QOL scales, both at the end of radiation and at a 2-year follow-up time.

Title: Omitting radiotherapy in women ≥ 65 years with early breast cancer and favorable histopathology after breast-conserving surgery, sentinel node biopsy and adjuvant endocrine therapy is safe

Villman KKA KA, Wickberg Å, Killander F, Lindman H, Bjöhle J, Edlund P, Tennvall-Nittby L, Bachmeier K, Carlberg M, Blomqvist C, Ahlgren J and Liljegren G. Örebro University Hospital, Örebro, Sweden; Skåne University Hospital, Lund University, Lund, Sweden; Akademiska Hospital, Uppsala University, Uppsala, Sweden; Karolinska Institute and University Hospital, Stockholm, Sweden; Gävle Hospital, Gävle, Sweden; Skåne University Hospital, Lund University, Malmö, Sweden and Karlstad Central Hospital, Karlstad, Sweden.

Body: Background: The benefit of radiotherapy in older women with endocrine responsive early breast cancer treated with breast-conserving surgery and endocrine therapy is unclear. The aim of this study was to verify if omission of radiotherapy in a predefined cohort of patients with good prognosis early breast cancer after breast conservation is safe.

Methods: Eligibility criteria were: consecutive patients with age ≥ 65 years, breast-conserving surgery (sector resection + sentinel node biopsy), clear margins, unifocal T1 N0, Elston grade 1 and 2, estrogen receptor-positive. After informed consent adjuvant endocrine therapy, either tamoxifen or an aromatase inhibitor, was prescribed for 5 years. Primary endpoint was ipsilateral breast tumor recurrence (IBTR). Secondary endpoints were contralateral breast cancer, recurrence-free survival (RFS) and overall survival (OS).

Results: Between 2006 and 2012, we included 603 women from 14 Swedish centers. Two patients did not fulfill the inclusion criteria and were excluded from the analysis. Median age was 71 years (range 65 to 90). At a median follow-up of 59 months (range 2 to 110) 13 IBTR (cumulative incidence at five years, 1.3% (95% CI, 0.6% to 2.7%), 4 regional recurrences (one combined with IBTR), 2 distant recurrences both without IBTR or regional recurrence and 11 contralateral breast cancers was observed. Twenty-nine patients were diagnosed with tumors of other origin. Seven of them were endometrial cancers. There were 39 deaths. Only one of the deaths (2.6%) was due to breast cancer and 11 (28.2%) were due to other cancers (2 endometrial cancers). Five-year overall survival was 93.9% (95% CI, 91.4% to 95.7%).

Conclusion: This study demonstrates, with a median follow-up of 59 months, that breast-conserving surgery and endocrine therapy without radiotherapy is a safe treatment option in women with early breast cancer and favorable histopathology aged ≥ 65 years. The risk of IBTR is comparable to the risk of contralateral breast cancer. The low rate of breast cancer deaths indicates that breast cancer mortality is of secondary importance in this subset of women.

Title: Hypofractionated nodal radiotherapy (RT) did not increase arm morbidity compared to conventional fractionated nodal RT

Leong N, Truong P, TANKEL K, Kwan W, Weir L and Olivetto I. Saskatchewan Cancer Agency Allan Blair Cancer Centre, Regina, SK, Canada; BC Cancer Agency Vancouver Island Centre, Victoria, BC, Canada; Alberta Health Services Tom Baker Cancer Centre, Calgary, AB, Canada; BC Cancer Agency Fraser Valley Centre, Surrey, BC, Canada; BC Cancer Agency Vancouver Centre, Vancouver, BC, Canada and Alberta Health Services Cross Cancer Institute, Edmonton, AB, Canada.

Body: Purpose: Regional nodal radiation therapy (RT) can cause adverse arm symptoms and lymphedema. Hypofractionation (HF), defined as >2 Gy/fraction, improves convenience but whether it increases arm morbidity is unclear. This study evaluates patient-reported arm symptoms in women treated with HF compared to conventional fractionation (CF) RT (defined as ≤2Gy/fraction).

Materials / Methods: Provincial cancer registries were used to identify subjects who received 3D, CT-planned nodal RT for pT1-3 pN0-2 M0 breast cancer from 2007-2009 in British Columbia and 2008 – 2010 in Alberta, Canada. Treatment eras were selected to enable sufficient follow-up time to develop late arm symptoms. Following research ethics approval, eligible patients were mailed an explanation letter and an externally validated, Self-reported Arm Symptom Scale (SASS) survey. The SASS included 8 questions about arm symptoms, with responses on a 5-point Likert scale regarding arm/hand problems (numbness, pain, stiffness, immobility and swelling), and 5 questions related to activities of daily living (ADL). Clinicopathologic characteristics and SASS scores were compared between HF vs. CF nodal RT cohorts using non-parametric analysis (on ordinal and scale responses) and binned chi-squared analysis (comparison for responses of 1 vs. > 1).

Results: 800/1759 eligible patients returned a completed survey (45.5%). Upon detailed chart review of responders, 92 cases with recurrence or metastasis were excluded. The remaining 708 cases formed the study cohort. Of these, 406 (57%) patients received HF RT (modal dose/fractionation 40 Gy/15 fractions (fx) and 45 Gy/20 fx), and 302 (43%) received CF RT (45 Gy/25 fx, 48-50 Gy/25 fx, and 50.4 Gy/28 fx). A boost was delivered to the breast in 22% of subjects, equally by fractionation group (p=0.31).

Median time interval since RT completion was 5.67 years. The mean age at diagnosis was 59.0 in HF vs 53.8 years in CF-treated cohorts (p<0.001). The mean # positive (n=3) and excised (n=12) nodes were similar between fractionation cohorts (p=0.44).

Primary tumor size was marginally larger in the CF group (2.8 vs. 2.7 cm, p=0.03). 42.9% of patients were treated with partial mastectomy with no significant difference in fractionation (p=0.54). Overall, 602 (75.3%) patients received chemotherapy. A trend toward increased use of CF after chemotherapy was observed (78.8% vs. 72.7%, p=0.07).

The mean sums of responses for the arm symptoms / ADL components of the SASS were 12.5 / 7.6 vs. 13.3 / 7.9 for the HF and CF groups respectively (p=0.17 / 0.85). On analysis of individual questions, the CF group had a higher prevalence of self-reported symptoms, including shoulder stiffness (p=0.04), trouble moving the arm (p=0.02), and ability to reach overhead (p<0.01). There was no difference in self-reported arm swelling between the two groups (p=0.57).

Conclusion: Hypofractionated nodal RT was not associated with an increase in patient-reported arm symptoms or disability compared to conventional fractionated nodal RT. Subjects treated with CF RT reported more disability in certain aspects of arm and shoulder function. These data support the use of shorter fractionation when the regional lymph nodes are part of the therapeutic target.
Title: Prospective longitudinal study of epidermal thickening in breast cancer patients treated with conventional versus hypofractionated radiotherapy

Torres MA A, Yang X, Mister D, Ali A, Kahn S and Liu T. Glenn Family Breast Center, Winship Cancer Institute, Emory University, Atlanta, GA.

Body: Purpose: We conducted two prospective longitudinal studies of epidermal thickening in breast cancer (BRCA) patients treated with either conventional (CRT) or hypofractionated radiotherapy (HRT) using ultrasound images to objectively measure radiotherapy (XRT)-induced skin changes. Methods: Following breast conserving surgery, 105 consenting Stage 0-IIIA BRCA patients were enrolled on two studies of whole breast XRT without regional nodal irradiation. In the first, 66 subjects were treated with conventional fractionation (50 Gy plus a sequential 10 Gy boost at 2 Gy per fraction). In the second, subsequent study, 39 patients with characteristics under-represented in trials of HRT were treated to 39.9 Gy at 2.66 Gy per fraction with a simultaneous integrated boost of 8.1 Gy at 0.54 Gy per fraction. Inclusion criteria for this trial included breast separation >25cm, age <50 years, chemotherapy treatment, or non-Caucasian race. Prior to XRT, the last week of XRT, and 12 weeks and 1 year post XRT, subjects underwent objective ultrasound measurements of epidermal thickness over all four quadrants of the treated breast. A skin thickness ratio (STRA) was generated normalizing for corresponding measurements taken of the untreated breast. Pertinent patient, tumor, and treatment characteristics were collected at all time points, as well as peripheral blood for gene expression assays and assessment of inflammatory markers. Results: HRT patients were significantly younger than CRT patients [mean age 52 (38-73) versus (vs.) 56 years (26-75), p=0.03]. There were no other significant differences in patient, tumor, or treatment characteristics. Baseline measurements indicated 68% of CRT (mean increase 27%, SD 0.30) vs. 71% of HRT patients (mean increase 23%, SD 0.29) had skin thickening in the treated versus untreated breast prior to XRT (p=0.50). At all subsequent time points, CRT patients had significantly higher mean STRA than HRT patients [1.53, SD 0.48 vs. 1.33, SD 0.34 during RT (p=0.03); 1.62, SD 0.48 vs. 1.31, SD 0.45 at 12 weeks post RT (p=0.002); and 1.45, SD 0.39 vs. 1.27, SD 0.40 at 1 year post RT (p=0.03), respectively]. At 1 year, 31% of CRT and 38% of HRT patients had an STRA which was either less than or equal to baseline, indicating full recovery. In multivariable analysis, baseline STRA (p<0.001), BMI (p=0.002), chemotherapy (p=0.004) and CRT treatment (p=0.02) predicted for higher STRA 1 year post XRT. Dmax and breast volume receiving 107% of the dose did not predict for STRA. Gene ontology analysis revealed an over-representation of genes, differentially regulated among patients with high and low STRA, involved in the immune and defense responses. Tumor necrosis factor 2 receptor levels were also significantly higher in CRT than HRT treated patients at 1 year (p=0.03). Conclusions: Our findings indicate that CRT is associated with higher and more severe changes in STRA up 1 year after XRT than HRT, even among patients perceived to be at high risk for XRT-induced skin toxicity and who were not well-represented in the original HRT trials. An increase in peripheral markers of inflammation may be one mechanism by which CRT, BMI, and chemotherapy are associated with higher STRA 1 year post XRT.
Factors affecting the administration of post-mastectomy radiation therapy (PMRT) in Michigan

Gorski DH H, Braun T, Munir K, Griggs JJ J, Breslin TM M and Henry NL Lynn. Wayne State University School of Medicine, Detroit, MI; Barbara Ann Karmanos Cancer Center, Detroit, MI; University of Michigan, Ann Arbor, MI and Northwestern University Feinberg School of Medicine, Chicago, IL.

Background: Evidence-based guidelines for locoregional therapy of invasive breast cancer treated with mastectomy include adjuvant PMRT for: ≥ 4 positive axillary lymph nodes (LN); T3 or above; or a positive surgical margin. We assessed PMRT uptake using data from the Michigan Breast Oncology Quality Initiative (MiBOQI), a Blue Cross Blue Shield of Michigan/Blue Care Network-sponsored collaborative quality initiative, and identified factors influencing its use in Michigan.

Methods: We prospectively collected clinical data on all patients with stage I-III breast cancer in 25 health systems belonging to MiBOQI and identified patients who underwent mastectomy from 2008 to 2013. Patients with previous cancer, bilateral disease, or treated with neoadjuvant chemotherapy were excluded. Univariate and multivariate analyses were performed to identify independent factors associated with the use of PMRT in patients with 0, 1-3, and 4+ positive LNs. Covariates included age, hormone receptor status, HER2 status, surgical margin, T category, Charlson comorbidity index, and immediate reconstruction. Two-tailed p-values <0.05 were considered significant. Analyses were carried out using SAS software, version 9.4 (SAS Institute, Cary, NC).

Results: We identified 6,596 patients with stage I-III invasive breast cancer. Of these, 4,455 had no positive axillary LNs; 1,481, 1-3 positive LNs; and 660, ≥ 4 positive LNs. There was wide variation in PMRT use across MiBOQI sites, from 13% to 63.% in patients with 1-3 positive LNs (overall 42%) and from 35% to 91% in patients with 4+ positive LNs (overall 69%). In multivariate analyses stratified by nodal status (0, 1-3, 4+), age ≥ 70 yrs was negatively associated with PMRT. We also noted lower PMRT use in women aged 51-69 with 0 and 1-3 positive LNs (Table 1).

Finally, there was no association between PMRT use and hormone receptor status, HER2 status, Charlson comorbidity index, or reconstructive surgery at the time of mastectomy.

**Conclusions:** PMRT use across Michigan was lower than the American College of Surgeons Commission on Cancer target of 90% in patients with 4 or more positive LNs. Contrary to common belief, immediate reconstructive surgery was not independently associated with decreased PMRT uptake. Understanding reasons for nonuse of PMRT may lead to interventions to increase its use by MiBOQI member institutions in patients for whom it is indicated.
Title: Delineation of internal mammary nodal target volumes in breast cancer radiotherapy

Body: Purpose/Objectives: The optimal clinical target volume (CTV) for internal mammary node irradiation (IMNI) is uncertain in an era of increasingly conformal volume-based treatment planning for breast cancer. We mapped the location of gross internal mammary lymph node (IMN) metastases in order to identify areas at highest risk for harboring occult disease.

Methods and Materials: Patients with axial imaging of IMN disease, including fluorodeoxyglucose F-18 (FDG18) positron emission tomography (PET-CT) and magnetic resonance imaging (MRI), were identified from a breast cancer registry. The IMN location was transferred by a radiation oncologist and breast radiologist onto the corresponding anatomic position on representative axial CT images of a patient in the treatment position. Distribution of lymph nodes, and their location was compared with consensus group guidelines of IMN target delineation.

Results: Sixty-seven patients with 130 IMN metastases were mapped. The location was in the first three intercostal spaces in 102 of 130 (78%) nodal metastases. Eighteen of 130 (14%) IMN were located caudal to the third intercostal space, while 10 of 130 (8%) IMN were located cranial to the first intercostal space, including 3 patients with isolated IMN metastases at that location in the absence of distant disease. Of the 102 nodal metastases within the first three intercostal spaces, 54 (53%) were located within the RTOG consensus volume. Relative to the internal mammary (IM) vessels, 19 (19%) nodal metastases were located medially with a mean distance of 2.2 mm (SD 2.9 mm), while 29 (28%) were located laterally with a mean distance of 3.6 mm (SD 2.5 mm). Ninety and ninety-five percent of lymph nodes within the first three intercostal spaces would have been encompassed within a 4 mm and 6 mm medial and lateral expansion on the IM vessels, respectively.

Conclusions: For women with indications for elective IMNI, a 4 mm medial and lateral expansion on the IM vessels within the first 3 intercostal spaces may be appropriate. In women with known IMN involvement, cranial extension to the confluence of the IM vein with the brachiocephalic vein +/- caudal extension to the 4th or 5th interspace with a 6 mm medial and lateral expansion may be considered, provided that normal tissue constraints are met.
Title: Risk factors of locoregional recurrence, locoregional failure pattern and role of postmastectomy radiotherapy for T1-2 breast cancers with 1-3 positive axillary lymph nodes

Body: Objective: To evaluate risk factors of locoregional recurrence (LRR), the locoregional failure pattern, and the role of postmastectomy radiotherapy (PMRT) for T1-2 breast cancers with 1-3 positive axillary lymph nodes.

Material and methods: 1348 patients with T1-2 breast cancer and 1 to 3 positive lymph nodes treated with mastectomy and without neoadjuvant systemic therapy during 1999-2010 were retrospectively analyzed. Six hundred and thirty (46.7%) patients were T1 and 709 (52.6%) were T2. Six hundred and sixty-seven (49.5%), 417 (30.9%) and 264 (19.6%) patients have 1, 2 and 3 axillary positive lymph nodes. After mastectomy, 235 (17.4%) received radiotherapy, 1249 (92.7%) received adjuvant chemotherapy, 958 (73.5%) received adjuvant hormonal therapy, and 39 (2.9%) received adjuvant trastuzumab. Overall survival (OS) and locoregional recurrence free survival (LRFS) rates were calculated by Kaplan-Meier method and the differences were compared by log-rank test. Cox logistic regression analysis was performed.

Results: With a median follow-up time of 79 months (range, 12-194 months), totally 155 patients died, 127 of whom died of breast cancer, 23 died of other illness or accident, 8 died of unknown reasons. Ninety-eight patients had LRR, 60 of them were isolated LRR. The 5- and 10-year cumulative LRFS were 95.7% and 91.6%, respectively. The 5-year LRFS rates were not statistically different between patients with or without PMRT (95.9% vs 94.5%, \( p = 0.338 \)). However, patients treated with PMRT had more high-risk factors including T2 diseases, PR negative, 3 positive nodes, positive node ratio more than 10%, non-luminal A subtype than those without PMRT. Multivariate analysis showed that patient who did not receive PMRT had a significant decreased LRFS compared with those who did (\( p = 0.037, HR = 2.519, 95\% CI 1.058 - 6.000 \)). For 1113 patients who did not receive PMRT, there was no significant difference in LRFS between different molecular subtypes, the 5-year LRFS rates were 98.0%, 94.2%, 96.4% and 92.8% for patients with luminal A, luminal B, Her2+, and triple negative subtype (\( p=0.129 \)). On multivariate analysis, significant factors associated with decreased LRFS were T2 stage (\( p = 0.014, HR = 2.146, 95\% CI 1.170-3.936 \)), PR negative (\( p = 0.017, HR = 2.651, 95\% CI 1.189-5.911 \)) and percentage of positive lymph node (PLN) >10% (\( p = 0.026, HR = 0.532, 95\% CI 0.305-0.928 \)). In patients with 3 risk factors treated without PMRT, the 5-year and 10-year locoregional recurrence risk (LRR) was both 15.7%. Among patients who had LRR, 48.1%, 35.9%, 13.2% and 2.8% had supraclavicular, chest wall, axilla and internal mammary node recurrence, respectively.

Conclusion: T1-2 breast cancer patients with 1-3 positive axillary lymph nodes had an excellent prognosis in modern treatment era, with a 10-year LRR risk less than 5%. Risk factors of decreased LRFS included T2 stage, PR negative and PLN >10%. PMRT should be considered for patients with all 3 risk factors. Supraclavicular nodal region and chest wall should be routinely irradiated.
The benefit of reduced radiation heart exposure in the prone vs. supine position, individually differs according to the anatomical features of the patient (Varga Z, Int J Radiat Oncol Biol Phys. 2009;75:94-110). Preferable positioning may be predicted by a statistical model. This validated calculator using the patient's body mass index (BMI), the median distance of the anterior surface of the left coronary artery (LAD) from the chest wall ($D_{\text{med}}$) and the heart area ($A_{\text{heart}}$) included in the radiation field in a single CT scan at the middle of the heart (median plane, $P_{\text{med}}$) provides quantitative estimates of the dose differences to the LAD or heart in the two positions (Varga Z, Acta Oncol. 2014;53:58-64).

In this prospective cohort study, the goal was to develop a reliable method to collect data for the calculator without acquiring a full series of CT scans in both positions. The study was approved by the Institutional Review Board of the University of Szeged, and all the enrolled patients gave their written informed consent to participation. Eligible patients needed postoperative left breast radiotherapy. In 100 patients, a single CT slice image representing the middle of the heart (reference plane, $P_{\text{ref}}$) was acquired by using the AP scout view in the supine position for the selection of the transversal plane appropriate for the measurements of $D_{\text{med}}$ and $A_{\text{heart}}$. Thereafter, CT series were acquired in both positions, and analyses were performed on 1. the conformance of the $P_{\text{ref}}$ with $P_{\text{med}}$, 2. the effect of plane miss on the choice of preferable position. 3. Finally the sensitivity and specificity of this simple clinical method was reevaluated based on the dosimetry data (mean LAD dose, V25Gy heart) obtained using the topogram for selecting the position.

In 55 cases, $P_{\text{ref}}$ was the same as $P_{\text{med}}$, while in 27 and 18 cases, $P_{\text{ref}}$ and $P_{\text{med}}$ differed by 2 or more planes, respectively. No difference was found between the values of $D_{\text{med}}$ or $A_{\text{heart}}$ as measured in $P_{\text{ref}}$ vs. $P_{\text{med}}$, independently whether $P_{\text{ref}}$ was identified correctly or not. The suggestion on treatment position per $P_{\text{ref}}$ measurements, was correct in 85 cases, was ambiguous in 8 cases and incorrect in 7 cases. Sensitivity of the calculator based on $P_{\text{ref}}$ measurements was 90% (both mean LAD dose and V25Gy heart), while specificity was 72% (mean LAD dose) and 68% (V25Gy heart). The simple clinical method was tested in additional 60 left breast radiotherapy cases, by taking a topogram and a CT series in the suggested position only. Mean LAD dose (mean [CI95%] prone vs. supine: 6.5 [5.7-7.3] Gy vs. 7.5 [5.6-9.5] Gy) and V25Gy heart (mean [CI95%] prone vs. supine: 0.87 [0.67-1.11] % vs. 1.13 [0.55-1.71]%) well corresponded to the institutional dose constraints based on dosimetry data achieved with individual positioning in >300 patients with left-sided breast cancer.

We consider this simple clinical tool appropriate for assisting individual positioning aiming at maximum heart protection during left breast irradiation.

*Supported by the VKSZ 12-1-2013-0012 project.
**Title:** Radiation therapy in 1-3 node positive mastectomy patients: Who benefits?

Ellis ED D, Scanlan JM M, Kaplan HG G, Kieper DA A, Morris AD D and Atwood M. Swedish Center for Research and Innovation, Seattle, WA; Providence Health and Services, Seattle, WA and Swedish Cancer Institute, Seattle, WA.

**Body:**

**Introduction** A recent meta-analysis on radiation therapy (XRT) demonstrated improved outcomes and recommended its use. However, these data were derived from the 1960’s-1980’s and might not reflect the effects of XRT when used in modern oncology practice [1]. Consequently, XRT benefits for mastectomy patients with 1–3 positive nodes at the time of surgery (SX) remain uncertain. In this retrospective study we examined XRT effects in a modern cohort of mastectomy patients with 1–3 positive nodes at SX, across multiple outcomes: loco-regional recurrence (LRR), distant recurrence (DR), total recurrence (TR), breast cancer (BCa mortality) and all-cause mortality (ACM).

**Subjects** The Swedish Cancer Institute’s breast cancer patient registry was used to identify mastectomy patients who had 1-3 positive lymph nodes at SX and known HER-2 receptor status. HER-2 positive patients who did not receive Herceptin were excluded.

**Methods** Clinical, pathological, treatment and outcomes data were extracted from our registry. Logistic multiple regressions were used to identify clinical and pathology elements available at the time of SX that correlated with LRR, DR, TR, BCaM and ACM. Regression model elements included: tumor receptor status - estrogen (ER), progesterone (PR) and HER-2, presence or absence of lymphovascular invasion (LVI), extension of LVI, number of LN+, node positivity ratio (positive/examined), surgical margins (SxM); patient age, chemotherapy, XRT and hormonal treatment.

**Results** The application of these filters to our breast cancer registry yielded 935 patients with a mean follow up time of 7 years. Our sample was “modern”: 95% of our patients were diagnosed after 1999, 80% after 2004. Logistic regression indicated that across all patients, XRT was associated with improved LRR (Nagelkerke R²=5%, p<.01), and ACM (Nagelkerke R²=1%, p<.05). The four clinical and pathologic elements that most strongly correlated with outcomes were LVI (+), LN+>1, PR (-) and SxM (+) and we stratified the population into risk groups based on the number of factors present; low-risk = no factors, medium-risk = 1 factor, High-risk = 2+ factors. We also stratified by treatments, comparing the effects of chemotherapy alone vs. chemotherapy plus XRT across the major patient outcomes and risk groups (see Table 1). This comparison only showed XRT effects for LRR in the higher risk groups.

* =p<.05, + =p<.07

**Discussion** XRT improved LRR in the medium and high risk groups, but lacked benefit in the low-risk group and did not provide statistically significant improvements in BCa survival. These results suggest caution in using XRT in low-risk patients, but it has some value in reducing LRR in medium and high-risk populations, without survival benefits.

Title: Can the risk of radiation-induced cardiac disease in breast cancer be mitigated with cardiac-sparing techniques?

Smith TL L, Mokhtech M, Bradley JA A, Lightsey JL L, Morris CG G and Mendenhall NP P. University of Florida College of Medicine, Gainesville, FL and University of Florida Health Proton Therapy Institute, Jacksonville, FL.

Body: Introduction: Data suggest that long-term survivors of breast cancer treated with radiation therapy (RT) have an increased risk of cardiac events despite an overall survival benefit, particularly women with left-sided breast cancers. We hypothesized that with cardiac-sparing radiation techniques there would be no difference in long-term cardiac risks between women with right- and left-sided breast cancers.

Materials and Methods: The outcomes of 775 consecutive women treated between 1984 and 1999 with breast-conserving therapy (BCT) (n=424) and post-mastectomy radiation therapy (PMRT) (n=351) for stage 0-3 breast cancer were assessed retrospectively through a review of medical records and contact with living patients. The choice of BCT vs PMRT was based on tumor board disposition and patient preference; mastectomy was recommended for multicentric or T3 breast cancers. Ninety-six percent of all node-positive patients received treatment to all nodal regions, including the internal mammary (IM), axillary (AX), and supraclavicular (SC) nodes. BCT patients had computed tomography-planned tangential breast radiation with photons with IM nodes treated within the tangent fields or with a separate en face electron field to minimize cardiac exposure. PMRT patients were treated with en face electron fields for the chest wall and IM for sparing of the lung and heart. The AX and SC nodes were treated with a matched anterior photon field with a posterior-anterior boost field (PAB) when necessary to achieve adequate dose in the AX with both BCT and PMRT. Overall, 411 patients were node-negative and 353 were node-positive. All patients have a minimum potential follow-up of 16.4 years; median actual follow-up for the BCT group was 15 years (range, 0.1-31.2) and for the PMRT group it was 9.5 years (range, 0.1-30.5).

Results: Overall survival (OS), cause-specific survival (CSS), and freedom from local-regional recurrence (FFLR) rates for the cohort at 15 years were 58.2%, 72.0%, and 90.8%, respectively. Rates of freedom from cardiac events (FFCE), pulmonary events, and second malignancy were 87.6%, 93.6%, and 86.3%, respectively. On multivariate analysis, OS was correlated with stage (p=.045), number of positive nodes (p=.002), age (p<.0001), diabetes (p = .0021), and modality (p=.0017). Not surprisingly, 15-year survival for patients treated with BCT was better than for patients treated with PMRT (70.9% vs 59.7%; p<.0001). CSS was associated with stage (p=.0207), number of positive nodes (p=.0409), and modality (p=.0003). FFLR was associated with number of positive nodes (p =.0484). FFCE was associated with pretreatment cardiac disease (p<.0001), stage (p=.0461), and age (p=.0056), but not with either breast cancer laterality (p=.1906) or modality (BCT vs PMRT; p=.7487).

Discussion: Long-term disease control and survival outcomes were better in BCT than PMRT patients, likely due to selection criteria. Cardiac events were associated with pretreatment heart disease, older age, and stage, suggesting that this population may benefit from advanced radiation techniques that can further limit cardiac dose. Neither breast cancer laterality nor treatment modality was associated with cardiac events.
Title: Abstract Withdrawn
Purpose: Radiation therapy is an important treatment modality in the curative management of early stage breast cancer. With increasing cancer survivorship, late effects of cancer treatment have become increasingly relevant. Breast fibrosis is a common late effect following therapeutic irradiation which can potentially result in pain, poor cosmesis, and functional impairment. Randomized trials have suggested that radiation fibrosis may be reversible or preventable using a medication regimen of Pentoxifylline and Vitamin E. These clinical trials have shown excellent patient compliance and tolerability of this regimen, but it is unclear if this tolerability translates to clinical practice. The goal of this study is to investigate the clinical tolerability and compliance with pentoxifylline and Vitamin E therapy in patients with radiation induced breast fibrosis while determining possible correlates to discontinuation.

Methods: We identified ninety patients who were prescribed Pentoxifylline (400mg three time daily) and Vitamin E (400 IU once daily) following definitive breast radiation therapy from January 2013 to December 2015. A retrospective cohort study was conducted utilizing medical record analysis. Data was collected including patient age, comorbid conditions, concurrent medications, duration of pentoxifylline and Vitamin E therapy, any dose adjustments, patient reported side effects, and any reported reason for discontinuation. Multivariate analysis of correlation between medication compliance and these categorical variables was assessed with Chi squared ($\chi^2$) analysis of independence.

Results: Raw patient compliance with Pentoxifylline and Vitamin E therapy was found to be poor with 33 of 87 (38%) of patients requiring either dose reduction or discontinuation of therapy due to side effects. The majority of patient complaints leading to dose adjustments were GI related with nausea (n=20) abdominal pain (n=4), and diarrhea (n=1) reported. There was a statistically significant relationship between concurrent antiemetic therapy and successful completion of pentoxifylline regimen. Patients completed therapy at a rate of 76% with concurrent antiemetic vs 48% without ($p=0.007$). There was a statistically significant relationship between concurrent proton pump inhibitor therapy and discontinuation of pentoxifylline. Patients completed pentoxifylline therapy at a rate of 33% with concurrent proton pump inhibitor vs 81% without ($p=<0.001$). Treatment compliance was not significantly correlated with age, pre-existing GERD, time since completing radiation therapy, concurrent use of aromatase inhibitor, tamoxifen, vitamin E, or chemotherapy.

Conclusion: Patient compliance with Pentoxifylline and Vitamin E for radiation induced breast fibrosis appears to be worse in clinical practice compared with previously reported randomized trials. Nausea was the most commonly reported side effect resulting in discontinuation of the regimen. Our data suggests concurrent antiemetic therapy is correlated with strong regimen compliance while concurrent proton pump inhibitor therapy is correlated with poor compliance independent of comorbid conditions. These data should be discussed with patients prior to initiation of treatment.
Title: Standardization of nodal radiation therapy (RT) through changes to a breast cancer clinical pathway (CP) in a large, integrated comprehensive cancer center network

Gebhardt BJ J, Horne ZD D, Heron DE E and Beriwal S. University of Pittsburgh Cancer Institute, Pittsburgh, PA.

Body: Purpose
The efficacy of adjuvant RT following breast conserving surgery (BCS) in reducing risk of local recurrence is established. The results of Z11, AMAROS and MA-20 studies led to wide variation in RT treatment volume for patients (pts) who have sentinel node biopsy positive disease. CP's are a mechanism of standardizing care when many therapeutic options exist and clinical practice varies unnecessarily. We sought to evaluate the impact of changes to a CP guiding adjuvant RT in sentinel node positive pts for invasive breast cancer (IBC) on practice patterns throughout a large cancer network.

Methods
In 2003, we implemented a CP for management of IBC with adjuvant RT. In 2009, we required entry of management decisions into an online tool integrated with medical records to track CP choices and subject off-pathway selections to peer-review. The CP for treatment of pts with positive sentinel lymph nodes (LN) following BCS was modified in February 2015 to promote uniform treatment of regional LN irradiation (RNI). In summary, the CP recommended modified tangents (MT) including level 1 and 2 nodes for all pts with micrometastases. For pts with macrometastases, CP recommended including level 1 and 2 LN in MT and add additional field to include level 3, supraclavicular LN +/- IM node for pts with any adverse factor present defined as T2 disease, LVSI, high grade, ER negative, ECE or premenopausal pts. Data from treatment decisions entered into the support tool from June 2009 to April 2016 were obtained.

Results
From 2009 until CP modification in 2015, 1089 treatment decisions were entered. Decisions were heterogeneous and included 24 distinct options. Following pathway amendment, 178 decisions were entered. Three pts were enrolled in clinical trials & 9 referred to other providers and excluded. Of the remaining 166 pts, 7 (4.2%) were treated off pathway for poor performance status, patient preference, or gross residual disease. The 159 (95.8%) on-pathway pts were analyzed. Median age was 61 (range 32-90) years. All pts underwent BCS for IBC and had positive sentinel LN. Forty-four (27.7%) pts had micrometastatic LN disease, and 115 (72.3%) had macrometastases, of which 82 (71.3%) had adverse risk factors. All 44 pts with micrometastases were treated with MT. Six (5.2%) pts with macrometastases were treated with WBT RT, 33 (28.7%) with MT, & 76 (66.1%) with MT and a 3rd field. Seventy-six (92.7%) pts with adverse risk factors were treated with MT and 3rd field (p<0.001).

Conclusions
CP's are useful tools for translating published research, national guidelines, and institutional experience into standardized patient management plans to promote evidence-based care and eliminate unnecessary variations in practice patterns that lead to inefficiency and inferior outcomes. Recognizing that our CP for adjuvant treatment of patients with positive sentinel LNs undergoing BCS allowed heterogeneous treatment selections, we modified the CP in 2015 based upon the latest evidence regarding RNI. We found that following the amendment, patients received RT fields guided by the CP leading to more standardized treatment based upon clinical risk factors and facilitating tracking of patient outcomes.
Radiotherapy associated with concurrent bevacizumab in patients with non-metastatic breast cancer

Dautruche A, Belin L, Cottu P, Bontemps P, Lemanski C, De La Lande B, Baumann P, Missohou F, Levy C, Peignaux K, Reynaud-Bougnoux A, Denis F, Gobillion A, Ady Vago N, Fourquet A and Kirova Y. Institut Curie, Paris, France; Institut Curie, Paris, France; Institut Curie, Paris, France; CHU Jean Minjoz, Besançon, Doubs, France; Institut Régional du Cancer de Montpellier, Montpellier, Hérault, France; Institut Curie, Rene Huguenin Hospital, Saint-Cloud, Hauts-de-Seine, France; Centre d’Oncologie de Gentilly, Nancy, Meurthe-et-Moselle, France; Centre Henri Becquerel, Rouen, Seine-Maritime, France; Centre François Baclesse, Caen, Calvados, France; Centre Georges-François Leclerc, Dijon, Côte-d’Or, France; CHU Tours, Tours, Indre-et-Loire; Centre Jean Bernard, le Mans, Sarthe, France and Roche SAS, Boulogne-Billancourt, Hauts-de-Seine.

Body: Purpose/Objectives
The purpose of this study was to determine early and late toxicities among patients with non-metastatic breast cancer (BC) receiving concurrent bevacizumab (BV) and radiation therapy (RT).

Materials/Methods
Multicentre, prospective study, of the toxicity of adjuvant concomitant association of BV and RT in patients with non-metastatic BC enrolled in Phase 3 BEATRICE, BEVERLY and BETH trial. Early and late toxicities were assessed by the Common Terminology Criteria for Adverse Events v. 3.0 during RT, 12 months and 36 months after its completion.

Results
Sixty-four patients were included from October 2007 to August 2010. They all received adjuvant RT and BV concomitant treatment, plus neo-adjuvant BV for 24 patients. RT was adjuvant and normo-fractionated. Twelve months toxicity was available for 60 patients and 36 months toxicity was available for 43 patients. Median follow-up was 46 months (18-77). Median age was 51 years old (23-68). Among 63 evaluated patients during RT, acute radiation dermatitis was observed in 48 (76%) patients: Grade 1 for 27 (43%), grade 2 for 17 (27%), grade 3 for 4 patients (6%). Grade 2 acute oesophagitis was observed in 1 patient. At 3 years, few toxicities were observed: 6 patients (14%) had grade 1 pain, 4 (9%) had grade 1 fibrosis, one (2%) had grade 1 telangiectasis, one (2%) had grade 1 paresis, 3 (7%) had grade 1 lymphoedema and one grade 3 lymphoedema. No grade 4 toxicity was observed. At 12 months, only one evaluated patient had a LVEF <50% and none at 36 months.

Conclusions
Concurrent bevacizumab with locoregional RT is associated with acceptable early and late 3-years toxicities in patients with BC. Determination of late toxicity at 60 months is currently underway.
Body: OBJECTIVES: To evaluate the cost effectiveness and economic impact of increasing the use of hypofractionated radiotherapy for the treatment of women older than 50 years, with early breast cancer (stages I and II) within the Brazilian National Health System (SUS). METHODS: Several studies show no difference concerning efficacy and safety between hypofractionated and conventional radiotherapy for the treatment of women older than 50 years with stages I and II disease. We built a cost-effectiveness Markov model in Excel which quantifies the cost and the amount of photon beams linear accelerator time used for the treatment of patients using hypofractionated (2.67Gy/fraction) or conventional (2Gy/fraction). The time horizon is 5 years. The perspective of the study is the SUS. The effectiveness was measured as amount of hours saved using hypofractionated in relation to conventional radiotherapy. Costs related to treatment are from DATASUS, and considered the cost of planning the radiotherapy, of the check-film and the use of photon beams linear accelerator. The discount we applied was 5% for costs and benefits. We performed univariate and probabilistic sensitivity analyses. The treatment fraction time was set as 15 minutes. We also built, in Excel, a budget impact model to simulate the increasing adoption of hypofractionated radiotherapy instead of conventional radiotherapy in the treatment of Brazilian women older than 50 years with early breast cancer. The model compares hypofractionated radiotherapy (2.67Gy/fraction) with conventional radiotherapy (2 Gy/fraction). We determined the number of women over 50 years with stages 1 and 2 breast malignant neoplasm that underwent adjuvant radiotherapy in 2013 and 2014, and then projected these populations for the years 2016 to 2020. We considered the costs of planning the radiotherapy, using the photon beams linear accelerator, and performing the check-film. We considered a yearly increase of 20% in the adoption of hypofractionated radiotherapy for the years 2016 to 2019 (2016 20%; 2017 40%; 2018 60%; 2019 80% and 2020 90%). The treatment fraction time was set as 15 minutes. RESULTS: The use of hypofractionated radiotherapy at 5 years was able to decrease the number of hours of treatment (-21,835 hours) and the total cost of treatment (-$11,790,229.64). The technology is cost saving. Based on the budget impact analysis, the annual incremental impact would be of -$243,202.65, -$490,294.13, -$741,085.61, -$995,388.73 and -$1,127,712.81 providing 3,378, 6,810, 10,294, 13,826 and 15,664 free hours of the linear accelerator for the years 2016, 2017, 2018, 2019 and 2020, respectively. These photon beams linear accelerator free hours may allow 613, 1,380, 2,306, 3,392 and 4,010 additional patients to have access to breast cancer treatment during the years of 2016 to 2020 respectively. CONCLUSIONS: Considering the conditions proposed in these models increasing the use of hypofractionation as a radiotherapy technique to treat women older than 50 years, with early breast cancer within seems to increase the system efficiency saving money, optimizing the treatment schedule and providing access to treatment for more patients.
Title: Two-year follow-up results of a multi-center trial of intra-operative electronic brachytherapy during breast conservation surgery for early stage breast cancer

Body: Objective
To assess the safety and efficacy of single-fraction, intra-operative radiation therapy (IORT) delivered with the Xoft® Axxent® Electronic Brachytherapy System® (eBx®) immediately following surgical resection for treatment of early stage breast cancer.

Methods
This phase 4, open-label, single-arm, prospective, non-randomized trial is still enrolling participants and is currently being conducted at 26 hospitals in the USA (25) and Portugal (1). 878 participants with biopsy-proven ductal carcinoma in situ (DCIS) or invasive ductal carcinoma who met the inclusion criteria underwent lumpectomy followed by single-fraction IORT to the lumpectomy cavity. Briefly, a small, presterilized lead shield piece was placed on the chest wall to reduce the dose to the ribs, and then a balloon applicator, suitable to the surgical bed, was placed in the lumpectomy cavity and inflated with saline (30-75 cc); skin was temporarily closed over the balloon and ultrasound was used to confirm a balloon surface-to-skin distance ≥ 1.0 cm. The Xoft System was used to deliver the 20 Gy dose at the balloon applicator surface. The balloon was deflated, lead shield and balloon removed and the surgical site sutured. The prespecified primary outcome of this 10-year follow-up study is recurrence of ipsilateral breast tumor at 5 years. Prespecified secondary outcomes include 10-year recurrence and cosmesis (Harvard Scale).

Findings
Of the 878 participants treated, 877 participants received the prescribed 20 Gy dose with a mean radiation treatment time of 594.5 seconds, whereas one participant received 14 Gy due to a source failure. 569 participants have reached 18-month (333), 2-year (199), and 3-year (37) follow-up. The mean age at enrollment was 65 years (range 41-90). 219 participants had DCIS and 658 had invasive ductal carcinoma. The DCIS nuclear grade was high (N=79), intermediate (N=100), or low (N=40). Invasive cancers were Grade 1 (N=282), 2 (N=282), or 3 (N=94). 664 participants had T1 lesions, 56 had T2 lesions, and 3 were unknown. The mean tumor size was 12.33 ± 10.5 mm. Cosmesis was excellent to good in 90% of participants who reached 2-year follow-up. The most frequent side effects were breast pain, seroma, induration, and erythema. There were nine deaths, none of which were breast cancer related, four ipsilateral breast recurrences, and three new contralateral breast cancers.

Conclusions
Early results from this multi-center trial demonstrate that IORT using the Xoft Axxent eBx System at the time of breast conservation surgery continues to be a promising treatment option for early stage breast cancer. The short course of radiation therapy for select patients has excellent to good cosmetic results and a low rate of high-grade adverse events and recurrences.

Body: Objective
To assess the safety and efficacy of single-fraction, intra-operative radiation therapy (IORT) delivered as a boost using the Xoft® Axxent® Electronic Brachytherapy System® (eBx®) immediately following surgical resection for treatment of early stage breast cancer.

Methods
This phase 4, open-label, single-arm, prospective, non-randomized trial is still enrolling participants and is currently being conducted at 26 hospitals in the USA (25) and Portugal (1). 878 participants with biopsy-proven ductal carcinoma in situ (DCIS) or invasive ductal carcinoma who met the inclusion criteria underwent lumpectomy followed by single-fraction IORT to the lumpectomy cavity. Briefly, a small, presterilized lead shield piece was placed on the chest wall to reduce the dose to the ribs, and then a balloon applicator, suitable to the surgical bed, was placed in the lumpectomy cavity and inflated with saline (30-75 cc); skin was temporarily closed over the balloon and ultrasound was used to confirm a balloon surface-to-skin distance ≥ 1.0 cm. The Xoft System was used to deliver the 20 Gy dose at the balloon applicator surface. The balloon was deflated, lead shield and balloon removed and the surgical site sutured. Upon the presence of additional risk factors, 37 participants subsequently received whole breast radiation therapy (WBRT); thus, these participants received an unplanned IORT boost and were removed from the primary analysis but will continue to be followed for the duration of the 10-year study. Cosmesis (Harvard Scale) was assessed in this subset of participants. The primary outcome for the main trial is recurrence of ipsilateral breast tumor at 5 years. Trial Registry: ClinicalTrials.gov; Identifier: NCT01644669.

Early Findings
37 boost participants received WBRT (up to 50 Gy) after IORT (36 received the prescribed 20 Gy dose; one received 14 Gy). Mean follow-up time was 430 days (range 13-1119). Mean age at IORT was 62 years (range 45-78). Boost participants had either DCIS (N=5) or invasive ductal carcinoma (N=32). The DCIS nuclear grade was high (N=3), intermediate (N=1), or low (N=1). Invasive cancers were Grade 1 (N=15), 2 (N=10), 3 (N=6), or unknown (N=1). 29 participants had T1, 3 had T2, and 5 had Tis lesions. Mean tumor size was 13.04 ± 10.26 mm. For the two participants who have reached 3-year follow-up, cosmesis was excellent (N=1) and fair (N=1). For the six participants who have reached 2-year follow-up, cosmesis was excellent (N=4), good (N=1), and fair (N=1). There was one serious adverse event with a Grade 3 for skin necrosis. The most frequent side effects were seroma (10%), edema (9%), pain (9%), erythema (6%), and induration (5%). There have been no deaths, recurrences, or new primary tumors among the boost participants to date.

Conclusions
Early results from this multi-center trial suggest that IORT as a tumor-bed boost using the Xoft Axxent eBx System at the time of breast conservation surgery is safe and has low morbidity. To date, the majority of participants receiving an unplanned IORT boost have had excellent to good cosmetic results and the majority of adverse events have been low-grade.

Influence of timing of radiation therapy following breast-conserving surgery on 10-year disease-free survival

van Maaren MC C, Bretveld RW W, Jobsen JJ J, Veenstra R, Groothuis-Oudshoorn KCGM CGM, Struikmans H, Maduro JH H, Strobbe LJA JA, Poortmans P and Siesling S. Netherlands Comprehensive Cancer Organisation, Utrecht, Netherlands; Medical Spectrum Twente, Enschede, Netherlands; Dutch Institute for Clinical Auditing, Netherlands; MIRA Institute for Biomedical Technology and Technical Medicine, University of Twente, Enschede, Netherlands; Medical Center Haaglanden, The Haque, Netherlands; Leiden University Medical Center, Leiden, Netherlands; University Medical Center Groningen, University of Groningen, Groningen, Netherlands; Canisius Wilhelmina Hospital, Nijmegen, Netherlands and Radboud university medical center, Nijmegen, Netherlands.

Body: Background
In the Netherlands, one of the indicators of quality of care is that radiation therapy (RT) should start within six weeks following breast-conserving surgery (BCS). However, there is still much controversy regarding timing of RT in literature. This study investigated the effect of timing of RT on disease-free survival (DFS) in a Dutch nationwide population-based cohort.

Methods
All women diagnosed with primary invasive stage I-IIIA breast cancer in 2003, treated with BCS plus RT, of whom the start date of RT was known, were included. Patients who received chemotherapy between surgery and RT were excluded, as this affects delay. Patients were categorised into three groups: <42 days, 42-55 days and >55 days, between surgery and start of RT. The primary outcome was 10-year DFS. Secondary outcomes were 10-year locoregional recurrence-free (LRRFS) and distant metastasis-free survival (DMFS). Multivariable Cox regression was used to correct for confounding. Since adjuvant systemic therapy largely influences DFS, all analyses were stratified for use of adjuvant systemic therapy (chemotherapy and/or endocrine therapy).

Results
In total, 2,759 patients were included. The median number of days between BCS and RT was 45 (IQR 37-54 days). The hazard ratio (HR) for 10-year DFS was 0.79 (95% CI: 0.65-0.96) for 42-55 days and 0.71 (95% CI: 0.56-0.90) for >55 days, both compared to <42 days. While no significant differences in 10-year LRRFS were found, 10-year DMFS (HR 0.64 [95% CI: 0.45-0.91]) was significantly higher for BCS-RT interval >55 days compared to <42 days. After stratification, no significant differences were found for any outcome in patients not treated with adjuvant systemic therapy, while in patients who were treated with adjuvant systemic therapy, 10-year DFS was significantly improved for 42-55 days (HR 0.70 [95% CI: 0.51-0.97]) and >55 days (HR 0.63 [95% CI: 0.42-0.96]) compared to <42 days. Significantly improved 10-year DMFS was confirmed after stratification for longer delays (HR 0.69 (95% CI: 0.47-1.00) for 42-55 days) and 0.59 (95% CI: 0.36-0.96) for >55 days, compared to <42 days)

### Conclusion and interpretation

In conclusion, patients treated with adjuvant systemic therapy following RT showed increasing 10-year DFS and DMFS with longer BCS-RT intervals, which was not the case for patients not receiving adjuvant systemic therapy. Possible explanations for these results have to be explored further.
Title: Abstract Withdrawn
A comparison of models (physician, the Van Nuys prognostic index, the Memorial-Sloan-Kettering Cancer Center DCIS nomogram) to predict ipsilateral breast events in patients with ductal carcinoma in situ (DCIS) of the breast after breast-conserving surgery failed to replicate results of the oncotype DCIS recurrence score

Leonard C, Lei R, Antell A, Nowels M, Fryman S, Howell K and Dennis C. Rocky Mountain Cancer Centers, Littleton, CO; Rocky Mountain Cancer Centers, Boulder, CO; University of Colorado Denver, Denver, CO and Rocky Mountain Cancer Centers, Aurora, CO.

**Purpose:** To compare ipsilateral breast event (IBE) risks in patients with DCIS of the breast post-lumpectomy, as estimated by breast radiation oncologists, the Van Nuys Prognostic Index (VNPI) studies, the Memorial Sloan Kettering Cancer Center (MSK) DCIS nomogram, and the 12-gene DCIS Recurrence Score assay.

**Materials/Methods:** 12-gene DCIS Recurrence Score of 91 DCIS lumpectomy cases were identified from our practice. Clinicopathologic factors (excluding DCIS score) were summarized for blinded review. 3 radiation oncologists independently estimated the 10-year IBE risk and rated the impact of age/menopausal status, tumor morphology, tumor span, and margin width. Corresponding VNPI and MSK nomogram estimates were generated. Differences and correlations between the IBE estimates and clinicopathologic factors were evaluated with univariate and multivariate analysis.

**Results:** Median age was 60, 25% margins < 3 mm, 48% DCIS span > 10 mm, 48% would have been ineligible for E5194. All comparisons were initially examined for similarity (non-significant differences) and subsequently tested for a significant correlation. In three possible physician comparisons only 1 (AA-CL) had similar IBE estimates and strong correlation (r=0.792). Comparison of physicians to either VNPI nomogram or MSK DCIS calculator had similar estimates with strong correlation in only 2 of 6 possible comparisons in the all cases and the E5194 eligible patient cohorts respectively; and in 1 of 6 comparisons in the E5194 ineligible cohort. The DCIS Recurrence Score showed no strong correlation in regard to similar IBE estimates for any comparisons including either physicians, VNPI nomogram or MSK DCIS calculator. Tumor size was highly correlated with all physician IBE estimates (r = 0.547 to 0.799), while margin size showed moderate to high inverse correlations (r = -0.324 to -0.619). All 3 physicians rated margin width as having the most impact on their IBE risk estimates, then tumor morphology and tumor span.

Conclusion: IBE risk estimates for this cohort of DCIS cases vary significantly among commonly available clinical predictive tools and individual physician estimates. Surgical margins and tumor size continue to factor prominently in physician decision algorithms. In our observations, neither the VNPI nomogram, MSK DCIS calculator nor physician IBE risk estimates have similar values with strong enough correlation to reliably replicate the DCIS Recurrence Score.
Title: Rates of ipsilateral breast tumor recurrence (IBTR) following breast conserving surgery (BCS) and hypofractionated radiotherapy for ductal carcinoma in situ (DCIS)

Dumitru D, Benson J, Wishart G and Provenzano E. Addenbrooke’s Hospital; Cambridge Breast Unit, Cambridge, Cambridgeshire, United Kingdom and Anglia Ruskin University, Cambridge, Cambridgeshire, United Kingdom.

Body: Background: The risk of IBTR following BCS for DCIS is dependent on both tumor and treatment-related factors including surgical margin width and adjuvant therapies. Management strategies should be risk stratified to avoid over/under-treatment with radiotherapy and endocrine therapy. De-escalation of treatments with safe omission of adjuvant therapies may demand a minimum margin of surgical clearance for non-high grade and selected high grade lesions.

Methods: A retrospective analysis was undertaken to examine rates of IBTR among patients undergoing BCS for core biopsy-proven DCIS between 1999 and 2010 when a minimum margin width of 5mm prevailed. The local institutional database identified 1260 DCIS cases with or without an invasive component among whom 323 had pure DCIS diagnosed mainly on screening (>90%). A total of 176 patients were treated with BCS alone (27.5%) or combined with breast radiotherapy [15 fractions of 2.67Gy to total dose of 40Gy without boost]. No patients received any form of hormonal therapy (tamoxifen/aromatase inhibitor). Ten patients died from non-breast cancer causes prior to development of IBTR leaving 167 unilateral and 1 bilateral patient (i.e. 168 cases) for analysis with high (72%), intermediate (17.8%) and low (9%) grade DCIS (or ungradeable).

Results: At a median follow up of 126 months (range 46 – 180) a total of 14 patients have developed IBTR as a first event (8.33%). Approximately half of these were non-invasive (n= 8) and half invasive (n=6). Half of DCIS recurrences (4/8) occurred in the first 12 months following surgery and all recurrent DCIS cases were manifest by 3 years compared with a steady recurrence of invasive disease up to 10 years of follow up. One case of invasive disease died from subsequent distant metastases with visceral deposits. There was no significant difference in rates of recurrence with (9/121) or without (5/46) irradiation (p=0.534). Among the 14 recurrent cases, 12 had conformal radial margins of 5mm whilst 2 cases had single minimum margins of 3mm and 2mm (accepted without re-excision due to advanced age, co-morbidity or lesion at edge of breast tissue). Characterization of molecular profiles (ER, HER2, Ki-67) for recurrent cases is ongoing.

Conclusion: These rates of local control with a target margin of 5mm and selective hypofractionated breast radiotherapy are consistent with published IBTR rates of approximately 1% per annum for DCIS patients treated with BCS and radiotherapy. Routine inclusion of hormonal therapy may be unnecessary for many patients receiving adjuvant radiotherapy with comparable 10 year recurrence rates of 7 - 8% reported in the International Breast Intervention Study (IBIS)-II.

Title: Looking beyond the margins: Economic costs and complications associated with repeated breast-conserving surgeries

Metcalf LN N, Zysk AM M, Underwood HR R, Edelman G, Vu L, Cittadine AJ J, Hyer KB B and Thompson AM M. Health Care Services Corporation, Richardson, TX; Diagnostic Photonics, Inc., Chicago, IL and University of Texas MD Anderson Cancer Center, Houston, TX.

Body: Background: Although considerable attention has been drawn to the problem of repeat breast-conserving surgery (BCS), the costs and complications due to these additional operations are not well-characterized. In this work, a retrospective review of insurance claims data for BCS patients was performed to assess complications and economic outcomes.

Methods: Private claims data were analyzed for 9,837 women undergoing BCS for breast carcinoma between January 2010 and December 2013. Patients enrolled in insurance plans in IL, TX, NM, and OK were included. Patients undergoing a second open breast surgery (mastectomy or BCS) within 90 days of the initial BCS were classified as having a repeat surgery. Complications were identified via a set of 8 CPT and 25 ICD9 diagnosis and procedure codes related to breast cancer treatment. The analysis included these complications and the total cost of all allowed healthcare claims within two years following diagnosis.

Results: 7,555/9,837 patients (77% ±0.8%, 95% confidence interval) had one BCS operation, and 2,282 patients (23% ±0.8%) had at least one repeat surgery. The mean patient age was 53 years. Women who underwent an additional operation waited an average of 24 days for the procedure.

The mean two-year total costs for patients undergoing a single BCS was $89,016 (±$1,884), and the cost for patients undergoing a repeat breast surgery was $105,088 (±$3,680; p < 0.0001), $100,637 (±$4,219) for a second BCS and $115,292 (±$7,259) for subsequent mastectomy. The mean added cost due to a repeat surgery was $16,072.

The percentage of patients experiencing at least one complication was 23.6% (±1.0%) for those undergoing one BCS only and 34.8% (±2.0%) for those undergoing a repeat operation (p < 0.0001). Patients undergoing repeated surgery were 88% more likely to experience multiple complications (5.5% ±0.5% vs. 10.4% ±1.3%) and nearly three times as likely to experience fat necrosis (2.5% ±0.4% vs. 7.2% ±1.1%). Infection, hematoma/seroma, and breast pain were the most common complications for patients who did not undergo a repeated surgery (9.9% ±0.7%, 8.7% ±0.6%, 6.9% ±0.6%). For patients undergoing a repeated surgery, infection, hematoma/seroma, and fat necrosis were the most common complications (15.3% ±1.5%, 13.9% ±1.4%, 7.2% ±1.1%).

Conclusions: For the 23% of women undergoing a second operation after BCS, complications were 48% more common, and the mean total cost of surgery was $16,072 more, demonstrating statistically-significant evidence of a patient-centered and fiscal imperative to reduce reoperations in BCS for breast cancer.

Title: Influence of race and age on mastectomy rates in women with stage I, hormone-sensitive breast cancers: A SEER-based study

Bazan JG G, Bittoni MA A, Fisher JL L and White JR R. The Ohio State University, Columbus, OH.

**Body:**

**Background:** Breast conserving therapy (lumpectomy [L] and breast radiotherapy [RT]) results in equivalent cancer control outcomes in comparison to mastectomy (M) for early stage breast cancer (BC) based on randomized controlled trials (RCT). Since 2004, RCT support that L alone without RT yields equivalent survival and acceptable local regional outcomes in women ≥70 years old with stage I (T1N0) hormone-sensitive (HS) BC on endocrine therapy. Based on this, we hypothesized that M rates should decrease substantially in this low risk elderly population and sought to examine the influence of race on M rates in this group and how these trends compare to younger aged Stage I HS patients.

**Methods:** We used the Surveillance Epidemiology and End Results (SEER) registry data to conduct this study. We included women with T1N0 HS BC classified as either ER-positive or PR-positive from 2000-2012 divided into 2 age groups [elderly (≥70 years old) and non-elderly (20-69 years old)] and 3 race groups [white, black, and Asian-Pacific-Islander/American Indian/Alaskan Native (API)]. We compared M rates in women diagnosed before 2004 compared to those diagnosed from 2005-2012. Statistical analyses were performed using differences in proportions (p<0.05 considered statistically significant).

**Results:** 261,079 women met the study criteria (N=87,009 elderly; N=174,070 non-elderly). In elderly Stage I HS BC, a 5.2% reduction in the M rate is seen: 32.6% before 2004 to 27.4% after 2004 (p<0.0001). M rates remained higher (with less reduction) in elderly Black (30.8 %) and API (33.6 %) vs. White (26.8%) [p<0.0001 for White vs. Black and for White vs. API]. In non-elderly Stage I HS BC, after 2004 M rates increased from 29.2% to 31.8% (p<0.0001). Non-elderly white women had the largest absolute increase in M rates (31.2% vs. 28.5%, p<0.0001) followed by API women (35.1% vs. 37.1%, p=0.0222). M rates did not change after 2004 in non-elderly black women (31.7% vs. 31.7%, p=0.9953).

**Conclusions:** In patients with favorable stage I HS BC, M rates have decreased only modestly in elderly women since 2004 when L alone w/o RT was established as appropriate treatment. In comparison, M has increased since 2004 in non-elderly women. These trends are driven mostly by white women in both the elderly and non-elderly. Further research is needed to identify why M, which is associated with higher cost and morbidity than L alone, has not changed substantially in elderly very favorable BC, particularly for non-whites.
Learning curve for the SAVI SCOUT breast localization and surgical guidance system

Shukla SC C, Shivers SC C, Mattingly A, Russell S, Mehindru A, Carter E and Cox CE E. Morsani College of Medicine at the University of South Florida (USF), Tampa, FL.

Background: The gold standard for localizing non-palpable breast lesions for surgical excision is wire localization (WL). Multiple disadvantages for WL include complicated scheduling and migration of the wire after placement. Radioactive seed localization (RSL) mitigates these disadvantages, but regulatory requirements regarding radiation limit more universal adoption. The SAVI SCOUT surgical guidance system (an FDA cleared medical device) eliminates the drawbacks of WL without the regulatory requirements of RSL. SCOUT utilizes electromagnetic wave technology and infrared light to provide intra-operative guidance during surgical excision. The purpose of this study is to describe the learning curve associated with adoption of this new technology.

Method: An IRB-approved prospective, single-arm, multi-site trial enrolled women with non-palpable breast lesions requiring localized surgical excision. After informed consent, a radiologist or surgeon used imaging guidance to implant the SCOUT reflector into the target lesion. Intraoperatively, the surgeon used SCOUT for localization of the reflector and removal of the target lesion. We evaluated the association of several independent variables with respect to successful localization and surgical excision including: tumor side, tumor quadrant, distance of reflector from the skin, and the number of SCOUT localized breast excisions performed by operating surgeon up to the 1st five cases. We studied the relationship between these independent variables and the following dependent variables: reflector detection post-placement, reflector detection pre-incision, and reflector localization post-incision. Statistical analysis utilized the z-test to perform a two-sided test of equality at an alpha level of 0.05 with adjustment for multiple comparisons by the Bonferroni method. T-tests were used to perform two-sided tests of equality for numeric variables.

Results: Across 11 institutions, 16 surgeons performed a total of 153 surgical excisions. Overall success rates of reflector detection pre-incision and post-incision were 98% (150/153) and 99% (151/153), respectively. The reflectors were successfully removed in 100% (153/153) of cases. Difficulty with reflector detection immediately post placement was significantly associated with reflectors more than 4 cm (P=0.034) or 5 cm (P=0.007) from the skin, or the procedure being the 1st SCOUT case by the operating surgeon (P=0.036). Operating surgeons performing their 1st SAVI localization procedure were significantly associated with difficult reflector detection post-incision (p=0.044). Subsequent procedures, up to the first five SCOUT localizations, noted no significant difficulty with reflector detection.

Conclusions: The SAVI SCOUT surgical guidance system is a viable surgical localization procedure for non-palpable breast lesions. Surgeons were 100% successful at removing the reflectors during surgical excision. Difficulty with reflector detection was not noted after the surgeon's 1st SCOUT procedure. Overall, it appears the learning curve for reflector placement and localization for non-palpable breast lesions is relatively short. However, depth of the reflector in relation to skin likely affects reflector detection during this early learning period.
Title: Abstract Withdrawn
Tumor and procedural factors associated with positive margins at lumpectomy in women undergoing breast conservation surgery

Boughey JC C, Keeney MG G, Glasgow AE E, Keeney GL L and Habermann EB B. Mayo Clinic, Rochester, MN.

**Background:** Negative margins are important in decreasing risk of local recurrence after breast conservation surgery. Further, positive margins on final pathology require a second operation, burdening patients and increasing costs. We identified factors predicting positive margins at lumpectomy prompting intraoperative re-excision in a large referral center.

**Methods**
With IRB approval we reviewed all breast cancer lumpectomy cases from January 2012 to December 2013. Associations between rates of positive margin (defined as tumor at ink) and patient and tumor factors were assessed using chi square tests and univariate and adjusted multivariable logistic regression, overall and stratified by DCIS or invasive cancer.

**Results**
385 patients (105 DCIS and 280 invasive disease) were identified. Overall positive margin rate at lumpectomy requiring intraoperative re-excision was 62.3% and was higher in DCIS than in invasive disease (78.1% vs 56.4%, OR=2.78, p=0.001).

Positive margin rates did not vary by surgeon, patient age, ER, PR or HER2 status of the tumor. On univariate analysis higher tumor grade was associated with a higher margin positive rate (grade 3 vs grade 1, OR=1.71, p=0.049).

Within the 105 DCIS cases, no factors had statistically significantly different odds of positive margins on univariate or multivariable analysis.

Within the 280 cases of invasive breast cancer, factors independently associated with lower odds of margin positivity were neoadjuvant chemotherapy (OR 0.30, p=0.037, relative to no neoadjuvant therapy) and seed localized excision (OR 0.24, p=0.03, relative to no localization).

**Multivariable Logistic Regression**

*adjusted for individual surgeons (all p >0.05)
DCIS was associated with higher rate of positive margins at lumpectomy than invasive breast cancer. Within invasive disease, neoadjuvant chemotherapy and seed localization were associated with lower rates of margin positivity. Strategies to decrease positive margins would be best employed in cases of lumpectomy for DCIS and for invasive disease treated without neoadjuvant chemotherapy. Seed localization may be one strategy to lower positive margin rates.
Title: The impact of a change in margin width on rates of re-excision following breast conserving surgery

Jiwa NE E, Ayyar S, Provenzano E and Benson JR R. Addenbrookes Hospital, Cambridge, United Kingdom.

Body: Background: Surgical margin status is a predictor of ipsilateral breast tumor recurrence but the definition of an adequate surgical margin following breast conserving surgery (BCS) remains controversial despite published recommendations for acceptance of ‘no tumor at ink’. BCS can be compromised by the need for a re-excision procedure which incurs inconvenience to patients and additional healthcare costs. We have previously shown that reducing the margin mandate from 5mm to 2mm does not influence rates of re-excision and the impact of adopting a more stringent margin policy of ‘no tumor at ink’ is now reported.

Methods: A retrospective analysis examined rates of re-excision amongst patients undergoing BCS for both invasive carcinoma with or without admixed ductal carcinoma in situ (DCIS) or pure DCIS over two sequential 12 month time periods either prior to (GROUP 1; n=225) or immediately following (GROUP 2; n=238) a change in minimum margin policy from 2mm to ‘no tumor at ink’ when the latter was deemed an adequate definition of a negative margin. A total of 611 patients underwent non-reconstructive breast surgery for symptomatic and screen-detected cancers during these time periods among whom 463 received BCS. Wire-localization was undertaken in 51% (114/225) and 42% (101/238) of patients in groups 1 and 2 respectively. Data was extracted from electronic patient records of histopathology reports and clinic letters with further information available from documentation of MDT discussions. Statistical analysis used Fisher-Exact test.

Results: Rates of re-excision were significantly lower for group 2 (32/238=13%) compared with group 1 48/225=21%). Re-excision encompassed cavity re-excision alone, cavity re-excision followed by mastectomy and completion mastectomy. Residual disease in re-excision specimens was significantly higher for group 2 (40.6%) compared with group 1 (16.6%) [p=0.02] with more than one-third of cases of residual disease in group 2 being exclusively DCIS. Three patients in each group required 2 additional operations to achieve negative margins. For groups 1 and 2, three-quarters or more cases (87% and 77% respectively) had only 1 or two margins positive and 2 cases in group 2 were re-excised for reasons other than a positive margin (e.g. tumor type). For group 1, re-excision cases were prompted by margin categories of 0mm (n=22), <1mm (n=18) and ≥1mm; <2mm (n=8) whilst for group 2 all re-excisions were prompted by tumor at ink (0mm). A hypothetical minimum margin of 1mm would have reduced the re-excision rate for group 1 to 40/225 or 17.7%.

Conclusion: Re-excision was usually prompted by margins of <2mm when a 5mm margin policy prevailed. A more relaxed margin mandate of ‘no tumor at ink’ has led to halving of re-excision rates from 21% to 13% as opposed to 17.7% for a minimum margin of 1mm. This reduction in rates of re-excision is accompanied by an increase in the proportion of cases with residual disease in re-operation specimens. Longer-term follow up is essential to monitor in-breast local recurrence.
Clinical applications of near infra-red imaging system for localization of non-palpable breast lesions in breast conserving surgery

Body: Backgrounds: Localization of non-palpable breast lesions is important for obtaining tumor-free resection margin and achieving better cosmetic outcome. Near infra-red (NIR) imaging system has been introduced for localization in breast surgery. This study aimed to evaluate the feasibility of localization using NIR imaging system in breast conserving surgery (BCS) (ClinicalTrials.gov identifier: NCT 02172989/ NCT02473159).

Materials and Methods: Between June 2014 and October 2015, 20 women with benign neoplasm and 5 patients with early breast cancer were enrolled and underwent BCS using NIR imaging system. Before surgery, Indocyanine green was injected intratumoraly in benign lesions and peritumoraly for resection margins in early breast cancer. Their pathologic results for resection volume and re-excision rate were compared with those of the patients with 99 benign neoplasm and 203 early breast cancer who were treated with BCS by conventional method, respectively.

Results: In the patients with benign lesions, the mean size in sonography was 1.48±0.98 cm in NIR group and 1.32±0.96cm in conventional group (P=0.4). There was no difference of pathologic lesion size and excised specimen size between these groups (1.57±0.78 cm vs 1.42±0.80 cm in pathologic lesion size; P=0.63, 4.28±0.48 cm vs 4.15±1.37 cm in specimen size; P=0.73). In NIR group, the ratio of excised specimen/lesion was lesser than that of conventional group (3.19 ±1.40 vs 4.31±3.86; P=0.008). In addition, positive margin rate after BCS in early breast cancer patients was 0% in NIG group and 19.7% in conventional group. And re-excision rate was 0% and 4.4%, respectively.

Conclusions: This study showed that localization using NIR image system could be a feasible method to obtain safe resection margins and optimum resection volumes in patients undergoing breast conserving surgery.

Title: Evaluating cosmetic outcome following breast conserving surgery in trials; panel verus objective evaluation and the role of patient reported outcome measures (PROMs)

Lagendijk M, Vos EL L, Corten EML ML, Verhoef C and Koppert LB B. Erasmus Medical Centre, Rotterdam, Zuid-Holland, Netherlands and Erasmus Medical Centre, Rotterdam, Zuid-Holland, Netherlands.

Objective
Cosmetic outcome is an important quality of life related endpoint following breast conserving surgery (BCS). We aim to compare the cosmetic outcome evaluated by panel and objective evaluation (BCCT.core software). Second patient reported outcome measures (PROMs) are compared to cosmetic evaluation by panel and BCCT.core.

Methods
Sixty-eight breast cancer patients were included after breast conserving surgery between 2007-2012. Cosmetic outcome was evaluated by; two independent 6-member panels, the BCCT.core by two observers and PROMs (EORTC-QLQ-C30/BR23, EQ-5D-5L and BREAST-Q 'breast conserving module'). First, reproducibility, repeatability and overall agreement of panel and BCCT.core was analysed using the interclass correlation coefficient (ICC). Second, the correlation between panel/BCCT.core with PROMs was analysed using the Spearman's rank correlation coefficient (spearman's ρ). Sensitivity of all PROMs to differentiate between a 'good' or 'bad' cosmetic outcome was evaluated.

Results
Sixty-four patients (94.1%) completed the EORTC-QLQ-C30/B23, 58 (85.3%) the EQ-5D-5L and BREAST-Q. Repetitability between both panels and BCCT.core observers was respectively 0.93 and 0.86 (ICC). Reproducibility for panel 1 and BCCT.core 1 was respectively 0.93 and 0.96. Overall agreement between panel and BCCT.core ranged between 0.59 – 0.69.

Table 1. Inter- and intra-observer agreement for cosmetic outcome - Interclass Correlation Coefficient (95% CI)

</tbody>
</table>
Conclusion
Comparable good reproducibility and repeatability was found for panel and BCCT. PROMs showed limited agreement but the PROM BREAST-Q was able to differentiate between a good or bad cosmetic evaluation. Combining PROMs with panel or BCCT.core in future trials evaluating cosmetic outcome following BCS could further improve and evaluate the use of PROMs.

Title: Re-evaluating outcomes of partial-breast irradiation using multicatheter brachytherapy for Japanese patients with breast cancer by European brachytherapy phase 3 trial

Sato K, Mizuno Y, Fuchikami H, Takeda N and Kato M. Tokyo-West Tokushukai Hospital, Akishima, Tokyo, Japan and Tokyo-West Tokushukai Hospital, Akishima, Tokyo, Japan.

Body: [Purpose] The Groupe European de Curietherapie-European Society for Therapeutic Radiology and Oncology (GEC-ESTRO) has reported the equivalent outcomes of partial-breast irradiation (PBI) using multicatheter interstitial brachytherapy (MCB) to whole-breast irradiation (WBI) in breast-conserving therapy, showing that the incidence of local recurrence was 1.44% with MCB-PBI and 0.92% with WBI. Based on the trial, MCB-PBI could be considered as an alternative method to WBI for low-risk breast cancer patients. However, it would be difficult to translate it directly into Japanese community practice. After categorization of Japanese patients using the inclusion and exclusion criteria of this trial, our databases were re-evaluated to validate the data for Japanese patients, and the possibility to extend the candidate for MCB-PBI was also investigated.

[Methods] Patients undergoing BCT were retrospectively examined between November 2007 and December 2015. The technique involved an open-cavity implant with a dose of 32 Gy in eight fractions. WBI was performed with a total dose of 50 Gy in fractions of 2 Gy. The 4-year clinical outcomes of MCB-PBI were evaluated in the two distinct categories, and comparisons of outcomes between MCB-PBI and WBI were performed in patients with unfavorable features.

[Results] Of a total of 501 lesions undergoing BCT, 301 lesions were treated with MCB-PBI and 200 lesions with WBI. At a median follow-up time of 52 months, the 4-year rate of ipsilateral breast tumor recurrence (IBTR)-free, disease-free, and overall survival in patients with MCB-PBI and WBI were 98.9% vs. 98.0% (p = 0.56), 97.0% vs. 95.3% (p = 0.78), and 99.6% vs. 98.2% (p = 0.38), respectively. In the exclusion cohort treated with MCB-PBI, IBTR-free and disease-free survival were significantly poorer than in the inclusion cohort. However, no significant differences in the outcomes between the two radiotherapy techniques were demonstrated with respect to either IBTR-FS (95.0% vs. 97.2%, p = 0.24), DFS (95.0% vs. 95.8%, p = 0.31), or OS (100% vs. 99.0%, p = 0.80) in patients with exclusion criteria.

[Conclusions] To our knowledge, this study includes the largest cohort of Asian patients undergoing MCB-PBI. Although the retrospective chart review with relatively short follow-up time and small number of patients does not allow reaching any definite conclusion, we could expect the same outcomes by MCB-PBI as those in the GEC-ESTRO trial with respect to the tumor control.
only for Japanese but for Asian patients with breast cancer. Moreover, no negative impact on the outcomes of MCB-PBI as compared to WBI was not found in patients with exclusion criteria.
Title: Re-excision rate in breast conservation surgery after neoadjuvant chemotherapy

Song JH, Park JY, Choi JE, Bae YK and Lee SJ. Yeungnam University Medical Center, Daegu, Republic of Korea and Yeungnam University Medical Center, Daegu, Republic of Korea.

Body: Background: The goal of neoadjuvant chemotherapy is to reduce tumor size and convert mastectomy to breast-conservation surgery (BCS). In response to neoadjuvant chemotherapy, the regression rate and pattern of breast cancer is variable. And the re-excision rate to secure negative resection margin is reported limitedly in this case. The purpose of this study was to compare the re-excision rate and BCS success rate of patients who received and who did not received neoadjuvant chemotherapy.

Method: In this retrospective cohort study, between January 2009 and December 2012, total 256 women were included who had clinical T2 breast cancer and were planed to receive BCS as initial operation or neoadjuvant chemotherapy. Fifty-nine patients of them received neoadjuvant chemotherapy. Clinical data were collected including age, preoperative or initial clinical tumor size, mammographic microcalcifications, ultrasound multifocality and axillary nodal status, retrospectively. In the resected specimen from BCS, we reviewed the pathologic tumor size, multifocality, histologic type, hormone receptor and Her-2-neu status, ki67, DCIS and EIC component. The re-excision rate and BCS success rate were investigated. Univariate analysis and regression model were used for identify clinicopathologic factors associated with re-excision. To reduce the effect of selection bias, propensity score matching-based analysis was also performed.

Results: Of the 256 patients, 178 patients (90.4%, 178/197) received BCS finally in neoadjuvant group and 56 patients (94.9%, 56/59) in non-neoadjuvant group (p=0.406). There was no statistical difference in the re-excision rate between two groups (35.6% (21/59) in neoadjuvant group vs 34.0% (67/197) in non-neoadjuvant group, p=0.946). In propensity-matched cohorts (N=118), the re-excision rate was same in two groups (35.6% (21/59) in neoadjuvant group vs 35.6% (21/59) in non-neoadjuvant group, p=1.000). BCS success rate was higher in neoadjuvant group(94.9% 56/59) than non-neoadjuvant group (86.4%(51/59)), but there was no statistical difference (p=0.205). In this cohorts, clinicopathologic factors associated with re-excision were pathologic multifocality (OR=4.56, p=0.0142), high ki67 (≥50%) (OR=0.7, p=0.0243) and DCIS component (OR=2.67, p=0.0261) in logistic regression model.

Conclusion: This study showed neoadjuvant chemotherapy could increase the BCS success rate but could not decrease the re-excision rate. The re-excision rate is more associated with pathologic finding rather than effect of neoadjuvant chemotherapy.
Title: Breast conserving therapy and mastectomy revisited: overall and breast cancer-specific survival and the influence of age, stage, receptor status and comorbidities in 143,376 patients

Lagendijk M, van Maaren MC C, Saadatmand S, Strobbe LJA JA, Poortmans P, Koppert LB B, Tilanus-Linthorst MMA MA and Siesling S. Erasmus MC Cancer Institute, Rotterdam, Zuid-Holland, Netherlands; Netherlands Comprehensive Cancer Organisation, Utrecht, Netherlands; Maxima Medical Center, Velthoven, Brabant, Netherlands; Camius Whilehelmina Hospital, Nijmegen, Netherlands and Radboud University Medical Center, Nijmegen, Netherlands.

Body: Background
Large randomised controlled trials confirmed in the 80's equal survival for breast-conserving surgery plus radiation therapy (BCT) and mastectomy. Recently, observational studies challenged this equivalence, showing superior survival rates for BCT. This study compared BCT with mastectomy on long-term overall (OS) and breast cancer-specific survival (BCSS) in a population-based cohort, investigating the influence of age, stage and presence of comorbidities.

Methods
Patients with primary Tis-2N0-2M0 stage breast cancer, diagnosed between 1999-2012, were selected from the Netherlands Cancer Registry. The cohort was divided into two time cohorts, 1999-2005 (to evaluate long-term outcome) and 2006-2012 (with modern adjuvant therapy). Cause of death was derived from the Statistics Netherlands (CBS). Multivariable analyses were performed separately for all invasive cancers, DCIS, T1-2N0-1 and T1-2N2 stages. In addition, the T1-2N0-1 stages were further stratified for age, receptor status and presence of comorbidities at diagnosis.

Results
A total of 143,376 patients were selected. In the 1999-2005 cohort, 51.4% of 65,666 patients were treated with BCT, compared to 58.9% of 80,772 patients in the 2006-2012 cohort.

In the 1999-2005 cohort, 9,413 patients (27.9%) died in the BCT group, compared to 14,956 patients (46.8%) in the mastectomy group. Of these deaths, 4,710 (50%) were breast cancer-related in the BCT group, compared to 7,845 (52.2%) in the mastectomy group. For all invasive carcinomas, BCT showed significantly higher adjusted BCSS [0.72 (95% CI: 0.69-0.76)] and OS [HR 0.74 (95% CI: 0.71-0.76)] than mastectomy. This remained significant in all other subgroups: DCIS and all T and N stages. Only for patients aged <40, BCT was equal to mastectomy regarding both BCSS and OS.

In the 2006-2012 cohort, 4,134 patients (8.7%) died in the BCT group, compared to 6,412 (19.3%) in the mastectomy group. Of these deaths, 2,036 (49.3%) were breast cancer-related in the BCT group, compared to 3,252 (50.7%) in the mastectomy group. Also for this cohort, BCT showed significantly higher adjusted BCSS [HR 0.75 (95% CI: 0.70-0.80)] and OS [HR 0.67 (95% CI: 0.64-0.71)]. This remained significant for DCIS and T1-2N0-1M0 patients. Equal BCSS and OS for BCT and mastectomy was observed in patients with T1-2N2 stage breast cancer. Within the T1-2N0-1 subgroup, additional stratification for age, hormonal receptor status and presence of comorbidities showed significant superior BCSS and OS for BCT in all stratification groups, except for patients aged <50, patients with HER2+ disease and patients without comorbidities.

Conclusions
This study confirms superior BCSS and OS for BCT compared to mastectomy for most patients with DCIS or invasive breast cancer, irrespective of comorbidities and receptor status. This was confirmed both for long follow-up and following modern adjuvant therapy. A limitation is found in the observational design where confounding by indication or residual confounding cannot be excluded completely. However, based on the results clinicians seem right to prefer BCT in most patients with primary breast cancer.

Title: A phase II, open-label, multi-center study of ANG1005, a novel brain-penetrant peptide-drug conjugate, in breast cancer patients with recurrent CNS metastases

Ibrahim NK, Tang S-C, Brenner AJ J, Kesari S, Piccioni DE E, Anders CK K, Carillo JA A, Chalasani P, Kabos P, Puhalla S, Garcia AA A, Tkaczuk KH H, Ahluwalia MS S, Lakhani N J J and Kumthekar P. MD Anderson Cancer Center, Houston, TX; Augusta University, Augusta, GA; University of Texas Health Science Center at San Antonio, San Antonio, TX; John Wayne Cancer Institute, Santa Monica, CA; University of California in San Diego, San Diego, CA; University of North Carolina - Chapel Hill, Chapel Hill, NC; UC Irvine School of Medicine, Orange, CA; University of Arizona Cancer Center, Tucson, AZ; University of Colorado Denver, Aurora, CO; Magee-Womens Hospital of UPMC, Pittsburgh, PA; University of Southern California Norris Comprehensive Cancer Center, Los Angeles, CA; University of Maryland Greenebaum Cancer Center, Baltimore, MD; Cleveland Clinic Lerner College of Medicine, Cleveland, OH; Cancer & Hematology Center of Western Michigan, Grand Rapids, MI and Northwestern University Feinberg School of Medicine, Chicago, IL.

Body: Background: The incidence of CNS metastatic disease in breast cancer patients (pts) seems to have increased in recent years with the improvement of systemic therapy. However, treatment options for CNS metastases have remained limited due to the inability of most agents to cross the BBB. ANG1005 is a novel peptide drug-conjugate, consisting of 3 paclitaxel molecules covalently linked to Angiopep-2, a peptide designed to utilize the LRP-1 transport system to cross the BBB/BCB and to penetrate malignant cells.

Methods: We conducted an open label phase II clinical study to test its activity in metastatic breast cancer (BC) pts with recurrent brain metastasis (BM), including BCBM pts with newly diagnosed leptomeningeal carcinomatosis (LC). Adult pts with measurable, recurrent BM from breast cancer, with or without LC (n=72 safety population; n=58 efficacy population) were enrolled in the study. ANG1005 was administered IV at 600 mg/m² q3w. HER2+ patients were allowed to continue trastuzumab +/- pertuzumab.

Intracranial (IC) response was assessed by Gd-MRI using CNS RECIST 1.1 and extracranial response (EC) was evaluated per RECIST 1.1.

Results: Median age was 47.5 (26-76) years. Safety was similar to that of paclitaxel with myelosuppression as the predominant toxicity (WBC: 83%, RBC: 71%, PLT: 69%). Pts received a median of 6 (1-29) prior therapies for BC, including 84% with taxanes. As prior therapy for BM, 87% pts had cranial surgery and/or radiation and 19% pts received systemic therapies. Intracranial tumor response is presented for all pts as well as the various patient subsets as shown below:

Abbreviations: TNBC, triple-negative breast cancer, a sub-group of HER2-; LC, leptomeningeal carcinomatosis

Table 1 definitions: data based on evaluable pts with clinical or radiological evaluation ≥ 4 weeks from C1D1; LC pts included 15 HER2+ and 8 HER2-; best response is the best response recorded from the start of the study treatment until the disease progression; confirmed PR requires a ≥28-day confirmation of response.

Extracranial tumor responses of 1 (3%) CR, 2 (7%) PRs and 24 (80%) SDs were seen in 30 evaluable pts, including after prior taxanes (93%). The 6 month OS in all pts was 50.2% (95% CI: 37.4, 61.6).
In general, CNS clinical symptoms post-ANG1005 were improved, including in LC pts.

**Conclusions:** ANG1005 is active against previously treated BC metastasis both within and outside the CNS. A randomized study is planned. Updated efficacy and safety data will be presented at the meeting.
Title: Prognostic factors and survival according to tumor subtype in women presenting with breast cancer brain metastases at initial diagnosis

Body: Background: Breast cancer represents one of the most common causes of brain metastases. The occurrence of this event is a catastrophic complication of metastatic breast cancer, associated with poor prognosis. However, the presence of brain metastases at the time of initial breast cancer diagnosis (BMIBCD) is uncommon. Because of this, the prognostic assessment and management of patients (pts) who present with BMIBCD is very challenging. The aim of this study was to analyze the influence of tumor subtype compared with other prognostic factors in the survival of pts who present with BMIBCD.

Methods: We evaluated women with brain metastases at the time of initial diagnosis of microscopically confirmed breast cancer, reported to the Surveillance, Epidemiology and End Results (SEER) 18 registries program from 2010 to 2013. Pts with other primary malignancy either before or after breast cancer were excluded. Pt characteristics were compared between tumor subtypes. Univariate and multivariate analyses were performed to determine the effects of each variable on overall survival (OS).

Results: Seven hundred forty pts were included. Median age was 60 years (range 26-93). After a median follow-up of 6 months (range 1-48), median OS for the whole population was 10 months and 20.7% of pts were alive at 36 months. At diagnosis, brain was the only site of metastasis in 125 pts, whereas 66.2% of pts had metastases in bone, 33.2% in liver and 44.7% in lung. Tumor subtype distribution was: 46.6% hormone receptor (HR)+/HER2-, 17% HR+/HER2+, 14.1% HR-/HER2+ and 22.3% triple negative (TN). Pts with TN brain metastases had higher grade (p<0.0001), higher rate of brain only (p=0.001) and lung metastases (p=0.03), had lower rates of bone metastases (p<0.0001) and were more likely to die from breast cancer (p<0.0001). Univariate analysis showed that older age (p=0.0002), black race (p=0.004), lobular histology (p=0.01), unmarried pts (p=0.01), the presence of liver (p<0.0001) and lung metastases (p=0.002) and TN pts (median OS 6 months; p<0.0001) had worse prognosis. The HR+/HER2+ subtype had the longest OS with a median of 22 months. In multivariate analysis, older age (hazard ratio 1.8; p=0.001), lobular histology (hazard ratio 2.08; p=0.006), TN subtype (hazard ratio 2.25; p<0.001), liver metastases (hazard ratio 1.6; p=0.001) and unmarried pts (hazard ratio 1.39; p=0.04) had significantly shorter OS. Race, tumor grade, bone metastases, lung metastases and brain only metastases had no association with OS.

Conclusions: To our knowledge, this is the largest study of BMIBCD. Although the prognosis of these pts is generally poor, it is important to notice that 20.7% of pts were still alive 3 years after diagnosis. There were substantial differences in OS according to tumor subtype, TN pts had the shortest OS. HR+/HER2- represented the largest proportion of cases, therefore these pts should not be ignored when designing clinical trials for pts with brain metastases. In addition to tumor subtype, other independent predictors of OS are age at diagnosis, marital status, histology and liver metastases.
Body: Introduction: Historically, brain metastases are considered to be uncommon in HR+/HER2- breast cancer compared to triple-negative or HER2+ breast cancer. However, improved systemic therapy and prolonged overall survival in patients with metastatic HR+/HER2- breast cancer may result in increased incidence of brain metastases as most currently available therapeutic agents do not penetrate blood-brain barrier giving the brain a sanctuary site status. Although certain tumor cells may also exhibit brain-specific tropism or may have selective growth advantage in the brain microenvironment, biological factors that govern metastases to brain, including role of PIK3CA mutations, are poorly understood. In this study, we review our clinical experience with the brain metastases among patients with metastatic ER+/HER2- breast cancer, including their association with PIK3CA genotype.

Methods: Since 2008, at our institution, a multiplexed tumor genotyping assay (SNaPshot), has been utilized to assess for presence of potentially actionable oncogenic driver mutations, including PIK3CA, using DNA derived from formalin-fixed, paraffin-embedded (FFPE) tissue. We identified patients with metastatic HR+/HER2- breast cancer who had tumor genotyping performed at any point during their care and who had at least 6 months of follow-up in our clinic. Relevant clinical information, including development of brain metastases, was gathered from chart reviews.

Results: From a total of 251 patients with HR+/HER2- metastatic breast cancer, 23.5% (N=59) developed brain metastases. Approximately 1/3rd of patients (31.7%, N = 20) had brain metastases seen on imaging as an incidental finding, while others presented with 1-2 symptoms that could be associated with CNS disease, including ataxia/weakness (34.9%), visual/speech difficulties (23.8%), altered mental status (14.3%), seizures (14.3%), and nausea (9.5%). PIK3CA mutations were identified in 45.2% of all patients, including mutations in both helical (exon 9) and kinase (exon 20) domains. Patients with tumors harboring PIK3CA mutations had significantly higher incidence of brain metastases, as compared to those without PIK3CA mutations (30.7%, versus 18.7%; p = 0.034). The median time between diagnosis of metastatic disease and diagnosis of brain metastasis was longer among those patients with PIK3CA mutation (32 months) as compared to those without PIK3CA mutation (18 months).

Conclusion: Brain metastases are common among patients with HR+/HER2- breast cancer, particularly HR+/HER2- breast cancer harboring PIK3CA mutations where it approaches the incidence historically seen in HER2+ breast cancer. Early recognition and appropriate diagnostic work-up of any symptoms potentially associated with presence of CNS disease is necessary in PIK3CA-mutant HR+/HER2- breast cancer. Further studies are needed to explain the mechanistic link between the PIK3CA mutant phenotype, phosphatidylinositol 3-kinase (PI3K) pathway activation and CNS disease.
Phase I dose-escalation trial of ONT-380 in combination with trastuzumab in patients (pts) with HER2+ breast cancer brain metastases

Metzger O, Barry W, Krop I, Guo H, Younger J, Lawler E, Walker L, Freedman R, Tolaney S, Winer E and Lin N. Dana-Farber Cancer Institute, Boston, MA; Massachusetts General Hospital, Boston, MA and Oncothyreon Inc., Seattle, WA.

Body: Background: Brain metastases remain an important cause of death for pts with advanced HER2+ BC. ONT-380 is an oral, potent and selective inhibitor of HER2 capable of penetrating the blood brain barrier in pre-clinical models. We evaluated the safety and preliminary efficacy of ONT-380 in combination with trastuzumab.

Methods: Open-label, dose finding, Phase I study to estimate the MTD(s) of ONT-380 + trastuzumab in pts with HER2+ BCBM. The study was conducted in parallel cohorts testing two schedules of ONT-380 (once-daily or twice-daily). The primary endpoint was determination of the MTD. A total of 15 pts were to be treated at the MTD of each schedule in order to select the best regimen for future phase 2 studies. Response was assessed by RECIST 1.1 (extracranial) and modified RECIST 1.1 (intracranial).

Results: Between Aug 2013 and March 2016, 41 pts were enrolled. Median age was 49 (range 29-65); ECOG performance status 0-1 (85%), 2 (15%). 34 (83%) patients had progressed after prior WBRT and/or SRS. Patients had a median of 2 prior treatments for metastatic breast cancer prior to enrollment. As of June 7, 2016, median number of cycles was 4 (range 1-32); 4 patients remain on active protocol therapy. 2 DLTs were observed among 5 pts treated at 450 mg BID (G3 thrombocytopenia and G3 ALT). The dose was de-escalated to 300 mg BID, and with 0/3 patients experiencing a DLT. 300mg BID was identified as the MTD and an additional 14 patients were enrolled at this dose level. 1/7 pts experienced a DLT at 750 mg QD (G3 ALT). At 900 mg QD, 2/2 pts experienced a DLT (2 patients had G3 ALT/AST). An additional 10 pts were enrolled at the MTD of 750 mg QD. The most common AEs, regardless of relationship, were fatigue, diarrhea, AST/ALT elevation, nausea, headache. Gr 3/4 AST/ALT elevation has occurred in 9/41 pts (22%), though has been reversible with dose interruption and reduction. One Gr 3 diarrhea has occurred at 450 mg BID, and 1 Gr 3 diarrhea has occurred at 750 mg QD. PK assessments showed similar exposure of ONT-380 for QD and BID regimens. Preliminary assessment CNS response is available for 19 pts in the QD cohort (5% PR, 89% SD, 5% PD) and 17 pts in the BID cohort (12% PR, 59% SD, 12% PD, 18% unknown). Preliminary non-CNS assessment for the same population is as follows: QD cohort (100% SD); BID cohort (6% PR, 71% SD and 23% unknown).

Conclusions: The combination of ONT-380 and trastuzumab is feasible. The combination has an acceptable safety profile with low incidence and severity of diarrhea and rash. Transaminase elevation was asymptomatic for all pts and resolved with drug interruption/delay. Preliminary evidence of activity was observed in CNS and non-CNS disease.
ETIRINOTECAN PEGOL: SURVIVAL ADVANTAGE OVER STANDARD OF CARE DRUGS IN A MODEL OF BRAIN METASTASES OF BREAST CANCER

BACKGROUND: Brain metastasis of breast cancer is a significant cause of death among women with disseminated breast cancer. Chemotherapy, radiation, and surgery for these metastases provide only minimal benefit with considerable toxicity. The long-acting topoisomerase I inhibitor etirinotecan pegol (EP) is a novel treatment for disseminated breast cancer. EP consists of irinotecan attached to a 20kDa branched polymer via a releasable linker. The large molecular weight of EP results in tumor accumulation, including brain metastases, providing increased and sustained exposure to cytotoxic SN38. In the Phase 3 BEACON study, EP showed a significant survival benefit (HR 0.51; 95% CI 0.30-0.86) in a prespecified subgroup of women with history of treated, stable brain metastases compared to treatment of physicians choice (TPC) consisting of one of seven approved chemotherapy drugs (median OS 10.0 vs 4.8 mo). Nektar has filed a conditional marketing authorization in Europe for EP in patients with advanced breast cancer and brain metastases. A Phase 3 trial in this patient population is being initiated to support a potential U.S. filing. To further support the biological rationale for EP in these patients, an experimental preclinical model of brain metastases of breast cancer was conducted to compare the efficacy of EP to TPC in BEACON and the planned subsequent study.

METHODS: Female athymic nude mice were inoculated with 1.75x10^5 MDA-MB-231-BrLuc cells via intracardiac injection. Starting on day 21, gemcitabine (60 mg/kg) and eribulin (1.5 mg/kg) were dosed IP every 4 days; EP (50 mg/kg), irinotecan (50 mg/kg), paclitaxel (6 mg/kg), vinorelbine (10 mg/kg), docetaxel (10 mg/kg), and vehicle (saline or dextrose) were dosed weekly via tail vein. Efficacy was measured by tumor burden and survival. Tumor burden was determined based on twice weekly bioluminescence measurements. Animals were euthanized according to international animal care guidelines.

RESULTS: Median survival for all control arm groups (docetaxel, vinorelbine, eribulin, gemcitabine, irinotecan, and paclitaxel) were 39, 43, 48, 35, and 42 days, respectively, none of which were significantly different from vehicle control median survival of 40 days (p>0.05). No animals receiving these drugs survived until the end of the 90-day trial. Median survival for the EP treatment group was 86 days (p<0.05) with a 40% survival rate at 90 days, the trial endpoint. Tumor burden increased nearly 100-fold in all TPC and vehicle groups, whereas EP significantly inhibited tumor growth. Quantitative autoradiography showed that EP accumulated ~10-fold in brain metastases, while accumulation in non-tumor brain tissue was only ~2-fold compared to irinotecan. EP at 50 mg/kg achieved plasma trough concentrations comparable to those observed in patients receiving the recommended dose of 145 mg/m^2 every 21 days.

CONCLUSIONS: In this model of brain metastases, EP preferentially accumulates in brain metastases, significantly reduces tumor burden progression and significantly improves survival in brain metastases of breast cancer compared to the most active chemotherapeutic agents available for advanced breast cancer and those used in the BEACON trial and planned subsequent Phase 3 study.
Factors related to the prognosis of breast cancer patients after the development of brain metastases

Background: Brain metastases (BM) are a serious relatively common complication of breast cancer (BC). We evaluated prognostic factors for survival after diagnosis of BM from BC in a contemporary cohort of pts.

Methods: Pts diagnosed with BM from BC between 1999 and march 2016 and treated at the Istituto Oncologico Veneto of Padua were evaluated. Overall survival (OS) was defined as time from BM diagnosis to death or last follow-up. Pts were classified in 4 categories according to the breast cancer-specific Graded Prognostic Assessment (GPA) index according to validated criteria (Sperduto et al, 2012), based on age, Karnofsky Performance Status (KPS) and BC phenotype. Cox proportional models were used to calculate HR and 95% CI.

Results: 199 pts were identified. Median age at BM diagnosis was 56 yrs (range 28-84). Tumor phenotype distribution was as follows: triple negative (TN, 20.1%), hormone receptor (HR)-HER2+ (16.8%), HR+HER2+ (24.0%) and HR+HER2- (39.1%). Median time to BM diagnosis was 48.9 months (range 0-327), with significant differences according to tumor phenotype (median 27.3, 31.8, 46.1 and 55.2 months in TN, HR-HER2+, HR+HER2+, HR+HER2-, respectively, p=0.009). With respect to OS, no significant difference was observed across tumor phenotypes, with TN patients experiencing the worse outcome (median: 4.7, 7.7, 11.0 and 6.2 months in TN, HR-HER2+, HR+HER2+, HR+HER2-, p=0.187). The breast-specific GPA index, which combines tumor phenotype with patient-related features, was significantly associated with OS (Table). The number of local treatment received (radiotherapy, either whole brain or stereotactic, or neurosurgery) and the administration of systemic treatment after BM diagnosis were significantly associated with better OS (Table). Patients in the less favorable GPA category (GPA index ≤1) were less likely to receive systemic treatment after BM diagnosis compared to other GPA categories (43% vs 71%, p=0.009); no association between GPA category and local treatment was observed. Patients undergoing increased lines of local treatments were more likely to receive systemic therapy (chi2 square test p<0.001). To avoid bias we performed two separate multivariate analyses including: i) GPA category and number of local treatments; ii) GPA category (patients with GPA index ≤1 excluded) and systemic treatment. GPA maintained a significant prognostic value in both models (p=0.002 and p=0.038, respectively). Both local and systemic treatments added independent prognostication beyond GPA (Table).

### Conclusions

Patient-related features, tumor phenotype and multimodal treatments all independently contribute to modulate the prognosis of pts with BM from BC.

Phase Ib/II single-arm trial evaluating the combination of everolimus, lapatinib and capecitabine for the treatment of patients with HER2-positive metastatic breast cancer with progression in the CNS after trastuzumab (TRIO-US B-09)

Hurvitz SA A, Martinez DA A, Singh R, Taguchi J, Chan D, Dichmann R, Castrellon A, Barstis J, Hu E, Berkowitz J, Mani A, DiCarlo B, Smalberg I, Hobbs E and Slamon DJ J. University of California, Los Angeles, Los Angeles, CA; University of California, Irvine, Irvine, CA; Cancer Center of Santa Barbara with Sansum Clinic, Santa Barbara, CA; Cancer Care Redondo Beach, Redondo Beach, CA; Central Coast Medical Oncology, Santa Maria, CA; Memorial Healthcare System, Hollywood, FL; San Luis Obispo Oncology/Hematology Health Center, San Luis Obispo, CA; Tower St. John’s Imaging, Santa Monica, CA and Oregon Health Sciences University, OR.

Methods: Patients with trastuzumab-pretreated, HER2+ metastatic breast cancer (MBC) with progression of disease (PD) in the brain and a measurable brain lesion participated. Patients were excluded if they had a prior mTOR inhibitor or an ECOG PS>2. Prior L and/or C, and prior surgery and/or radiation to the brain were allowed. The primary endpoint was CNS ORR at 12 weeks (cycle 3) by RECIST 1.1. Secondary endpoints included safety, progression-free survival, overall survival and extra-CNS ORR.

To test the safety of the combination of L+C+E, a 3+3 dose escalation phase was conducted (starting doses: L 1000 mg QD, E 5 mg QD, C: 750 mg/m² BID d1-14). Treatment was given Q21 days. Patients were evaluated for dose limiting toxicities during C1. Tumor imaging was conducted every 3 cycles. MRI of the brain was performed every 2 cycles through cycle 6 and then every 3 cycles. Neurological symptom assessment was conducted on day 1 of every cycle. Study participants continued to receive treatment until PD, unacceptable toxicity or withdrawal of consent for 12 mos.

Results: Nineteen patients were enrolled at 11 sites in the US and treated with at least one dose of study drug. Of 18 patients with data available, median age was 58.5 (45-68), median number of systemic therapies for MBC was 2 (0-6), and 94.4% had prior radiation and/or surgical resection of brain metastases. 10 patients participated in the dose escalation phase of the study. The maximum tolerated doses were determined to be L 1000 mg QD, E 10 mg QD + C 1000 mg/m² BID days 1-14; however, given tolerability concerns, dose expansion proceeded with Cohort 2 dose for C (750 mg/m² BID d1-14). Of 17 eligible patients with imaging results available to date, 2 (12%) had a partial response in the CNS at week 12, one of whom continues on study (currently in cycle 13). Stable disease was observed in 7 patients. The most common grade 3/4 adverse events (AE) (CTCAE v4.0) related to E and/or L in 18 treated patients were anorexia (5.5%), dehydration (5.5%), diarrhea (17%), fatigue (5.5%), fever (5.5%) hyperglycemia (5.5%), hypokalemia (11%), and oral mucositis (17%).

Conclusions: This is the first report of this regimen for patients with HER2+ MBC to the brain. This regimen is generally well-tolerated and shows promising activity in the CNS of heavily pretreated patients. Final efficacy and toxicity analyses for all 19 patients will be presented.
**Title:** The incidence and outcomes of brain metastases in HER2-positive metastatic breast cancer with the advent of modern anti-HER2 therapies

Strulov Shachar S, Deal AM M, Vaz-Luis I, Dees EC Claire, Carey LA A, Hassett MJ J, Garrett AL L, Benbow JM M, Hughes ME E, Mounsey L, Lin N and Anders CK K. Lineberger Comprehensive Cancer Center, Chapel Hill, NC; Rambam Health Care Campus, Haifa, Israel and Dana-Farber Cancer Institute, Boston, MA.

**Body: Background:** Human epidermal growth factor receptor 2 (HER2) is over-expressed in approximately 20 - 30% of breast cancers. HER2-positive breast cancers frequently metastasize to the brain. In recent years, many new drugs have been approved for HER2-positive metastatic breast cancer (MBC). In the metastatic setting, trastuzumab was approved in 2000, lapatinib 2007, and pertuzumab and ado-trastuzumab emtansine in 2012. We sought to describe the incidence, time course, and prognostic factors of BM in patients (pts) with HER2+ MBC during the time when dramatic changes in systemic therapy occurred.

**Patients/methods:** The study included pts with HER2-positive MBC treated at two academic hospitals: Dana Farber Cancer Institute (DFCI) (2000-2007 [DFCI-T1], 2008-2011 [DFCI-T2]) and University of North Carolina (UNC) (2012-2014). We examined the incidence of BM (at diagnosis [dx] and within 1-2 years of MBC dx). We combined the two cohorts to examine outcomes – time to BM, survival following MBC, and survival following BM – using the Kaplan Meier method and Cox regression modeling.

**Results:** We identified 185 (DFCI n=128, 97 diagnosed 2000-2007 and 31 diagnosed 2008-2011; UNC n=57, all diagnosed 2012-2014) pts with HER2-positive MBC. Through a median of 4 years follow-up after the MBC dx (min 2, max 11), 118 had died and 67 were censored. The median age at MBC dx was 52 (min 25, max 88), 149 (82%) were Caucasian, 88 (48%) had hormone receptor (HR) positive BC, and 67 (37%) had de-novo (i.e., non-recurrent) MBC. BM was present at the MBC dx for 8% of pts in DFCI-T1, 16 % of pts in DFCI-T2, and 16% of pts at UNC. Within 1 year of the MBC dx, BM was present in 21% of DFCI-T1, 29% in DFCI-T2, 23% of UNC pts. Within 2 years of the MBC dx, 67 (36%) pts had developed BM, of which one third (22) were diagnosed at initial MBC presentation. In unadjusted analyses, there were no differences in time to BM dx by age (p=0.2), race (p=0.1) or HR status (p=0.1). The median survival following the development of BM for all pts was 1.5 years. A multivariable model predicting survival after the MBC dx, found factors associated with shorter survival included having (vs. not having) BM at the initial MBC dx, having received (vs. not having received) adjuvant HER2-directed therapy prior to the MBC dx, and having recurrent (vs. de novo) MBC (P≤0.02 for all). Age, HR status, race and time period of MBC dx were not significant in the multivariable model.

**Conclusions:** Among pts diagnosed in the modern era, after new therapies became available, BM remains a common problem for pts with HER2-positive MBC. While no obvious trends in the incidence of HER2-positive MBC are suggested, conclusions regarding incidence trends should be considered hypothesis-generating until larger, population-based data become available. Nevertheless, a dx of BM early in the course of MBC treatment and prior receipt of adjuvant trastuzumab appeared to confer a more aggressive disease course. Coordinated, prospective collection of the incidence and outcomes of BM among pts with HER2-positive MBC, studies of pts who develop BM >2 years after their MBC dx, and clinical trials of treatment strategies for pts with trastuzumab-resistant BM are needed.
Title: Clinical characteristics of CNS metastases of different breast cancer subtypes – Results from a cohort study

Lindman H, Nilsson A and Gullbo J. Uppsala University Hospital, Uppsala, Sweden.

Body: Introduction: Secondary breast cancer in CNS is a rising clinical problem despite an ongoing improvement of the prognosis in breast cancer in general. The commonly proposed reason is the decreased passage through the blood-brain-barrier (BBB) of otherwise effective systemic therapies. The prognosis of patients (pts) with metastases (met) in CNS is poor and the therapy is mainly based on local therapy with surgery or stereotactic radiotherapy or alternatively, whole brain radiotherapy. However, therapy differs among centers and guidelines are based on relatively small studies with inhomogeneous groups of pts. The value of systemic therapy is not clearly established. Data has shown different outcome in different breast cancer subtypes.

Patients and Methods: Pts treated between 2009 and 2016 with metastases in CNS (brain, medulla and/or meningeal) were identified in our treatment database. This represents all breast cancer pts in Uppsala County with CNS involvement during that time period. We categorized the pts based on number of brain met and on the tumor subtype. We compared the pattern of metastases, the relationship to extra-CNS met and time, response to given therapy and survival.

Results: Of 68 pts 51% had oligometastases in brain, 41% multiple brain metastases and 7% meningeal metastases only. Median age was 58 years (range 34-81) median size of largest tumor was 16 mm. The most common subtype was HER2 positive (HER2) 37% followed by Luminal B (LumB) 31%, Triple negative (TNBC) 18% and Luminal A (LumA) 15%. The subtypes had different clinical appearance according to table:

<table>

</tbody>
</table>

In more than 50% of the TNBC pts was CNS the first site of disseminated disease. This was the case in only 24% of the LumB pts and none of the LumA pts. Systemic therapies were given to 91% of all pts and radiological complete responses in CNS were reported in 24% (HER2 32%, TNBC 17%, LumB 24% and LumA 10%). The median survival was 13 months, but differed significantly between the different subtypes and was surprisingly short for LumA, which not could be explained by death by metastases outside CNS. Eventually, developed 25% of all pts meningeal involvement. CNS met were the prime reason for death in 72% of the pts.

Conclusions: This cohort study describes the clinical appearance and prognosis of CNS metastases in breast cancer pts during a seven years period in the institution treating all pts in the County of Uppsala. Distinctive clinical differences between the breast cancer subtypes could be noticed which possible represents different mechanism in the metastatic process as well as different treatment response. The survival in the luminal subgroups was short and CNS met developed considerably later in the course of the disease when pts might have developed a more aggressive and therapy resistant disease.
Introduction

T-DM1 treatment significantly improved overall survival and had a lower incidence of grade ≥3 adverse events (AEs) vs capecitabine plus lapatinib in patients (pts) with HER2-positive advanced breast cancer (BC) in the EMILIA study, including pts with treated, asymptomatic CNS metastases (mets). KAMILLA is an ongoing, single-arm, open-label, phase 3b global safety study of T-DM1 in pts with HER2-positive locally-advanced or metastatic BC (target n=2220). In this interim analysis we describe clinical characteristics, safety, and efficacy in pts with stable CNS mets at baseline (BL).

Methods

Eligible pts received prior HER2-directed therapy and chemotherapy and progressed on or after most recent treatment for advanced BC, or within 6 months of completing adjuvant therapy. Pts with asymptomatic CNS mets were eligible, including pts with stable CNS disease with prior radiation therapy. Pts received T-DM1 3.6 mg/kg every 3 weeks until unacceptable toxicity, withdrawal of consent, or disease progression. This exploratory analysis describes pts with BL CNS mets. Median progression-free survival (PFS) was estimated using the Kaplan-Meier method.

Results

As of April 4, 2016, data were available for 2017 treated pts, of whom 399 (20%) had BL CNS mets, with a median follow-up of 33 months. Table 1 presents demographic and BL characteristics.

Conclusions This subgroup analysis of KAMILA is the largest reported cohort of pts with CNS mets treated with T-DM1. The overall safety profile of T-DM1 in pts with BL CNS mets was comparable to that of pts without CNS mets. As might be expected in pts with CNS disease, serious neurological AEs occurred more frequently in pts with BL CNS mets vs those without. Response to T-DM1 was seen in the CNS in pts with BL CNS mets, however, median PFS was lower in pts with BL CNS mets vs those without BL CNS mets.
2016 San Antonio Breast Cancer Symposium

Title: Abstract Withdrawn
Circulating tumor DNA (ctDNA): A real-time application of precision medicine to the management of metastatic breast cancer (MBC)

Rossi G, Austin LK J, Rademaker AW W, Gradishar WJ J, Santa-Maria CA A, Curry-Edwards RL L, Jain S, Flaum LE E, Lima Barros Costa R, Zagonel V, Platanias LC C, Giles FJ J, Talasaz A and Cristofanilli M.  U.O.C. Oncologia Medica 1 - Istituto Oncologico Veneto- IOV IRCCS, Padova, PD, Italy; Thomas Jefferson University Hospital, Philadelphia, PA; Guardant Health, Inc, Redwood City, CA; Northwestern University, Feinberg School of Medicine, Chicago, IL; Robert H Lurie Comprehensive Cancer Center of Northwestern University, Chicago, IL and Northwestern Medicine, Chicago, IL.

Body: Background: Molecular diagnostic, in particular next-generation sequencing (NGS) technologies, improved the detection of actionable mutations (muts) in MBC at baseline and recurrence. We evaluated the ability of ctDNA to detect molecular abnormalities, monitor disease progression and predict outcome.

Methods: We conducted a retrospective study of 91 patients (pts) with locally advanced and MBC, who had longitudinal assessment of their disease by ctDNA analysis. The plasma-based assay was performed utilizing Guardant360 (Guardant Health, CA), a digital NGS technology to sequence a panel of >50 cancer genes. After tabulating number of muts and quantification of overall ctDNA detected for every patient at baseline, a receiver operating characteristic (ROC) analysis was performed to identify the best cut-offs that separated the pts who had a disease progression from those who hadn't, and the patients who died from those still alive. The overall survival (OS) analysis has been performed using Kaplan-Meier curves.

Results: 84 pts (92%) had stage IV cancer. 63% cases were ER+, 27% HER2+, 29% TNBC. 277 blood samples were collected and 84% had muts. 65% of the pts had serial samples. The average number of alterations detected in each sample was 3 (0-27) and the average ctDNA fraction detected was 4.5% (0-88.2%). The most common alterations were: TP53 (52%), PIK3CA (40%), ERBB2 (20%), NOTCH1 (15.5%), APC (14%), MET (13%). 16 pts (19%) were initiated on a targeted therapy based on ctDNA test results. At the time of analysis 36 pts (39.6%) were dead, 55 (60.4%) were currently alive. PFS was 5.2 months (ms) and OS was 21.5 ms. A statistically significant difference in PFS and OS by log rank test was found between % ctDNA at baseline < 0.5 versus ≥ 0.5 (p = 0.003 and p = 0.012, respectively) and number of muts at baseline < 2 versus ≥ 2 (p = 0.059 borderline and p = 0.0015). Moreover, a statistically significant association by Fisher’s exact test was found between the number of alterations and the % ctDNA detected in the baseline sample (% of pts with muts ≥ 2 was 19% when % ctDNA < 0.5, versus 85% when % ctDNA ≥ 0.5%; p < 0.0001).

**Conclusions:** ctDNA liquid biopsy provides a real-time, quantitative NGS-based assessment of MBC which is useful for treatment planning, disease monitoring and prognostic evaluation. Future prospective studies should consider the use of ctDNA for molecular and prognostic stratification.
Title: Multivariate analysis of subtype and gene expression signatures predictive of pathologic complete response (pCR) in triple-negative breast cancer (TNBC): CALGB 40603 (Alliance)

Hoadley KA A, Hyslop T, Fan C, Berry DA A, Hahn O, Tolaney SM M, Sikov WM M, Perou CM M and Carey LA A. The University of North Carolina at Chapel Hill, Chapel Hill, NC; Alliance Statistics and Data Center, Duke University, Durham, NC; Alliance Statistics and Data Center, MD Anderson Cancer Center, Houston, TX; Alliance Protocol Operations Office, University of Chicago, Chicago, IL; Dana-Farber/Partners CancerCare, Boston, MA and Women and Infants Hospital of Rhode Island, Providence, RI.

Body: Support: U10CA180821, U10CA180882

Background: The addition of either carboplatin (Cb) or bevacizumab (Bev) to standard neoadjuvant chemotherapy (NACT) increases pCR rates in TNBC overall and in the dominant subset of basal-like cancers (Sikov et al, JCO 2015; Sikov et al, SABCS 2014). Multigene expression signatures more accurately reflect tumor biology for response prediction and prognosis than individual gene expression. We evaluated the ability of multivariate analysis of gene expression signatures to create predictive models for achievement of pCR in TNBC.

Methods: RNA sequencing was successful on 389 pretreatment samples from patients with available pCR data, and used to assign PAM50 subtype and calculate gene signatures scores for 489 published expression signatures. Elastic net, a penalized regression model for high dimensional variable selection, was used to select features associated with pCR in all TNBC and in the basal-like subset. Models were derived in a training set (2/3 of samples) and validated in a separate test set (1/3). A separate model was derived using 196 TNBC samples from patients treated only on the standard NACT +/- Cb arms for application to external TNBC neoadjuvant data sets not treated with Bev.

Results: Consistent with our prior partial data set, 343 (88%) of the cancers were classified basal-like, in whom the in breast pCR rate was 54%; the remainder were classified normal-like (n=32) or HER2-enriched (n=14) with a non-basal pCR rate of 56%. Elastic Net analysis in all TNBC generated a model of 23 signatures and treatment assignment with 68% sensitivity and 64% specificity. The area under the curve was 0.64 (p-value=0.0019). Nineteen modules, including immune cell signatures (Th1, NK, IgG), immunoglobulin variable region expression, addition of Cb and Bev and expression of genes at regions 15q25, 17p11.2-13.3, and 8p22 were positively associated with response. The latter two regions are associated with aggressive breast cancer, and while not part of the 17p13 signature, this region contains TP53, a gene important in TNBC. Six modules were associated with resistance, including luminal progenitor, TGFB, NOTCH, FOS/JUN, 8p amplicon, and eosinophil signatures. When limited to basal-like samples, a model including 32 modules and addition of Cb and Bev was generated, with 62.3% sensitivity and 59.1% specificity. Seventeen features were selected in both models. Omitting Bev-treated patients, a model using just the gene expression signatures was developed. The predictive value of this model will be assessed using an external cohort of TNBC patients treated with neoadjuvant docetaxel and Cb (NCT01560663) and results presented.

Conclusions: Multivariate analysis of gene expression signatures derived from pretreatment samples enabled the construction of models to predict achievement of pCR in TNBC. These models performed well on our test set, and will be assessed for their predictive ability in other TNBC data sets. If validated by future analyses, this could help us identify patients likely to achieve pCR with standard NACT and may benefit from the addition of agents such as Cb or Bev.

ClinicalTrials.gov Identifier: NCT00861705.
Title: CSMD1 SNPs selectively affect anastrozole response in postmenopausal breast cancer patients

Cairns J, Ingle J, Dudenkov T, Kalari K, Buzdar A, Kubo M, Robson M, Ellis M, Goss P, Shepherd L, Goetz M, Weinshilboum R and Wang L. Mayo Clinic, Rochester, MN; The University of Texas MD Anderson Cancer Center, Houston, TX; Riken Center for Integrative Medical Science, Yokohama, Japan; Memorial Sloan Kettering Cancer Center, New York, NY; Baylor Cancer Center, Houston, TX; Massachusetts General Hospital, Boston, MA and NCIC Clinical Trials Group, Kingston, ON, Canada.

Body: BACKGROUND: Based on prospective clinical trials, there is no evidence for differences in efficacy between the 3 aromatase inhibitors (AIs) anastrozole, exemestane, and letrozole. The purpose of this study was to identify germline genetic variants associated with response to AIs and to help identify novel mechanisms associated with drug disease efficacy.

METHODS: A genome-wide association study (GWAS) was performed for 624 patients (Steroids 2015;99:32-38) to identify SNPs associated with estrogen level change in women with estrogen receptor (ER) positive breast cancer treated with anastrozole. Replication of associated SNPs was performed in a GWAS from the MA.27 trial that compared adjuvant anastrozole and exemestane treatment of post-menopausal women with ER+ breast cancer. Functional studies were subsequently performed to determine SNP effects and underlying mechanisms.

RESULTS: Our initial GWAS identified SNPs within CSMD1 that were associated with changes in estrogen levels during anastrozole therapy. An additional SNP in CSMD1 was also associated with breast cancer events in CCTG MA.27. Functionally, we showed that CSMD1 regulates CYP19 expression in a SNP-, and in an anastrozole- dependent fashion. These phenomena were not observed for either letrozole or exemestane. In MA.27, an anastrozole- specific effect was also seen with the minor allele having a protective effect on time to distant metastasis (HR=0.49, p=0.00259), but this was not the case for exemestane (HR=0.71, p=0.111). Our in vitro functional studies indicated that overexpression of CSMD1 sensitized anastrozole or letrozole resistant cells to anastrozole but not to the other two AIs. The SNP in CSMD1 that was associated with increased CSMD1 and CYP19 expression levels increased anastrozole sensitivity, but not letrozole or exemestane in lymphoblastoid cell lines (LCLs) homozygous for either WT or variant CSMD1 SNP genotypes. Based on these observations, we explored whether anastrozole has additional mechanisms beyond its function as a CYP19 inhibitor. Utilizing an estrogen response element (ERE) luciferase reporter assay in a CYP19 CRISPR knockout breast cancer T47D cell line and a surface plasmon resonance (SPR) assay, we found that anastrozole can also function as an ERα agonist, and can bind to, and result in, proteasome dependent ERα degradation, especially in the presence of E2. Treatment of these CYP19 CRISPR knockout cells with anastrozole in the presence of increasing concentrations of E2 results in greater sensitivity compared with anastrozole alone, while the addition of E2, as expected, does not improve letrozole or exemestane sensitivity. These same observations were also seen in letrozole and anastrozole resistant cells.

CONCLUSIONS: Our findings suggest that anastrozole might be more effective than letrozole or exemestane in patients with the CSMD1 SNP. Furthermore, anastrozole can function as an ERα agonist, binding to ERα and resulting in its degradation, especially in the presence of E2. These findings should help to make it possible to develop precision endocrine therapies for women who are candidates for AIs.
Title: Breast cancer brain metastases show limited intrinsic subtype switching, yet exhibit acquired ERBB2 amplifications and activating mutations

Body: BACKGROUND: Metastasis is the major cause of mortality in breast cancer (BrCa) patients. Our understanding of brain metastasis (BrM) is limited, reflected by a lack of effective treatments. We aimed to (1) determine BrCa gene signature differences between primary tumors and matched BrM and (2) uncover BrM-specific alterations that may be clinically actionable.

MATERIALS and METHODS: NanoString expression profiling of 127 genes from 5 major prognostic tests (MammaPrint, EndoPredict, PAM50, OncotypeDX, MGI) was performed on 20 patient-matched primary (10 ER-neg, 10 ER-pos) and metastatic brain tumors. Subtype classification was performed using genefu. Protein changes in ER and HER2 (ERBB2) were confirmed by IHC. BrM-specific ERBB2 gains were corroborated in a publicly available dataset of 18 additional patient-matched cases (dbGAP phs000730.v1.p1). To test whether ERBB2 amplification and base pair mutation is metastasis-site specific, we further analyzed an expanded cohort of 7,884 breast tumors enriched for metastatic samples (52%) including liver (16.7%), lung (4.3%), bone (3.6%), and brain (2.0%) using comprehensive hybrid-capture sequencing of ERBB2.

RESULTS: 17/20 BrM retained the PAM50 subtype of the primary BrCa. Despite this concordance, 17/20 BrM harbored expression changes (< or > 2-fold) in clinically actionable genes including gains of FGFR4 (30%), FLT1 (20%), AURKA (10%) and loss of ESR1 expression (45%). The most recurrently upregulated gene was ERBB2, showing a >2-fold expression increase in 35% of BrM. 3 of 13 (23.3%) cases originally HER2-negative, and thus HER2-therapy naive, in the primary BrCa were IHC-positive (3+) in the paired BrM with an observed metastasis-specific amplification of the ERBB2 locus. In an independent dataset, 2 of 9 (22.2%) HER2-negative BrCa switched to HER2-positive with one BrM acquiring ERBB2 amplification and the other showing metastatic enrichment of the activating V777L ERBB2 mutation. Analysis of a large cohort of breast tumors (n=7,884) showed that across all organs ERBB2 amplification and/or base pair mutation was similar (p=0.18) between primary (13%) and metastatic disease (12%), however, a strong and significant enrichment was seen for BrM (primary 13% vs BrM 24%, p<0.0005).

CONCLUSIONS: Taken together, these results demonstrate that the majority (85%) of patient-matched BrM retain the intrinsic subtype of the primary cancer. However, despite this transcriptional similarity, alterations in clinically actionable genes are common, with BrM acquiring ERBB2 amplifications and/or base pair mutations at a frequency of ~20%, even in HER2-therapy naive tumors. In a large cohort of primary and metastatic breast cancers, there is also a unique enrichment for ERBB2 alterations in BrM. This study provides a strong rationale to molecularly profile metastatic lesions to both better understand biological mechanisms of metastases and to perhaps refine therapeutic decision-making in advanced cancers.
Title: Comparison of mutational landscapes of primary breast cancer and first metastatic relapse: Results from the ESOPE study

Body: Background
Genomic profile of breast cancer metastases (M) may differ from that of the primary tumor (PT). In a multicenter prospective study (ESOPE, NCT 01956552) including 130 patients with biopsies of the first metastatic deposit, we have shown that luminal breast cancers are the most prone to phenotypical subtype changes (Comte et al, ASCO 2016#550). We report here the first results of a comparative PT/M targeted next generation sequencing (NGS) mutational analysis.

Methods
Of 130 patients, 117 paired PT/M samples obtained before any treatment were available for analysis. Targeted Sequencing was done using Illumina HiSeq2500 technology with a custom made 95 breast cancer associated genes panel. Sequence data were aligned to the human reference genome (hg19) using Bowtie2 algorithm. Median depth was 607X and 87% of targets achieved 100X depth. SNVs and indels were called using GATK UnifiedGenotyper. We retained COSMIC confirmed non synonymous, exonic/splice variants and observed at a frequency lower than 0.1% in population. Further confirmation of detected variants was performed with comparison to public databases (cbioportal, tumorportal), and potential pathogenicity was evaluated with 4 different public algorithms. We present here the results obtained from the first 35 matched PT/M samples (liver mets 68%), focusing analysis on 40 genes including PIK3CA (20 genes), ER (6 genes) and MAPK (11 genes) pathways, RUNX1, CDH1 and TP53 genes.

Results
Patients characteristics are representative of patients with first line metastatic breast cancer (Comte et al, ASCO 2016#550). Among the 40 genes analyzed in the 70 samples, we detected 134 somatic mutations (70 in PT and 64 in M) including 15 indels and 119 SNV. Among these 134 mutations there were 74 different mutations (66SNV and 8 indels) classified pathogenic for 26 and of unknown pathogenicity for 48 of them. We detected at least 1 mutation in 31 PT and in 28 M. Median numbers of mutations were 1 in PT (range 1-9) and 1 in M (range1-22) samples (p=0.295, Wilcoxon rank sum test). Top ten mutated genes in PT included PIK3CA, TP53, NCOR1, NF1, GATA3, CDH1, ERBB3, PTEN, HRAS, INPP4B. In M samples, the 10 top genes were PIK3CA, TP53, ERBB3, AKT3, CDH1, ERBB4, GATA3, INPP4B, MET, MTOR. Only 3 ESR1 mutations were detected, including 1 PT/M pair and 1 M. Beyond highly shared PIK3CA and TP53 mutations, overall crude PT/M discordance rate was 31%. Analysis by histological subtypes showed PT and M specific mutational profiles, suggesting a role in ERBB gene family (notably ERBB3) and MAPK driven pathways in early metastatic progression. Specific metastatic site analysis suggested enrichment in MAPK pathway mutations in liver metastases when compared to other sites. Variant allelic fractions were globally not significantly different between PT and M samples.

Conclusion
In this prospective multicenter series of systematic biopsies of first metastases, we report a targeted mutational analysis of matched PT and M samples not modified by previous therapy exposure. Early analyses suggest specific genotypical changes according to tumor subtype and/or metastatic site. Extended and updated results will be reported at the meeting.
Title: Comprehensive characterization of matched pre-treatment biopsies and residual disease of doxorubicin treated breast cancer

Body: Background
Neoadjuvant chemotherapy is standard of care for locally advanced breast cancer. Unfortunately not all patients benefit from this treatment. Even after decades of research, we still cannot predict which tumor will or will not respond. This may in part be due to tumor heterogeneity, as the sample taken before treatment not necessarily represents the tumor cell population that causes therapy resistance.

Methods
To test this hypothesis, we collected pre-treatment biopsies, resection specimens, and matched blood from 21 breast cancer patients treated with doxorubicin and cyclophosphamide in a neoadjuvant setting. Specifically, tumors were selected with a tumor percentage >50% after chemotherapy to enrich for resistant samples and ensure high quality data. RNA and whole exome sequencing were performed to characterize somatic mutations, copy number alterations and gene expression profiles. Histopathological characteristics were determined to obtain a comprehensive profile of all tumor samples.

Results
The comparisons of somatic variants and copy number alterations revealed a very diverse image: in several cases, high-level amplifications, large genomic gains or losses, and mutations in known oncogenes or tumor suppressors such as MAP3K1 and RUNX1 were either lost or gained during treatment, while in other cases no such changes were detected. We observed a remarkable number of genetic alterations involved in cell cycle progression and DNA damage checkpoints, including amplification of MDM2, CCND1 and CDK4, and copy number loss or mutations in CDKN1B and ATM. Strikingly, both cases of CDKN1B loss were identified in pre-treatment biopsies and no longer detectable in the surgery specimen. In contrast, CCND1, CDK4 and MDM2 amplifications were retained, although CCND1 expression decreased significantly in CCND1 amplified tumors. In addition, eighty percent of tumors showed a decreased cell proliferation after chemotherapy, where the high-proliferative ER+ (Luminal B) tumors were most strongly affected. This trend was also visible in a validation cohort of 94 ER+ samples, but the prognosis of Luminal B tumors that showed a decrease in proliferation was still significantly worse than that of Luminal A tumors that did not show an altered proliferation rate.

Conclusion
Our results confirm that biologically relevant genomic alterations can differ between pre- and post-treatment samples, which greatly impacts biomarker discovery. In addition, our findings emphasize the chemotherapy insensitivity of CCND1 amplified ER+ breast cancers, and stress the need for better treatment regimens for these patients. In contrast, genomic loss of CDKN1B may be a marker for sensitivity to doxorubicin.
Title: High-throughput genome analysis and therapeutic decision for patients with HER2-negative metastatic breast cancer: First feasibility and molecular results of the randomized phase II study SAFIR02 BREAST (UCBG-0105/1304)

Gonçalves A, Bachelot T, Lusque A, Arnedos M, Campone M, Bièche I, Lacroix L, Pierron G, Dalenc F, Filleron T, Sablin M-P, Jimenez M, Ferrero J-M, Lefevre-Plesse C, Bonnefoi H, Attignon V, Soubeyran I, Jezequel P, Commo F and André F. Institut Paoli Calmettes, Marseille, France; Centre Léon Bérard, Lyon, France; Institut Claudius Regaud- IUCT-O, Toulouse, France; Gustave Roussy Cancer Campus, Villejuif, France; Institut de Cancérologie de l'Ouest, Nantes, France; Institut Curie, Paris, France; Unicancer, Paris, France; Centre Antoine Lacassagne, Nice, France; Centre Eugène Marquis, Rennes, France and Institut Bergonié, Bordeaux, France.

Body: Background A genomic-driven therapeutic strategy in metastatic breast cancer (MBC) was recently demonstrated as feasible in the clinical practice, but its actual impact on patient outcome remains elusive. SAFIR02 study is an ongoing national multicentric phase II randomized trial evaluating targeted therapies matching specific genomic alterations (GA) administered as maintenance after objective response and/or stable disease obtained with chemotherapy in HER2-negative MBC patients. This analysis reports on feasibility of the procedure and the rate of identified actionable targets.

Methods Eligible MBC patients (PS=0/1, first- or second-line of chemotherapy, HER2-negative/hormone receptor (HR)-negative or endocrine resistant HR-positive; measurable per RECIST 1.1; accessible to tumor biopsy; no bone metastases-only disease, no major organ dysfunction) were subjected to tumor biopsy for genomic analysis (CGH arrays, Affymetrix Cytoscan; NGS, Ion Torrent PGM, AmpliSeq, panel of around 50 genes). Actionable GA were identified and corresponding targeted therapies were proposed by a multidisciplinary tumor board (MTB). Patients received cytotoxic-based treatment at physician's choice and those with stable or responding disease after 6 to 8 cycles (or at least 4 if stopped for toxicity reason) and targetable GA, were offered randomization between targeted therapy or chemotherapy maintenance until progression or intolerance (main study). Since January 2016, an amendment was made to propose to patients without targetable alteration a randomization between anti-PD-L1 (MEDI4736) or standard chemotherapy maintenance (substudy).

Results Between March 2014 and May 2016, 457 patients have been enrolled at 21 centers. Genomic analyses could not be obtained in 107 cases (23%) due to either biopsy failure (n= 40; 9%) or low cellularity (n=67; 14%). Of the 307 patients reviewed by the MTB, 197 (64%) had an actionable GA, including PIK3CA-PIK3CB-PIK3R1 (n=51), FGF4 or FGFR1/2 (n= 42), BRCA1/2 (n=15), AKT1/2/3 (n=13), BRAF/KRAS/NRAS (n=13), HER2/3 (n=10), NF1-FRS2 (n=10), MTOR-RPTOR-TSC2 (n=8), PTEN (n=7), STK11 (n=7), IGFB1R (n=7), EGFR (n=5). Therapeutic proposals by MTB included AZD5363 (n=71), AZD4547 (n=42), AZD2014 (n=23), selumetinib (n=23), olaparib (n=16), AZD8931 (n=15), vandetanib (n=5), bicalutamide (n=2). In an exploratory analysis involving 157 patients, the rate of targeted therapy proposal by MTB markedly differed between triple-negative patients (TNBC; 24 of 48, 50%) and HER2-negative/HR-positive patients (92 of 109, 84%; p=6.14. 10^-6, Chi-2 test). At the time of the analysis, 85 patients have been randomized (main study, 68; substudy, 17). Causes of randomization failure (n=108) included disease progression (n=45) or death (n=25), non-eligibility criteria (n=27), patient/physician's decision (n=11).

Conclusion A large number of patients had identified targetable GA. Of note, the rate of targeted therapeutic proposal was significantly lower in TNBC than in HER2-negative/HR-positive patients. Rapidly progressing disease may impede ultimate randomization.
Clinically dormant ER+ breast tumors exhibit AMPK activation

Hampsch RA A, Dillon LM M and Miller TW W. Dartmouth College, Hanover, NH.

While adjuvant anti-estrogen therapy has shown immense clinical benefit for patients with estrogen receptor-positive (ER+) breast cancer, >30% of patients experience cancer recurrence within 15 years of initial diagnosis. Anti-estrogen therapies inhibit ER activity either directly (tamoxifen, fulvestrant) or by reducing systemic estrogen levels (aromatase inhibitors, AIs). Extending adjuvant anti-estrogen therapy from 5 to 10 years further prevents recurrence; however, with both 5- and 10-year treatment regimens, a large proportion of patients who relapse do so after cessation of therapy (“late recurrence”). Additionally, disseminated tumor cells in bone marrow have been found after 4 years of adjuvant anti-estrogen therapy in “disease-free” patients. These data collectively indicate that anti-estrogens elicit clinical benefit as adjuvant therapies, in part, by maintaining a population of residual micrometastatic cancer cells in a “clinically dormant” state (i.e., undetectable by routine clinical methods). Understanding how such dormant cancer cells survive will enable the development of more effective adjuvant therapies.

We developed several luciferase-labeled xenograft models of ER+ breast cancer that recapitulate clinical dormancy in vivo. Low systemic levels of estrogen in mice can be further suppressed by ovariectomy, mimicking the effects of AI-induced estrogen deprivation seen in patients. In ovariectomized mice, palpable tumors form upon 17b-estradiol supplementation, but quickly regress upon estrogen withdrawal. While regressed tumors become non-palpable within 2 wk, a small proportion of cancer cells survive these estrogen-deprived conditions for >4 months in a clinically dormant, growth-suppressed state. This estrogen deprivation-induced clinically dormant cell population retains tumorigenic potential, as 17b-estradiol retreatment induces tumor recurrence. RNA expression profiling revealed AMPK alpha 2 as one of the most highly expressed genes in clinically dormant residual tumor cells compared to acutely estrogen-withdrawn tumors. Increased AMPK kinase activity was confirmed through immunohistochemical analysis of phospho-ACC, and AMPK substrate.

AMPK activation using glucose deprivation or the anti-diabetes drug metformin promoted estrogen-independent survival and growth of ER+ breast cancer cells in vitro. Metformin treatment may also slow estrogen withdrawal-induced tumor regression and promote tumor cell survival in ER+ breast cancer xenografts. As a cellular energy sensor, AMPK has been shown to promote autophagy, a process linked with anti-estrogen resistance. Immunofluorescent staining of estrogen deprivation-induced clinically dormant residual tumor cells revealed decreased levels of the autophagy marker p62 compared to 17b-estradiol-driven tumors. Early data suggest that inhibition of autophagy with hydroxychloroquine abrogates cell survival conferred by metformin in estrogen-depleted conditions. Thus, AMPK may be promoting the survival of ER+ breast cancer cells in estrogen-deprived conditions by increasing autophagic flux. These data have implications for the interpretation of data from ongoing clinical studies testing metformin for the treatment of cancer.
Title: SFX-01 targets Wnt signalling to inhibit stem-like cells in breast cancer patient-derived xenograft tumours

Body: Background: SFX-01 is a novel therapeutic comprising synthetic sulforaphane (SFN) stabilised within α-cyclodextrin. Breast cancer stem-like cells (CSCs) have been identified in all molecular subtypes and are likely drivers of breast cancer metastasis and treatment resistance. We recently established that CSC activity in ER+ BC, represent a source of therapeutic resistance (Simões et al, Cell Reports, 2015).

Material and methods: We investigated SFX-01 effects on breast CSC activity using mammosphere formation efficiency (MFE) and aldehyde dehydrogenase (ALDH) activity using the ALDEFLUOR assay in patient samples and patient-derived xenograft (PDX) tumours. Cells from primary (n=12) and metastatic (n=15) samples were treated with SFX-01 (5 µM) or vehicle control. Using a 2 or 8 week in vivo treatment, early (HBCx34) and metastatic (BB3RC31) ER+ PDX tumours were treated with SFX-01 (300mg/Kg/day) alone or in combination with tamoxifen (TAM, 10 mg/kg/day) or fulvestrant (FULV, 200 mg/kg/week). Tumours were dissociated and MFE and ALDH activity assessed.

Results: SFX-01 in vitro reduced MFE of both primary (0.19±0.02 vs control 0.52±0.06: p<0.001) and metastatic patient samples (0.43±0.04 vs control 0.93±0.07: p<0.001). SFX-01 treatment in vivo for 2 weeks reduced MFE of HBCx34 (0.35±0.03 vs control 0.64±0.09: p<0.01) and BB3RC31 (0.78±0.04 vs control 0.89±0.06: p<0.05) and also ALDH activity of HBCx34 (3%±0.6 vs control 6.3%±0.4: p<0.01) and BB3RC31 (1%±0.2 vs control 3%±0.6: p<0.05). TAM and FULV increased MFE and ALDH activity after 2 weeks of treatment in vivo, which was abrogated by combination with SFX-01; for example HBCx34 MFE with TAM alone: 0.81±0.07 vs TAM+SFX-01: 0.34±0.02 (p<0.01) and ALDH+ with TAM alone 10%±0.4 vs TAM+SFX 4.2%±0.4 (p<0.01). TAM+SFX-01 suppressed tumour growth at 8 weeks vs TAM alone in HBCx34 but not BB3RC31. FULV treatment maintained tumour growth suppression at 8 weeks and no additive effect was seen with SFX-01, although MFE and ALDH activity were suppressed. Mechanistically, SFX-01 potently inhibited the canonical Wnt pathway in MCF-7 cells and their endocrine-resistant derivatives and we are currently exploring SFX-01 activity on other CSC regulatory pathways.

SFX-01 has been shown to be well tolerated in SAD and MAD studies in normal volunteers and clinical studies designed to test tolerability and efficacy in combination with the three major classes of endocrine therapy (AI, TAM and FULV) in advanced BC will begin in Q4 2016.

Conclusions: Our data demonstrate the potential of SFX-01 for clinically meaningful improvements to endocrine therapy in ER+ breast cancer by reversing CSC mediated resistance.
Title: Recurrent functionally diverse in-frame ESR1 gene fusions drive endocrine resistance in breast cancer

Lei JT T, Shao J, Zhang J, Iglesia M, Cao J, Chan DW W, He X, Kosaka Y, Schmidt C, Matsunuma R, Haricharan S, Crowder R, Hoog J, Phommaly C, Goncalves R, Ramalho S, Lai W-C, Hampton O, Rogers A, Tobias E, Parikh P, Davies S, Ma C, Suman V, Hunt K, Watson M, Hoadley KA A, Thompson A, Chen X, Perou CM M, Creighton CJ J, Maher C and Ellis MJ J. Baylor College of Medicine, Houston, TX; Washington University School of Medicine, St. Louis, MO; University of North Carolina, Chapel Hill, NC; Kitasato University School of Medicine, Minato, Japan; University of Sao Paulo School of Medicine, Sao Paulo, Brazil; State University of Campinas, Sao Paulo, Brazil; Mayo Clinic, Rochester, MN and MD Anderson Cancer Center, Houston, TX.

Body: Background. We previously reported an alternative ESR1 somatic gain-of-function chromosomal translocation event in a patient presenting with aggressive, endocrine therapy resistant estrogen receptor (ER) positive disease, producing an in-frame fusion gene consisting of N-terminal ESR1 and the C-terminus of the Hippo pathway coactivator YAP1 (ESR1-YAP1). We recently identified another ESR1 fusion through RNA sequencing (RNA-seq) in advanced stage ER+ disease from a chest wall recurrence in a male patient that was refractory to multiple lines of treatment. Two examples of fusions discovered in primary breast cancer samples include ESR1 fused in-frame to C-terminal sequences from NOP2 (ESR1-NOP2), identified in a resistant cohort from a RNA-seq screen focused on 81 primary breast cancers from aromatase inhibitor clinical trials, and a second ESR1 fusion, fused in-frame to the entire coding sequence of POLH (ESR1-POLH), that was identified from RNA-seq analysis of 728 Cancer Genome Atlas breast samples. This current study extends our previous characterization of ESR1-YAP1 by comparing functional and pharmacological properties of these three additional ESR1 gene fusion events of both early stage and advanced breast cancers.

Methods. In vitro and in vivo experiments were conducted to test ESR1 fusions to induce therapeutic resistance, and metastasis. The transcriptional and binding properties of each fusion was also examined. Pharmacological inhibition with Palbociclib, a cyclin-dependent kinase 4/6 inhibitor, was utilized to assess drug sensitivity in ESR1 fusion containing breast cancer cells and in a patient derived xenograft (PDX) model expressing ESR1-YAP1 (WHIM18).

Results. The YAP1 and PCDH11x fusions conferred estrogen-independent and fulvestrant-resistant growth. Immunohistochemistry revealed significantly higher numbers of ER+ cells in lungs of mice xenografted with T47D cells expressing the YAP1 and PCDH11x fusions compared to YFP control, NOP2 and POLH fusions. Results from ChIP-seq and microarray studies suggest that these two fusions promote proliferating and metastasis through genomic action by binding estrogen response elements (ERE) and subsequent gene activation. We thereby define these fusions as “canonical” fusions compared to “non-canonical” NOP2 and POLH fusions, which demonstrated dramatically decreased genomic binding ability. The non-canonical fusions induced genes associated with basal-like breast cancer and promoted HER2, EGFR, and MAPK gene expression signatures in contrast to genes associated with cell cycle/proliferation induced by canonical fusions. The proliferative ability of canonical fusion-containing ER+ cells was inhibited by Palbociclib in a dose-dependent manner. In vivo WHIM18 tumors in mice fed with Palbociclib-containing chow demonstrated significantly reduced tumor volume, growth rate, and weight compared to tumors in mice on control chow.

Conclusions. In-frame ERE activating canonical fusions occur in end-stage drug resistant advanced breast cancer and can be added to ESR1 point mutations as a class of recurrent somatic mutation that may cause acquired resistance. Growth induced by these fusions can be antagonized by Palbociclib and is potentially clinically helpful.
Title: FOXA1 induces a pro-metastatic secretome through ER-dependent and independent transcriptional reprogramming in endocrine-resistant breast cancer

Lester and Sue Smith Breast Center, Baylor College of Medicine, Houston, TX; Dan L. Duncan Comprehensive Cancer Center, Baylor College of Medicine, Houston, TX; Baylor College of Medicine, Houston, TX; Baylor College of Medicine, Houston, TX; Baylor College of Medicine, Houston, TX; Center for Cardiovascular Regeneration, The Methodist Hospital Research Institute, Houston, TX and Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA.

Body: Background: Metastasis in ER-positive (+) breast cancer (BC) occurring years to decades after initial diagnosis presents a daunting challenge for clinical care and preclinical research due to limited known key players and experimental models. FOXA1 is a pioneer factor for ER-chromatin binding and function, and is highly expressed in ER+ BC metastases, yet the underlying mechanism is unclear. Tumor-secreted proteins play a crucial role in the reciprocal interplay between cancer cells and host microenvironmental factors at both primary and secondary sites. We hypothesized that high FOXA1 provokes an ER-dependent transcriptional program that includes a unique pro-tumorigenic secretome essential for promoting ER+ BC metastasis.

Methods: A lentiviral doxycycline (Dox)-inducible FOXA1 overexpression vector and a dual luciferase/GFP (LG) tracking vector were integrated to construct a stable MCF7-LG/FOXA1 cell model. Ovariectomized nude mice bearing MCF7-LG/FOXA1 xenografts in the presence of exogenous estrogen (E2) were randomized to ± Dox, each with continued E2, E2 deprivation (ED), or tamoxifen (Tam). Survival surgery removing the therapy-naïve (E2 arm) and relapsed (ED/Tam arms) tumors was performed when tumors reached ~1000 mm³. All mice then received ED/Tam 'adjuvant' therapy, with longitudinal luminescence imaging to monitor local/distant recurrences. Mice were or will be euthanized at the ethical end-point. Integrative bioinformatics was performed using RNA-seq and FOXA1/ER ChIP-seq data from our preclinical models to identify secretome targets for functional intervention. Times to tumor regression (TTR) and progression (TTP) were defined by when the tumor reached half or twice the volume at randomization.

Results: Median (m) TTR was achieved in ED (31/34 days, -/+Dox, P = 0.184) but not in Tam groups — Tam delayed tumor growth but failed to prevent progression in all mice with mTTP of 94/93 days (-/+Dox, P = 0.517). Despite no difference in mTTP at Tam-/+Dox, a quarter of +Dox tumors (3/12) had volume doubled by day 11. No metastases were observed by imaging in any of the mice before surgery ('neoadjuvant' setting). Local relapse and lymph-node/lung metastases were detected after surgery ('adjuvant' setting). At day 90 in the adjuvant Tam group with previously relapsed tumors, +Dox mice succumbed to metastasis more often than -Dox mice (7/8 vs. 3/10, P = 0.023). Compared to the adjuvant Tam+Dox mice with previous therapy-naïve tumors, the Tam+Dox with previously relapsed tumors showed higher distant metastasis rate (7/8 vs. 5/14, P = 0.026). Analysis of the ED setting is pending due to late recurrence. Data integration and functional study revealed a set of cytokines, growth factors, and extracellular matrix components (including IL-8, CTGF, and LOX), regulated by FOXA1 often in conjunction with ER, that are highly involved in FOXA1-induced metastasis. Global secretome profiling by mass spectrometry and target validation are ongoing. Conclusions: FOXA1 overexpression increases metastatic potential in ER+ BC. We established a pertinent metastatic xenograft mouse model to characterize a pro-metastatic secretome with diagnostic and therapeutic potential for treating metastatic ER+ BC.

**Title:** Inhibition of mutant HER2 results in synthetic lethality when combined with ER antagonists in ER+/HER2 mutant human breast cancer cells

Croessmann S, Zabransky DJ J, Cutler, Jr. RE E, Lalani AS S, Park BH H and Arteaga CL L. Vanderbilt University Medical Center, Nashville, TN; Johns Hopkins School of Medicine, Baltimore, MD and Puma Biotechnology, Inc., Los Angeles, CA.

**Body:** Background: Human epidermal growth factor receptor 2 (ERBB2 or commonly known as HER2) missense mutations have been reported in 2-4% of breast cancers and occur primarily in the absence of HER2 gene amplification. Based on TCGA, approximately 60% of these tumors are hormone-dependent and express estrogen receptor (ER) a. Among ER+ breast cancers with HER2 missense mutations, more than 80% are in the HER2 kinase domain. We examined herein whether ER+/HER2 mutant breast cancer cells are resistant to anti-estrogen therapies and, thus, whether they should be treated with combined ER and HER2 inhibitors.

**Methods:** Three common HER2 activating mutations (G309A, L755S, V777L) and wild type (WT) HER2 were incorporated into ER+ MCF7 cells using AAV-mediated homologous recombination. The isogenic incorporation of a heterozygous mutation more accurately represents primary human tumors as compared to transfection and overexpression of exogenous vectors. We examined cell viability and ER transcriptional activity, using an ERE-luciferase reporter, in response to estrogen deprivation and treatment with fulvestrant (a selective ER downregulator) and neratinib (an irreversible, pan-HER tyrosine kinase inhibitor), either alone or in combination. Signaling downstream mutant HER2 was examined by immunoblot analysis. *In vivo* anti-tumor efficacy of fulvestrant ± neratinib is currently being assessed in ovariectomized athymic mice bearing MCF7/HER2^{V777L} xenografts.

**Results:** MCF7 cells containing HER2 kinase missense mutations (L755S and V777L), but not cells with HER2^{WT} or an extracellular domain mutation (G309A), were able to proliferate exponentially in estrogen-free medium. MCF7/HER2^{L755S} and MCF7/HER2^{V777L} were also resistant to 1 mM fulvestrant, despite fulvestrant's ability to downregulate ER in these cells. Additionally, MCF7/HER2^{L755S} and MCF7/HER2^{V777L} showed increased levels of pERK and p70S6K. Treatment with 200 nM neratinib potently inhibited growth of MCF7/HER2^{L755S} and MCF7/HER2^{V777L} in estrogen-free conditions and resensitized them to fulvestrant while partially downregulating HER2 levels. Addition of 1 nM estradiol markedly rescued all three HER2 mutant cells from neratinib-induced cell death suggesting that the inhibition of both ER and mutant HER2 is required for tumor cell apoptosis. Using ERE-luc reporter assays, neratinib did not inhibit basal or estrogen-induced ER transcriptional activity or ERα Ser118 phosphorylation, thus not supporting HER2 mutation-to-ER crosstalk in these genetically engineered cells. This result also suggests that the ER and HER2 mutant pathways can operate independently and it is the dual pathway inhibition that results in synthetic lethality.

**Conclusions:** These data suggest that, in ER+ breast cancers and similar to HER2 gene amplification, HER2 kinase domain mutations induce resistance to antiestrogen therapies. Therefore, we propose simultaneous therapeutic targeting of both ER and HER2 signaling pathways is required for maximal inhibition of ER+ breast cancers also harboring HER2 activating mutations, as is currently being investigated in the phase II SUMMIT trial (NCT01953926).
Mismatch repair deficiency induces endocrine therapy resistance in breast cancer

Haricharan S, Schmelz J, Schmidt C, Singh P, Holloway K, Anurag M, Suman V, Olson JA A, Hunt K, Bainbridge MN N and Ellis MJ J. Baylor College of Medicine; Mayo Clinic; University of Maryland School of Medicine and UT MD Anderson Cancer Center.

Body: Estrogen receptor positive (ER+) breast cancer accounts for the majority of breast cancers diagnosed worldwide but fortunately, outcomes are markedly improved by pharmacological interventions that interrupt ER function. Unfortunately, suppression of relapse risk from early stage disease with endocrine therapy (anti-estrogens or aromatase inhibitors) is only ~50%, and for advanced disease, pan endocrine therapy resistance is almost inevitable. While many mechanisms for intrinsic and acquired endocrine resistance have been explored, links between defects in DNA repair, the fundamental drivers of cancer pathogenesis, and endocrine therapy resistance have been understudied. Here we link mismatch repair (MMR) deficiency to poor clinical outcomes in ER+ breast cancer using whole exome DNA sequencing data and mRNA expression analysis. We subsequently demonstrate that MMR deficiency bypasses ER dependent cell cycle regulation through disruption of Chk2/p21-mediated feedback inhibition of CDK4 in breast cancer cell lines and tumor samples, as well as through correlations with human clinical data. We also show that pharmacological targeting of CDK4 significantly inhibits growth of MMR-deficient ER+ breast cancer cells in vitro and in vivo. This mechanism provides a new explanation for why endocrine therapy resistant ER+ breast cancers can respond to CDK inhibition and suggests that primary tumors exhibiting MMR deficiency are good candidates for adjuvant CDK4 inhibitor treatment.
**Title:** 10-year follow-up and biomarker discovery for adjuvant endocrine therapy; results of the TEAM trial

Blok EJ, Derks MGM GM, Kuppen PJK JK, Meershoek-Klein Kranenbarg EM M, Engels CC C, Liefers G-J, Putter H, Seynaeve CM M, Kroep JR R, Nortier JWR WR, Rea DW W, Hasenburg A, Markopoulos CJ J, Paridaens R, Bartlett JMS MS and van de Velde CJH JH. Leiden University Medical Center, Leiden, Netherlands; Leiden University Medical Center, Leiden, Netherlands; Erasmus Medical Center, Rotterdam, Netherlands; University of Birmingham, Birmingham, United Kingdom; University Hospital Freiburg, Freiburg, Germany; Athens University Medical School, Athens, Greece; University Hospital Leuven, Leuven, Belgium and Transformative Pathology, Ontario Institute for Cancer Research, Toronto, Canada.

**Body:** Optimal endocrine therapy for postmenopausal, hormone-receptor positive (HR+) early breast cancer remains a point of discussion. The Tamoxifen Exemestane Adjuvant Multinational (TEAM) phase III trial showed no significant differences for disease free survival (DFS) and overall survival (OS) at 5 years between exemestane monotherapy and sequential treatment (tamoxifen followed by exemestane). We now report disease related outcomes at 10 years of follow-up (FU), and an explorative analysis to assess the predictive value of clinicopathological and immune-related biomarkers.

In the TEAM trial, postmenopausal women with HR+ positive early breast cancer were randomly assigned to exemestane alone or sequential therapy. For this analysis, TEAM patients from countries that completed 10 years of FU were included. The primary endpoint was DFS at ten years, analyzed by intention to treat. Secondary outcomes were OS and cumulative incidence of relapse. An explorative per protocol analysis for relapse free survival (RFS) was performed to identify predictive pathological and immunological biomarkers, including centrally determined ER (ER-poor 0-6 vs ER-rich 7-8) and PR (0-4 vs 5-8) Allred scores, and the immunological markers CD8, FoxP3, classical HLA class 1 and HLA-G which were described earlier (Engels et al, Breast Cancer Treat Res, 2015).

In total, 6120 patients were eligible for the current analysis, 3075 patients with exemestane monotherapy and 3045 patients randomized to sequential treatment. Median follow up was 9.83 years. DFS was 66.8% in the exemestane group and 66.8% in the sequential group (hazard ratio (HR) 0.96, 95% CI 0.88-1.05, p=0.389). OS was 74% in the exemestane, and 73% in the sequential group, respectively (HR 0.98, 95% CI 0.89-1.09, p=0.737). The cumulative incidence of relapse was 20% and 22% in the exemestane and sequential groups, respectively (HR 0.88, 95% CI 0.79-0.99, p=0.031).

In the explorative per protocol analysis (n=4041), Allred score were available for 2996 patients; immunological markers for 1754 patients. Patients with above median numbers of FoxP3-positive T-cells showed a benefit of exemestane monotherapy for RFS (HR 0.56, 95% CI 0.42-0.75, p<0.001) in contrast to patients with low numbers of FoxP3-positive cells (HR 1.0, 95% CI 0.77-1.32, p=0.97, p-value for interaction 0.004). A high tumor differentiation grade was associated with more benefit for exemestane monotherapy (grade 1/2 HR 0.78, 95% CI 0.65-0.94, p=0.01, grade 3/4 HR 0.61, 95% CI 0.49-0.75, p<0.001), with a borderline significant interaction (p=0.07). ER Allred score showed a borderline significant treatment by marker effect interaction (ER-rich HR 0.69 (95% CI 0.58-0.81, p<0.001); ER-poor HR 0.94 (95% CI 0.65-1.34, p=0.71, p for interaction 0.12).

After ten years of follow up, both exemestane monotherapy and sequential therapy remain appropriate options for postmenopausal HR+ early breast cancer patients. Interestingly, the number of regulatory T-cells was a predictive factor for the benefit of exemestane monotherapy, which implies a role of the local immune system in endocrine therapy. Furthermore, data suggested that patients with a higher differentiation grade or ER-rich tumor derive more benefit from exemestane monotherapy.
Body: Background: Somatic mutations in \textit{ERBB2} are a new class of oncogenic drivers in HER2–non amplified MBC. Neratinib is an irreversible pan-HER tyrosine kinase inhibitor that inhibits the growth of \textit{ERBB2}-mutant breast tumors in preclinical models and has encouraging single-agent clinical activity in patients (pts) with \textit{ERBB2}-mutant, HER2–non amplified MBC. Bi-directional signaling between HER2 and ER may limit the effectiveness of endocrine and HER2 directed therapy, if each is given alone, in ER+ MBC with \textit{ERBB2} amplifications/mutations. Preclinical data suggest that dual blockade of ER and HER2 signaling results in enhanced anti-tumor activity in ER+ HER2+ MBC. SUMMIT, a multicenter multi-histology phase II 'basket' trial, is investigating the efficacy of neratinib monotherapy (in ER+ and ER– pts) and neratinib + fulvestrant (ER+ pts only) in \textit{ERBB2}-mutant MBC. 

Methods: MBC pts with \textit{ERBB2} mutations documented by local testing were eligible and received oral neratinib 240 mg qd. Pts with ER+ MBC received fulvestrant 500 mg, a selective ER degrader, in addition to neratinib on d1 & 15 of month 1 then on d1 q4w. Patients received high dose loperamide prophylaxis during cycle 1. Primary endpoint is objective response rate (ORR) at 8w, defined using RECIST 1.1 and/or modified PERCIST assessments. Secondary endpoints include ORR, clinical benefit rate (CBR), progression free survival (PFS), and safety. Mutation profiling and central confirmation of \textit{ERBB2} mutation(s) from available fresh or archival tumor tissues and plasma DNA were performed retrospectively by next-generation sequencing (MSK-IMPACT). Clinicaltrials.gov: NCT01953926.

Results: As of 23 Sep 2016, 35 efficacy-evaluable \textit{ERBB2}-mutant MBC pts received neratinib, either as monotherapy (n=24) or in combination with fulvestrant (n=11). Efficacy findings are shown in the table.

CR, complete response; PR, partial response.
\textsuperscript{a}There was 1 pt with PR at week 16; \textsuperscript{b}At time of data cut-off 4 pts are still on treatment.
The overall safety profile of neratinib + fulvestrant was similar to that previously reported with neratinib monotherapy. Grade 3 diarrhea rate was 24% with neratinib monotherapy and 18% with neratinib + fulvestrant.

**Conclusions:** Encouraging clinical activity has been observed with neratinib + fulvestrant in heavily pretreated pts with ERBB2-mutant, ER+ MBC. Clinical efficacy in the ER+ MBC cohort met pre-specified efficacy requirements; a confirmatory trial of neratinib + fulvestrant for targeting ERBB2 mutations in ER+ MBC is warranted. The safety profile of neratinib was acceptable and diarrhea was manageable with loperamide prophylaxis.
Title: Abstract Withdrawn
Title: The predictive value of sentinel node biopsy (SNB) in early breast cancer after neo-adjuvant chemotherapy (NACT): A prospective study

Body: Background

SNB has replaced axillary lymph node dissection (ALND) in those patients (pts) with clinically node negative axilla. This has reduced the morbidity, in particular lymphedema considerably. SLN after NACT is feasible but not accurate in clinically node positive (cN1-3) pts (false negative rate around 10%). Therefore, continuous efforts have to been made in randomized prospective studies to improve the detection rate of SNB in order to avoid the morbidity of ALND. The purpose of this study is to determine the negative predictive value of the sentinel node in breast cancer after NACT.

Method

A single institution prospective study regarding the negative predictive value of the sentinel node in breast cancer after NACT was conducted in the Multidisciplinary Breast Clinic of the Antwerp University Hospital from 29/03/2010 until 12-2015 (Study number: B30020108368). Inclusion criteria for study participation were: breast cancer, age above 18 years, female, tumor stages T2-T4 N0-3 or T1N1-N3. All pts were staged by a mammography, ultrasound of the axilla, MRI of the breast, 18F-fluoro-2-deoxy-glucose\(^\text{18F-FDG}\) positron emission tomography (PET-CT) scan and bone scintigraphy. They received NACT consisting of 12 cycles of Paclitaxel or 4 cycles of Docetaxel followed by dose dense doxorubicin or epirubicin/cyclofosfamide or vice versa as a standard initial treatment. After 6 weeks a \(^{18}\text{F-FDG}\) PET-CT scan was performed for early tumor response evaluation. At the day of operation, all the pts had a preoperative injecting with a 99mTC-labelled nanocolloid in the peri-areolar region. A gamma detector was used to localize the SLN(s). All SLN(s) were removed and a complete ALND was performed.

Results

A total of 150 pts were enrolled in our study of which 129 were eligible for analysis. 53 pts had a positive SLN of which 32 have a positive axillary lymph nodes (ALN) (PPV 60%); 76 pts has a negative SLN of which 6 had a positive ALN (NPV 92%). The sensitivity is 84% and the specificity 76% with a false omission rate (FOR) of 8%. 45 pts had an initial clinical N0 (cN0 is defined as clinical negative and no suspect lymph nodes on ultrasound, on MRI breast and \(^{18}\text{F-FDG-PET CT}\) scan). 45 pts had negative SLN, with no ALN and 2 pts had a positive SNL of which 1 pts had axillary involvement (NPV 100%). The FOR of cN1: 5%, cN2: 37%, cN3 33%. A total of 22 pts out of 84 pts (26%) of which 15/49 cN1 (30%), 6/23 (26%) cN2, 1/12 (8%) have after 6 weeks of chemotherapy, \(^{18}\text{F-FDG}\) normalization on \(^{18}\text{F-FDG PET-CT}\) scan. A total of 17 pts had a negative SLN and ALN. The FOR was 0%

Conclusion

SNB after NACT in case of cN0 is very reliable with high NPV and low FOR. In case of \(^{18}\text{F-FDG-PET CT}\) normalization after 6 weeks of chemotherapy and a negative SLN, no ALND has to be performed.
Title: What to do with non-visualized sentinel nodes; to dissect or not to dissect the axilla?

Verheuvel NC C, Voogd AC C, Tjan-Heijnen VCG CG and Roumen RMH MH. Máxima Medical Center, Veldhoven, Netherlands; School for Oncology and Developmental Biology (GROW) Maastricht University Medical Center, Maastricht, Netherlands; School for Oncology and Developmental Biology (GROW) Maastricht University Medical Center, Maastricht, Netherlands and Netherlands Comprehensive Cancer Organisation (IKNL), Utrecht, Netherlands.

Body: Background Both in the literature and in international guidelines evidence is scarce on clinicopathological characteristics and axillary treatment recommendations in patients with a non-visualized sentinel node (nvSN) during the sentinel lymph node (SLN) procedure. Therefore, this study aims to evaluate the prevalence of nvSN in a Dutch population of breast cancer patients and to compare their characteristics and prognosis with patients in whom the SLN could be visualized. Moreover, we have distributed a questionnaire among certified oncological surgeons in the Netherlands in order to determine their routine regarding the axillary treatment after a nvSN.

Methods A retrospective population based study was performed including patients diagnosed with invasive breast cancer in the Netherlands between January 2000 and December 2013. Patients were included if they had no clinically palpable lymphadenopathy (cN0) or clinically apparent metastases (cM0). Patients receiving neo-adjuvant systemic treatment, patients with palpable axillary nodes and patients who did not undergo a SLN procedure were excluded. Also, a questionnaire containing 10 questions regarding clinical routine during the sentinel node procedure and axillary treatment of nvSN patients was distributed among 150 oncological (breast) surgeons.

Results Of the 101,289 patients who fulfilled the inclusion criteria, 2545 (2.5%) had a nvSN. Univariate and multivariate analyses show that patients with a nvSN were older (p<0.001), were more often diagnosed in the years 2000-2005 (p<0.001), had a larger tumor (p=0.003) with more often a mastectomy (p=0.02) and were more likely to have ≥3 positive lymph nodes (p<0.001) compared to patients in whom the SLN could be visualized. However, adjusted survival analyses showed a borderline not-significant survival difference between these groups (HR=1.23, 95%CI=0.99-1.28). Of the 2545 patients with a nvSN, 2127 (84%) patients underwent an axillary lymph node dissection (ALND). Multivariate analyses show that patients receiving an ALND were more often diagnosed in the years 2000-2005, had a larger tumor and more often received adjuvant systemic therapy with both hormonal and chemotherapy. Adjusted survival analyses showed no statistically significant association between ALND and survival (HR=0.89, 95%CI=0.92-1.27).

The questionnaire was completed by 122 (24%) oncological (breast) surgeons. It showed that 39% of the respondents estimated the prevalence of a nvSN to be 1-2%. Most surgeons are currently more reserved to perform an ALND than before the Z0011 trial, depending on various clinicopathological characteristics; 23 respondents answered to opt for an alternative axillary treatment option.

Conclusion NvSN patients had worse disease characteristics compared to patients in whom the sentinel node could be visualized, though an ALND was not associated with a better survival. The results of the questionnaire show that surgeons are more reluctant to perform an ALND in case of a nvSN, especially after publication of the Z0011 trial, and that they would like the guideline to be revised and clarified regarding the axillary treatment in case of a nvSN.
Title: Use of axillary ultrasound impacts outcome of node positive breast cancer patients

Verheuvel NC C, Voogd AC C, Tjan-Heijnen VCG CG and Roumen RMH MH. Máxima Medical Center, Veldhoven, Netherlands; School for Oncology and Developmental Biology (GROW) Maastricht University Medical Center, Maastricht, Netherlands; School for Oncology and Developmental Biology (GROW) Maastricht University Medical Center, Maastricht, Netherlands and Netherlands Comprehensive Cancer Organisation (IKNL), Utrecht, Netherlands.

Body: Background The Z0011 trial initiated a paradigm shift in the treatment of axillary node positive breast cancer patients. Treatment strategy, however, starts with the information gathered by the diagnostic axillary work up. This can either be done by sentinel lymph node biopsy (SLNB) or ultrasound guided lymph node biopsy (UGLN). We examined whether there are relevant clinical and prognostic differences between patients found node positive by these two diagnostic selection processes.

Methods Patients diagnosed with invasive breast cancer in the Netherlands between January 2000 and December 2013 were studied. Patients with no clinically palpable lymphadenopathy (cN0) and node-positive disease after an axillary lymph node dissection (ALND) were included. Patients with stage IV breast cancer, with clinical stage T3-T4 breast tumor according to the TNM-classification, those treated within the neo-adjuvant setting, patients with palpable axillary nodes (cN≥1) and patients who did not undergo an ALND were excluded.

Results A total of 14,730 patients fulfilled the inclusion criteria, of whom 9,448 were included in the SLNB group and 5,282 in the UGLNB group. Patients in the UGLNB group were older at diagnosis (p<0.001), had larger tumors (p<0.001), a higher tumor grade (p=0.001), and were more likely to have a negative hormonal receptor status (p<0.001) and to undergo a mastectomy (p<0.001). Patients in the UGLNB group were also more likely to have ≥3 positive axillary lymph nodes (p<0.001) and, after adjustment for these differences, had a worse overall survival (HR=1.64; 95% CI=1.53-1.75) compared to the node-positive patients in the SLNB group.

Conclusion Our multicenter study shows that patients with a positive UGLNB have less favorable disease characteristics and a worse prognosis compared to patients with a positive SLNB. The diagnostic selection process plays an important role when axillary treatment strategies are considered. Therefore, we conclude that the conclusions of the Z0011 trial cannot (yet) be applied to patients with a positive UGLNB.

**Title:** A phase II clinical trial of VST-1001 (dilute fluorescein) in lymphatic mapping and sentinel lymph node localization in clinically node negative breast cancer

Ross MI, Black DM, Mittendorf EA, Porretta JM, Bedrosian I, Caudle AS, Hwang RF, Meric-Bernstam F, Babiera GV, Brulotte M, Andtbacka RHI and Matsen CB. University of Texas MD Anderson Cancer Center, Houston, TX; Huntsman Cancer Institute, University of Utah, Salt Lake City, UT and Vestan Inc., Salt Lake City, UT.

**Body:**

**Background:** Combined use of a radiocolloid and a vital blue dye is recommended for accurate lymphatic mapping and sentinel lymph node (SLN) identification in breast cancer. However, vital blue dyes can cause tattooing, skin necrosis and severe allergic reactions. Moreover, the vital blue dyes are only able to detect 70% or less of SLNs in large multi-center trials. Hence, there is an unmet need to develop new lymphatic mapping agents that could potentially replace vital blue dyes. We have previously, in a Phase I trial, reported on the safety of VST-1001 (dilute fluorescein) in SLN identification. Here we report the Phase II data of VST-1001 and direct visualization devices in lymphatic mapping, SLN identification, and safety in clinically node negative breast cancer.

**Methods:** This prospective Phase II, multi-center, non-randomized, single-arm, open-label, single-dose clinical trial enrolled patients (pts) with DCIS and clinical stage I/II breast cancer eligible for SLN biopsy. All pts had SLN localization with technetium-99m-sulfur colloid (Tc$^{99m}$SC) and intraoperative lymphatic mapping with 0.1% VST-1001 injected peritumorally, periareolarly, and/or intradermally. SLN radioactivity was identified with a gamma probe, and VST-1001 fluorescence was induced by light emitting diodes and detected as yellowish-green fluorescence in the visible light range with notch filter spectacles. The primary endpoint was the ability of VST-1001 to localize lymph nodes. SLN concordance of Tc$^{99m}$SC radioactivity and VST-1001 fluorescence, and safety were also assessed.

**Results:** Eighty-seven women and 2 men with a median age of 60 yrs (range, 37-77) were enrolled. Primary tumor T-stage was: 12.4% T0, 62.9% T1, 23.6% T2, and 1.1% T3. Of the 89 pts, 87 (97.8%) had at least 1 radioactive SLN, and 86 (96.6%) at least 1 fluorescent SLN. Of a total of 198 SLN identified (mean 2.2 SLN/pt), 74.2% were fluorescent and radioactive, 11.6% were radioactive only, 8.6% were fluorescent only, and 5.1% were not radioactive or fluorescent. 82.8% of all SLNs were fluorescent. Twelve (13.5%) pts had microscopic metastatic breast cancer in 14 (7.1%) SLNs. The fluorescent only SLN was identified in a patient with only 1 SLN and without VST-1001 the metastasis would have been missed. The only adverse event related to VST-1001 was intraoperative grade 2 allergic reaction of the ipsilateral breast in one pt. Intravenous anti-histamines were administered and the erythema resolved.

**Conclusions:** VST-1001 safely localized lymph nodes in breast cancer. VST-1001 was able to localize lymph nodes that were not radioactive and had a high co-localization concordance with Tc$^{99m}$SC. VST-1001 also appears to have a higher rate of SLN localization compared to that historically reported for vital blue dyes. In light of these data, VST-1001 may be an alternative SLN localizing agent to be used in conjunction with Tc$^{99m}$SC in breast cancer pts, eliminating many of adverse events observed when using vital blue dyes without compromising SLN identification.
Title: Patterns of axillary evaluation in older patients (pts) with breast cancer and impact on adjuvant therapy

Body: Background:
Axillary lymph node status has traditionally been a key factor in informing adjuvant therapy recommendations for pts with breast cancer. With increased emphasis on tumor biology, this information may be less relevant, particularly in older populations where competing comorbidity frequently influences treatment decisions. We examined patterns of axillary surgery in older breast cancer pts and the impact axillary surgery has on treatment receipt.

Methods:
We identified women aged ≥65 with Stage I-III invasive breast cancer diagnosed during 2012-2013 from the National Cancer Data Base who did not have clinically positive nodes and underwent cancer-directed surgery. Nodal surgery type and receipt of adjuvant therapies were examined. Multivariable logistic regression was used to examine the associations of axillary surgery receipt with pt, clinical and facility factors.

Results:
Among 69,414 eligible women, 40% were aged 65-70, 42% aged 71-80 and 18% aged >80. 91% had axillary surgery (67% sentinel lymph node biopsy, 11% axillary lymph node dissection, 13% unspecified axillary surgery), and 24% of pts had pathologically positive nodes. 10% of pts (stage IIB-III) received adjuvant chemotherapy, 81% (hormone receptor positive) received adjuvant hormonal therapy, 67% (breast conservation or stage III postmastectomy) received radiation. In adjusted analyses, increasing age and neoadjuvant hormonal therapy were strongly associated with lower odds of axillary surgery. Region and mastectomy were strongly associated with higher odds of axillary surgery. The table shows variables associated with axillary surgery.

*Adjusted for table variables plus race, hormone receptor status, and facility type (none significantly associated with axillary surgery)

Axillary surgery and younger age were significantly associated with receipt of adjuvant chemotherapy, radiation, and hormonal therapy.

Conclusion:
Within the NCDB, 91% of pts age ≥65 with clinically node-negative breast cancer undergo surgical staging of the axilla, and axillary surgery was associated with adjuvant therapy receipt. The impact of routine node assessment on treatment and outcome has been questioned, and further study in this population of pts is warranted.
Title: Selective elimination of axillary surgery after primary systemic treatment in clinically node-positive breast cancer patients by combining PET/CT and the MARI procedure (marking the axilla with radioactive iodine seeds)

van der Noordaa MEM EM, Straver M, van Duijnhoven FH H, Groen E, Stokkel M and Vrancken Peeters M-J. Antoni van Leeuwenhoek Hospital / Netherlands Cancer Institute, Amsterdam, Netherlands and University Medical Center Utrecht, Netherlands.

Body: Background The increasing use of primary systemic treatment (PST) for patients with breast cancer enables more breast conserving surgery. In addition, PST converts node-positive into node-negative disease in 20-40% of patients. However, the current guidelines still recommend axillary lymph node dissection (ALND) for clinical node-positive disease (cN+), even if it became node-negative after PST, since false-negative rates of sentinel lymph node biopsy after PST range from 5-30%. Recently, an alternative technique has been introduced to stage the axilla after PST: the MARI-procedure (sensitivity 97%; FNR 7%), in which a tumour-positive lymph node is marked with a radioactive iodine seed before the start of PST and selectively removed after PST. In the present study, we propose a new strategy for treatment of the axilla in cN+ patients by combining results of the pre-PST PET/CT with the post-PST MARI-procedure.

Material and methods All patients who received a MARI-procedure from July 2014 until May 2016 were included. Before the start of PST a PET/CT was performed for axillary staging and the detection of distant metastasis. A radioactive iodine seed was placed in a proven tumour-positive axillary lymph node (MARI-node), after which PST was given according to Dutch national guidelines. At our institute, we have implemented a protocol in which results of the pre-PST PET/CT and the post-PST MARI-procedure determine the type of axillary treatment. Patients with 1-3 positive axillary lymph nodes (ALNs) on PET/CT and a tumour-negative MARI-node receive no further axillary treatment. Patients with ≤3 positive ALNs on PET/CT and a tumour-positive MARI-node receive axillary radiotherapy, as well as patients with >3 positive ALNs on PET/CT and a tumour-negative MARI-node. An ALND is only performed in patients with >3 positive ALNs on PET/CT and a tumour-positive MARI-node.

Results In total 168 patients received a PET/CT and a MARI procedure, of whom 43% were hormone receptor positive, 28% triple negative and 29% Her2-positive. One hundred and eight patients (64%) showed ≤3 and 60 patients (36%) >3 suspected ALNs on PET/CT before the start of PST. The axillary pathologic complete response was 39%. In 134 patients (80%) an ALND was omitted; of these patients 94 (56%) were treated with axillary radiotherapy and 40 patients (24%) received no further axillary treatment. In 34 patients (20%) an ALND was performed (Table 1). The median number of positive additional nodes at ALND was 5 (range 0-16). During a median follow-up of 6 months there were no local recurrences.

ALN: axillary lymph nodes; ALND: axillary lymph node dissection; MARI: Marking the Axilla with Radioactive Iodine Seeds

Conclusion Combining pre-PST axillary staging with PET/CT and post-PST staging with use of the MARI-procedure results in a reduction of 80% of axillary lymph node dissections in breast cancer patients with clinical node-positive disease.
Title: A nomogram to predict the survival benefit of surgical axillary staging in T1 breast cancer patients

Chen K, Zhu L, Li S, Su F and Song E. Breast Tumor Center, Sun Yat-sen Memorial Hospital, Sun Yat-sen University, Guangzhou, Guangdong, China.

Body: Purpose:
Whether axillary staging (AS) surgery can be spared in selected breast cancer patients is unknown. The European Institute of Oncology of Milan initiated the SOUND trial[9] (Sentinel node vs. Observation after axillary UltraSouND) and randomized T1 breast cancer patients with clinically negative axilla into SLNB vs. observation. Amy Cyret al. initiated a similar study (NCT01821768) and recently started to recruit patients in the United States. Consistent with the rational of these two studies, we hypothesize that surgical axillary staging (AS), whether by SLNB and/or ALND, may not be associated with improved clinical outcomes in selected patients with a small tumor (T1). This retrospective cohort study developed a nomogram to predict the cancer-specific survival (CSS) of T1 breast cancer patients with and without AS and estimate the survival benefit of AS in these patients.

Method:
We used surveillance, epidemiology and end results (SEER) data to identify 232,195 breast cancer patients with T1 tumors diagnosed between 1990 and 2008. Patients with zero and 1 to 89 axillary lymph nodes examined were classified as the non-AS and AS groups, respectively. Patients who were diagnosed in even (1990,1992, etc) and odd (1991, 1993, etc) years were used as training and validation cohort, respectively. In the training cohort, we used the Kaplan-Meier method and competing risk analysis to screen for prognostic factors for CSS. A nomogram to predict the CSS, with receiving AS or not as one of the predictors, was developed and validated internally and externally, using the C-index and calibration plots. The survival benefit of AS for a specific patient can be estimated by the difference of two predicted CSS, when the patient were considered as having and not having AS.

Results:
With a median follow-up of 109 months, the CSS of the study population were 96.3%, 92.3% and 88.5% at 5, 10 and 15 years, respectively. In the training cohort, we used competing risk analysis, with non-CSS as the competing risk, to show that age, marital status, race, T-stage, N-stage, histology, grade, ER, PR, AS, breast surgery (breast conservation / mastectomy) and radiotherapy were significantly associated with CSS. A nomogram was developed based on these predictors and validated internally (C-index=0.707, 95% CI 0.702-0.712) and externally (C-index=0.704, 95% CI 0.698-0.710). The nomogram was well calibrated. With this nomogram, AS was predicted to have less than 2% benefit of 5yr-, 10yr- and 15yr-CSS in 60.6%(140599/232195), 15.5%(36074/232195) and 8.6%(20043/232195) of the entire study population, respectively.

Discussions and Conclusions:
The SOUND trial set the non-inferiority margin of 2.5% for 5-year DDFS when comparing the SLNB group with the observation group. In our study, the internally and externally validated nomogram predicted that 60.6% of the T1 patients may have less than 2% benefit of 5yr-CSS. We suggested that this nomogram may aid in individualized surgical decision-making by providing the predicted benefit of AS in T1 breast cancer patients.

**Title:** The development of nomograms to predict axillary lymph node status in breast cancer patients

Chen K, Liu J, Zhu L, Song E, Su F and Jacobs L. Sun Yat-sen Memorial Hospital, Sun Yat-sen University, Guangzhou, China and Johns Hopkins Hospital, Johns Hopkins University, Baltimore.

**Body:** Purpose: Prediction of the axillary lymph node (ALN) status preoperatively is critical in the management of breast cancer patients. Several predictive models (MSKCC, Paris and Shanghai model) of ALN status were developed to predict the probability of having $\geq 1$ ALNs(+) (N1 or above). However, none of them can predict the probability of having $\geq 3$ or $\geq 4$ ALNs(+). This study aims to develop a new set of nomograms to accurately predict the probability of having $\geq 1$, $\geq 3$ and $\geq 4$ ALNs(+).

Methods: We searched the National Cancer Database to identify eligible female breast cancer patients with profiles containing critical information. Patients diagnosed in 2010-2011 and 2012-2013 were designated as the training and validation cohort, respectively. In the training cohort, we used logistic regression to investigate risk factors for positive ALNs. A new set of nomograms, based on these risk factors, was developed to predict the probability of having $\geq 1$, $\geq 3$ and $\geq 4$ ALNs(+). In the validation cohort, we used ROC analysis with bootstrap correction and calibration plots to assess the discriminative ability and accuracy of the nomograms, respectively, and compared them with previously reported nomograms.

Results: In the training cohort (n=102,454), we identified age, locations of lesions, ethnicity, T-stage, histology, presence of mixed histology, HER2, grade and LVI as significant risk factors for $\geq 1$ ALNs(+), $\geq 3$ ALNs(+) and $\geq 4$ ALNs(+). ER and PR status were significant risk factors for $\geq 1$ ALNs(+), but not for $\geq 3$ ALNs(+) or $\geq 4$ ALNs(+). Based on these risk factors, we developed a set of three nomograms that were predictive of the probability of $\geq 1$ (Nomogram-A), $\geq 3$ (Nomogram-B) and $\geq 4$ (Nomogram-C) ALNs(+).

In the validation cohort (n=104,199), the AUC values of the Nomogram-A, -B and -C were 0.802 (95% CI 0.799-0.805), 0.855 (95% CI 0.851-0.859) and 0.865 (95% CI 0.860-0.869), respectively. The average estimation errors between actual and predicted probabilities were 1.45%, 0.96% and 0.72% for NomogramA, B and C, respectively. The AUC values of the MSKCC, Paris and Shanghai nomograms were 0.791 (95% CI 0.788-0.794), 0.781 (95% CI 0.778-0.784) and 0.769 (95% CI 0.766-0.773), respectively. The MSKCC, Paris and Shanghai nomograms exhibited a slightly worse calibration, with an average estimation error of 7.05%, 1.28% and 1.86%, respectively.

Conclusion: We developed a set of nomograms to predict the probability of having $\geq 1$, $\geq 3$ and $\geq 4$ ALNs(+) in early stage breast cancer patients. Nomogram-A performed slightly better than MSKCC, Paris and Shanghai model, regarding the discriminative ability and prediction accuracy. Nomogram-B and C has been demonstrated to be discriminative and accurate. We believed this set of nomogram can be informative for clinical decision making for early stage breast cancer patients.
Title: Cumulative analysis of breast cancer sentinel lymph node identification rate by radioisotope: A 13-year experience

Body:
Purpose: To investigate the breast cancer sentinel lymph node (SLN) identification rate by radioisotope navigation over the past 13 years at a single cancer centre institution.

Method: Retrospective, breast cancer sentinel lymph node data in the past 13 years was collected. Between May 2002 to August 2008, sulphur colloid was the radioisotope agent used at the institution. Between August 2008 to August 2012, the radioisotope agent was switched to phytate. Then, between September 2012 to June 2015, injection method of phytate was switched from subdermal to intradermal. The SLN identification rate from each three periods were compared and analysed.

Results: In a 13-year period (May 2002~June 2015), a total of 5455 breast cancer axillary sentinel lymph node samples were collected. Each surgeon's first 50 cases were excluded, thus a reduction to 5105 samples were derived. 155 cases were bilateral. Out of the 5105 samples, 40 did not undergo radioisotope mapping.

During the 13-year period, total successful SLN identification rate was 96.7%(4897/5065). During the sulphur colloid period (May 2002~August 2008), successful SLN identification rate was 99.1%(996/1005). During the subdermal phytate period (August 2008~August 2012), successful SLN identification rate was 95.1%(2200/2313). During the intradermal phytate period (September 2012~June 2015), successful SLN identification rate was 97.4%(1701/1747).

After injection of radioisotope agent, lymphatic scan mapping may fail. However, radioisotope signals may still be detected by radioisotope navigator intra-operatively. During the sulphur colloid period (May 2002~August 2008), mapping failure rate was 5.2%(52/1005). SLN identification rate by intra-operative navigator after scan mapping failure was 96.1%(50/52). During the subdermal phytate period (August 2008~August 2012), mapping failure rate was 21.7%(501/2313). SLN identification rate by intra-operative navigator after scan mapping failure was 79.0%(396/501). During the intradermal phytate period (September 2012~June 2015), mapping failure rate was 12.8%(223/1747). SLN identification rate by intra-operative navigator after scan mapping failure was 83.4%(186/223).

Conclusion: Different radioisotope agent may affect the identification rate of axillary sentinel lymph nodes in breast cancer patients. Change of injection method, such as from subdermal to intradermal, may improve identification rate in use of same radioisotope agent. Even when lymphatics scan mapping failed, intra-operative radioisotope navigator may still successfully identify axillary sentinel lymph nodes and avoid unnecessary dissection due to mapping failure.
**Title:** SentimagIC: A non-inferiority trial comparing super paramagnetic iron oxide vs. Tc99 and blue dye in the detection of axillary sentinel nodes in patients with early stage breast cancer

Alvarado M, Bold R, Gittleman M, Beitsch P, Blair S, Harmer Q, Kivilaid K, Teshome M, Thompson A, Mittendorf E and Hunt K. University of California San Francisco, San Francisco, CA; University of California Davis; BreastCare Specialists Allentown; Dallas Surgical Group; University California San Diego; Endomagnetics; RCRI and University of Texas MD Anderson.

**Body:** Background: Sentinel lymph node biopsy (SLNB), performed using radioisotope tracer with or without blue dye, is a highly accurate method for staging the axilla in early breast cancer. A radioisotope tracer with or without blue dye is the most commonly used technique for SLNB. Superparamagnetic iron oxide mapping agents detected by a handheld magnetic probe have been explored to overcome the disadvantages of the standard technique which include the short half-life, availability, handling and disposal issues for radioisotope, and the risk of allergic reactions to blue dye. Iron oxide mapping agents have been shown to be non-inferior to the standard technique in European studies. The SentimagIC trial was designed to establish the non-inferiority of a new formulation of the magnetic tracer, SiennaXP, to the combination of radioisotope and blue dye and was required to support a US regulatory submission.

Methods: Between January and December 2015, 160 patients with clinically node negative early stage breast cancer were recruited from six centers in the United States. Subjects received radioisotope injection then an intraoperative subareolar injection of SiennaXP and isosulfan blue dye prior to SLNB being performed. The sentinel node identification rate was compared between SiennaXP and the standard technique to evaluate concordance and non-inferiority.

Results: 147 procedures were completed in 147 subjects. A total of 369 histologically confirmed nodes were excised. The nodal detection rate was 94.3% (348/369) with SiennaXP and 93.5% (345/369) with the standard technique (difference 0.8%, 95% binomial confidence interval lower bound -2.1%). The per-subject detection rate was 99.3% (145/146) with SiennaXP and 98.6% (144/146) with the standard technique (one subject excluded due to not contributing any analyzable nodes). There were 22 subjects with positive SLNs, of whom 21 (95.4%) were detected by both SiennaXP and the standard tracers. In one subject, a positive node was not identified by any tracer, but was removed as clinically suspicious. The number of nodes excised per subject was 2.4 for both SiennaXP and for the standard combined technique.

Conclusion: This study showed SiennaXP is non-inferior to the standard dual technique of radioisotope and blue dye for axillary sentinel lymph node detection in early stage breast cancer and this provides a potential alternative to radioisotope and blue dye.

Title: Development of prediction model for omission of sentinel lymph node biopsy in T1 breast cancer

Body: INTRODUCTION
Axillary sentinel lymph node (SLN) biopsy is a standard method for axillary nodal staging in the treatment of breast cancer. However, along with the trends to SLN performed only without additional axillary lymph node dissection, it's time to be considered omission of SLN for selective patients. We developed a prediction model to assess the negative probability of sentinel lymph node metastasis, specifically focus on the patients with clinical T1 breast cancer.

METHODS and MATERIALS
The study group consisted of 513 consecutive patients with clinical T1 breast cancer, who had undergone primary surgery between 2007 and 2012. The clinicopathologic factors and imaging modalities including breast ultrasound (US), magnetic resonance imaging (MRI), chest computed tomography (CT), and positron emission tomography (PET) were evaluated. Patients who fulfilled our inclusion criteria were randomized into experimental and validation set by 3:1 ratio. In the experimental group (n = 256), multivariate logistic regression analysis was used to analyze the association of each variable with the likelihood of SLN metastases. A prediction model was developed based on the patients in the experimental group and was validated with internal patient cohorts.

RESULTS
Of the 513 patients, 119 (23.1%) were found to have SLN metastases. In univariate analysis, presence of lymphovascular invasion (P < 0.001) and suspicious finding of preoperative image studies (US, PET, and MRI, P < 0.001) were independent positive predictors of SLN metastases. In multivariate analysis of experimental group, estrogen receptor status (P = 0.012), presence of lymphatic invasion (P < 0.001), and suspicious finding of preoperative image studies (US, PET, and MRI, P < 0.001) were each associated with involvement of SLN. A prediction model based on this analysis consists of 9 rows including 6 variables (age, estrogen receptor status, presence of lymphatic invasion, and results of preoperative US, PET or CT, MRI). The sum of assigned points for all six variables made corresponding value of negative probability of SLN metastasis. The accuracy of prediction model applied to the validation group, as measured by the area under the receiver operating curve was 0.789.

CONCLUSIONS
The prediction model developed here may be a useful tool to assess SLN involvement for clinical T1 breast cancer patients. And prospective study for additional validation of the prediction model is currently in preparation, exploring the possibility of SLN biopsy omission.
Title: Can axillary lymph node clearance be avoided in women with node positive breast cancer receiving primary chemotherapy?

Body: Background
For patients who receive primary chemotherapy for their early breast cancer the current practice for lymph node positive (LN) disease at presentation is in transition, with a drive towards sentinel LN biopsy (SLNB) rather than axillary node clearance (ANC) for patients who achieve a good response to primary chemotherapy. Boileau et al initially reported that approximately 30% of patients could potentially avoid clearance, but with a recommendation for further evaluation before including SLNB in guidelines for biopsy proven node-positive disease prior to primary chemotherapy for early breast cancer.

Methods
This was a retrospective single centre study. Examining the records of all patients who had received primary chemotherapy between January 2010 and October 2014.
Patients were identified through the Guy’s Breast Cancer Database and chemotherapy prescribing system. To fully assess the LN status, all patients were cross-referenced with the electronic notes on our electronic noting system (MOSAIQ), radiology on Patient Archiving and Communication System (PACS) and histology on our Electronic Patient Record (EPR).

Results:
1526 patients were identified, of whom 156 underwent primary chemotherapy. 111 patients had suspicious nodes on imaging (ultrasound and/or MRI) and underwent LN biopsy. 69 patients had positive nodes pre-chemotherapy. 28 of these 69 patients (40.6%) had negative nodes at ANC, of these 14 (50%) had complete pathological complete response (pCR) in their primary tumour(s) of whom 12 (86%) had radiological CR prior to surgery. Of the 41 who remained positive only three achieved pCR of their primary tumour after chemotherapy.
22 patients were LN positive post primary chemotherapy, despite having been identified as initially LN negative. Of these 9 had a negative pre chemotherapy biopsy, and only 1 of these 22 patients had a pCR.

Discussion:
We have confirmed that ANC may be avoided in selected patients with LN involvement at presentation. In our series over 40% could have had SLNB instead. Factors supporting this approach include those patients who have an excellent radiological response to primary chemotherapy. Conversely, 22 of 87 (25%) had positive LN after chemotherapy having been initially thought to be LN negative at presentation, highlighting the possible need for multiple nodal sampling prior to chemotherapy as well as further nodal assessment after chemotherapy for complete staging.
Title: Lymphatic microsurgical preventive healing approach (LYMPHA) for the primary prevention of lymphedema

Body: Background/Objective
The incidence of breast cancer related lymphedema is as high as 40% in patients undergoing axillary lymph node dissection (ALND) and radiation. We report our experience performing lymphatic-venous anastomoses (LVA) using Lymphatic Microsurgical Preventive Healing Approach (LYMPHA) at the time of axillary node dissection performed in patients at highest risk for developing lymphedema. This preventative microsurgical procedure was first described by Boccardo, Campisi et al in 2009.

Methods
Female patients with node positive breast cancer requiring ALND were offered LYMPHA beginning January 2013. Exclusion criteria included allergy to lymphazurin blue dye, pregnancy and pre-existing lymphedema. Immediately following ALND a LVA was performed with optical magnification. Axillary reverse mapping (ARM) using blue dye injected in the ipsilateral upper arm allowed for the identification and preservation of afferent lymphatic vessels, 1-3 (mean 1.5) were sutured into a branch of the axillary vein distal to a competent valve. Limb volume was assessed via circumferential arm measurements and (L-Dex®) bio-impedance spectroscopy. Limb volumes and clinical exam were used to define lymphedema (LE).

Results
Over 42 months, 52 patients were consented for LYMPHA and 42 completed the LYMPHA procedure. The majority had locally advanced disease, 96% receiving chemotherapy (54% receiving neoadjuvant chemotherapy) and 63% receiving adjuvant radiation. In the 10 patients unable to undergo LYMPHA, all were early in each surgeon's experience. Among these patients, 6 had no suitable lymphatic identified, 3 had no suitable vein and one had extensive axillary disease precluding anastomosis. Of the 42 patients who successfully underwent LVA, 32 had modified radical mastectomy, and 10 patients had breast conserving therapy with ALND. Mean current follow-up is 22 months (range 2-42). 3 of the 42 LYMPHA patients (7.14%) developed clinically-apparent LE. Among the 10 patients without completed LYMPHA, persistent LE developed in 3 (30%). Two patients from each cohort had transient LE which resolved by their 6 month follow up visit. A retrospective review of our historic LE rate from 2009-2014 for patients undergoing ALND demonstrated a LE rate of 31.3%. All patients (32) who had post-operative lymphoscintigraphy demonstrated patency of their LVA. We estimate that performing LYMPHA added 30-45 minutes to operative time. No procedure-related complications were reported.

Conclusion
Data in our high-risk cohort of patients undergoing ALND shows that LYMPHA is feasible, safe, and practical method for the primary prevention of clinical lymphedema. This technique serves to significantly reduce the rate of clinical LE (7.1 vs 31.3 %) in breast cancer patients. Follow up is ongoing to evaluate the significance of transient lymphedema and bio-impedence measurement abnormalities in our patient population. As our experience grows, we anticipate that the majority of patients undergoing ALND would benefit from the LYMPHA procedure. Larger multi-institution and randomized trials are warranted to further evaluate the effectiveness of LYMPHA.

Title: Clinical application of multimodal fluorescent-radioactive system in advanced breast cancer patients with neoadjuvant therapy; interim analysis for 65 patients

Body: Purpose
This study aimed to evaluated the identification rate and operation time of sentinel lymph node biopsy (SLNB) by a multimodal fluorescent-radioactive system (MFS) using a mixture of indocyanine green (ICG), radioisotope (RI) compared with the RI alone in advanced breast cancer patients with neoadjuvant therapy.

Methods
In this phase II randomized study, we enrolled 65 patients with advanced breast cancer with neoadjuvant therapy. Then, they received SLNB with either MFS or RI. We compared the identification rate, operation time of SLNB and number of sentinel lymph nodes. We also evaluated the safety. We analyzed the data of 65 patients for interim analysis.

Results
The mean age of the MFS group and RI group was 51.7 and 45.9 years (p=0.024), respectively. There were no differences in histopathological characteristics, including tumor size, node positivity, and hormone receptor status between two groups. The radiologic study showed the clinically complete response in axillary lymph nodes after neoadjuvant therapy. In MFS group, sentinel lymph nodes (SLNs) were identified in 30 patients and we could not identify the SLNs in one patient. In RI group, we identified the SLNs in 33 patients and also could not identify them in one patient. (p=0.947). The average numbers of SLNs in the MFS and RI group were similar. (2.32±1.10 vs. 2.18 ± 1.57, respectively; p=0.668) The operation time of SLNB was similar in the each group (11.65 ± 6.49 vs. 9.47 ± 6.26, respectively, p= 0.174) There were no complication, including allergic reactions, skin staining or necrosis.

Conclusions
This study is the randomized trial that compared MFS using ICG and RI and the conventional RI method for SLNB in the advanced breast cancer with neoadjuvant therapy. The multimodal fluorescent-radioactive system is a feasible and safe method for SLNB for the breast cancer patients with neoadjuvant therapy. We will evaluate the 130 patients for final analysis.
Title: Comparison of axillary nodal status between different defined clinically node negative breast cancer: Is ACOSOG Z0011 criteria applicable to preoperative cytologically negative axilla?

Liang Y, Chen X, Zhu Y, Wu J, Huang O, Zong Y, Zhu S, Gao W, He J, Zhu L, Chen W, Li Y and Shen K. Comprehensive Breast Health Center, Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China and Rui Jin Hospital, Shanghai, China.

Body: Background Axillary ultrasound (AUS) and US-guided fine-needle aspiration (FNA) are now part of the preoperative axillary assessment. The ACOSOG Z0011 trial demonstrated axillary lymph node dissection (ALND) may be omitted in patients with T1-2 tumor, clinically negative axilla and 1-2 positive sentinel lymph nodes (SLN). But for clinically node negative patients with AUS suspicious but FNA negative axilla, whether they could receive the same surgical procedure and omit ALND referencing to Z0011 criteria as clinically node negative patients identified by AUS has not been illustrated. The purpose of this study was to evaluate potential differences in axillary lymph node (ALN) metastatic status between clinically node negative patients identified by AUS (AUS group) and FNA (FNA group). Methods Patients with T1-2 tumor and clinically negative axilla treated in Shanghai Ruijin Hospital from Jan 2013 to Dec 2015 were enrolled. ALN metastatic status were compared between AUS group and FNA group. Results A total of 1007 patients were included. Preoperative axillary status (AUS negative or FNA negative) did not differ significantly between ALN positive and ALN negative patients (p = 0.170). Similarly, ALN metastatic status (negative, 1-2 positive or ≥3 positive) did not differ significantly between AUS group and FNA group (p = 0.405).

Conclusions Patients with clinically node negative axilla identified by FNA were comparable to those identified by AUS in ALN metastatic status. Indicating that patients with preoperative FNA negative axilla could receive the same surgical procedure and
may omit ALND referencing to Z0011 criteria as preoperative AUS negative patients.

Title: The combination of preoperative computed tomography lymphography and intraoperative fluorescence imaging navigation for sentinel lymph node biopsy of early breast cancer patients

Abe H, Teramoto A, Yamasaki K, Yoneda K, Ogawa M, Kawasaki M and Kameyama M. Breast Center, Bell Land General Hospital, Sakai, Osaka, Japan and Bell Land General Hospital, Sakai, Osaka, Japan.

Body: Background: Sentinel lymph nodes (SLN) biopsy has been established as a standard of care in the treatment of early breast cancer. This technique represents a minimally invasive, highly accurate method of axillary staging and is an alternative to conventional axillary lymph node dissection. The combination of the radioisotope and dye-staining methods is the most accurate way to identify SLN. We had reported feasibility and safety of a new technique of SLN identification using fluorescence imaging of indocyanine green (ICG) injection without any need for training. Recently, SLN identification using computed tomography lymphography (CTLG) has been reported in Japan. This study investigated a usefulness of the combination of CTLG and fluorescence imaging for SLN biopsy of early breast cancer patients.

Patients and method: Between January 2013 and March 2016, 296 breast cancer patients without clinical evidence of lymph node metastasis were treated. On the day before the operation, CTLG was performed using 64-row multidetector CT. We performed an intradermal injection in the periareolar area, using 4 ml of contrast agent with 1 ml of local anesthetic. The contrasted lymph route and SLN were identified in reconstructed three-dimensional imaging. The SLN spot was indicated by CT laser light navigator system. We established typical pattern of the lymphography: stain defect of SLN, stagnation of lymphatic route for preoperative diagnosis of metastatic SLN. During the operation, fluorescence images were obtained using the fluorescence imaging system, Photodynamic Eye (pde-neo, Hamamatsu Photonics Co., Japan). After 0.5 ml dye mixed indigocarmin and ICG was injected intradermally into the periareolar skin, lymphatic route was observed with fluorescence images. SLN biopsy was performed referring to the point by axillary compression technique by plastic device. Intraoperative pathological analysis of SLN was examined.

Results: The median age of the 296 patients was 59 (range 28 – 90) years old. One patient was male and others were female. CTLG and fluorescence imaging were safely performed in all patients. CTLG could visualize lymphatic route and accurately identify SLN in 284 (95.9 %) and 290 (98.0 %) cases, respectively, whereas fluorescence imaging identified successfully lymphatic route and SLN in all patients. Lymphatic routes of CTLG were completely consistent with those of fluorescence imaging. The number of SLN identified by CTLG was significantly lower than that by fluorescence imaging (1.1 vs. 1.6, p<0.01). Thirty-nine of 296 patients had metastatic SLN pathologically, and 10 of them had micrometastases of SLNs. The accuracy for metastatic diagnosis of SLN using CTLG without micrometastasis was 83.9 %, sensitivity was 82.1 % and specificity was 84.1 %. The positive predictive value was 35.9 % and negative predictive value was 97.7 %.

Conclusion: The combination of CTLG and fluorescence imaging revealed easy and effective to detect SLN. The fluorescence imaging was more high detection rate and number of SLN than CTLG. Otherwise, preoperative diagnosis of SLN metastasis using CTLG would be useful to detect negative SLNs.
Body: Background
Axillary lymph node status remains the single most significant prognostic factor for patients with primary breast cancer. Clinical and pathologic data have been used to develop statistical models to predict the axillary nodal status; the diverse accuracy may reflect the complexity of factors related to axillary metastasis.

Artificial neural network (ANN) is a computational method proposed as a supplement to standard statistical models for predicting complex biological phenomena. ANN is composed of artificial neurons and interrelated by synaptic weights, effective in multifactorial analysis and has the ability to explore underlying nonlinear relations of interconnected variables.

The aim of this study was to create an ANN-based preoperative decision tool for prediction of nodal axillary status (N0, N+ with 1-3 positive lymph nodes and N+ with ≥ 4 positive nodes). In the clinical setting, this may contribute to improved selection of patients for no axillary staging for those predicted with disease-free axilla (N0), sentinel node biopsy for patients with predicted 1-3 nodal metastases, and axillary lymph node dissection or neoadjuvant therapy for patients displaying four or more involved axillary lymph nodes.

Methods
The cohort constituted of consecutive patients diagnosed with primary breast malignancy between January 2009 and December 2012 at Skåne University Hospital in Lund, Sweden. The exclusion criteria were palpable axillary nodes or cytology-verified axillary metastasis and neoadjuvant chemotherapy. Data on mode of detection were retrieved. Clinical parameters included age, BMI, menopausal status and the location of the tumor within the breast. A breast pathologist extracted the histopathological variables of the tumor and lymph node. The ANN consisted of 3 layers, an input layer using 1-22 separate variables, one hidden layer, and a single node output layer, with the nodal status N0, macro-metastases N+1-3 and N+ ≥ 4, respectively as output. The ANN was trained by back-propagation using gradient descent of a cross entropy error, for 2000 epochs. Area under the receiver operating characteristic curve (AUC) was used to assess the performance of the ANN-based predictive models for axillary nodal status. Evaluation was performed in a stratified 5-fold cross validation scheme, repeated 10 times. Sensitivity and specificity are given for a cutoff value corresponding to optimal balanced accuracy.

Results
The cohort consisted of 800 patients, classified into N0 64 % (n=514), N+1-3 positive nodes 29% (n=232) and N+ ≥ 4 positive nodes 7% (n=54). The AUC was 0.72 for prediction of node negativity; sensitivity 74% and specificity 64%. AUC was 0.77 for N+ ≥ 4; sensitivity 67% and specificity 79%. The predictive model for N+1-3 macro-metastases is in progress. Tumor size and lymphovascular invasion are the two principal risk variables selected to construct the ANN predictive model for N+ ≥ 4. However, for N0, the predictive model is characterized by a complicated integration of numerous clinicopathological risk variables.

Conclusions
Based on clinicopathological and mammography-screening data, ANN can be valuable in predicting axillary nodal status and as a guidance tool for directing patients to personalized treatment of the axilla.
Title: SentiNot: A way to avoid sentinel node biopsy (SNB) in patients with a preoperative diagnosis of ductal cancer in situ (DCIS)

Karakatsanis A, Olofsson HM M, Eriksson S, Andersson Y, Bergkvist LÅ Å, Mohammed I, Sundqvist M, Abdsaleh S, Olofsson Bagge R, Sund M and Wärnberg F. Section for Endocrine and Breast Surgery, Uppsala University Hospital, Uppsala, Sweden; Uppsala University Hospital, Uppsala, Sweden; Västmanland County Hospital, Västerås, Västerås, Sweden; Uppsala Clinical Research Centre, Uppsala, Sweden; Section for Breast Surgery, Kalmar County Hospital, Kalmar, Sweden; Institute of Radiology, Oncology and Radiotherapy, Uppsala University Hospital, Uppsala, Sweden and Norrlands University Hospital, Umeå, Umeå, Sweden.

Body: Background

The risk for node metastasis in preoperative diagnosis of DCIS is low. ASCO guidelines suggest that SNB could be performed when mastectomy is planned or in those cases where the probability of upgrading to invasive cancer postoperatively is high. Despite that, SNB is performed almost in 54% of DCIS procedures in the Uppsala-Örebro Region. Thus, morbidity and resources have to be balanced against the risk of a reoperation.

Methods

Patients with a preoperative diagnosis of DCIS grade 3, grade 2 ≥20mm or planned for a mastectomy will be included. Sienna+ is injected in the breast at the first operation. If the specimen contains invasive cancer, a SNB is performed in another session. Sienna+ can be detected in the axilla at least four weeks after the injection. Endpoints of the trial are the feasibility of detection of the SN as well as how many SNBs are avoided.

Results

In the first 34 cases, six had invasive breast cancer

On reoperation (median 29 days, iqr 10) SNB was successful in four cases with SPIO, one with Tc\textsuperscript{99} and three cases with blue dye. Totally, the combination of SPIO and blue dye was successful in all cases. No metastases were found.

Conclusion

It is possible to load the SN with SPIO and reoperate within 4 weeks from the first operation. A rough 83.4% of all patients with DCIS who would have undergone SNB avoided it. Our preliminary results show that 5.6 SNB was avoided for each patient that
was operated. SN was detected in all cases with a combination of SPIO and blue dye, but only in 66.7% SPIO. It seems that increased experience with SPIO will increase the effectiveness of this procedure.
Title: The non-invasive treatment for sentinel lymph node metastasis by photodynamic therapy using a verteporfin solubilized phospholipid polymer aggregate

Shimada K, Matsuda S, Jinno H, Konno T, Ito A, Arai T, Ishihara K and Kitagawa Y. Kawasaki Municipal Ida Hospital, Kawasaki, Kanagawa, Japan; Keio University School of Medicine, Shinjuku, Tokyo, Japan; Teikyo University School of Medicine, Itabashi, Tokyo, Japan; The University of Tokyo, Bunkyo, Tokyo, Japan and Keio University, Yokohama, Kanagawa, Japan.

Body: Introduction:
Sentinel lymph node biopsy (SLNB) has become a standard procedure for axillary lymph node evaluation in clinically node-negative breast cancer patients. Recent trial suggested that patients with 1 or 2 sentinel lymph nodes (SLNs) involvement could be treated with SLNB alone.

Although SLNB is much less invasive procedure comparing with axillary lymph node dissection (ALND), it is still associated with complications such as lymph edema, numbness and pain.

Photodynamic therapy (PDT) against cancer is a non-invasive optical therapeutic method in which the topical or systemic delivery of photosensitizing drugs is followed by its subsequent activation with broadband red light.

In this study, the usefulness of PDT for treating SLN metastasis was evaluated in murine model.

Materials and Methods:
Verteporfin, a hydrophobic photosensitizer (PS) forms a soluble conjugate in aqueous medium with a water-soluble and amphiphilic PMB polymer as a solubilizer. The PMB forms stable and well-dispersed molecular aggregate when its concentration is over 1.0 mg/mL based on the hydrophobic interactions among polymer chains. The verteporfin can form conjugate (PMB-verteporfin) with hydrophobic domain in the PMB aggregate. The PMB-verteporfin was injected at dorsum manus of BALB/c nude mice. The concentrations of verteporfin in tissues were determined by measuring the fluorescence emitted at 700 nm (with excitation at 430 nm). To develop a murine SLN metastasis model, 5 x 10^5 human epidermoid carcinoma A431 cells with stable expression of GFP were injected to the forearm of BALB/c nude mice. Seven days after inoculation of cancer cells, 20 µL of PMB-verteporfin was injected at dorsum manus of BALB/c nude mice and 75 J of light energy was delivered using a 640 nm diode laser for a total treatment time of 1 min. Fifty-three mice were randomly assigned to the combination of PMB-verteporfin injection and light exposure (A), light exposure alone (B), PMB-verteporfin injection alone (C), and no treatment (D) groups. Ten days after PDT, brachial lymph nodes, which were considered as SLNs were harvested and evaluated by stereoscopic fluorescence microscope. And, DNA was extracted from harvested lymph node. Human Alu family sequence was detected by 7300 Real Time PCR system (Applied Biosystems, Carlsbad CA USA) to estimate metastatic volume.

Results:
The concentration of verteporfin in SLN was significantly higher than other organs including lung, liver, kidney and brachial skin. The group A significantly reduced the SLN metastasis (13%) comparing with , group B (57%), group C (46%) and group D (52%).

The Ct value in a PCR of the combination of group A (Ct=29.17) significantly reduced the SLN metastasis comparing with group B (Ct=22.45, p=0.018), group C (Ct=25.58, p=0.018) and group D (Ct=25.54, p=0.005).

Conclusions:
These data suggested that PDT using PMB as a nanotransporter of verteporfin could be a minimally invasive treatment of SLN metastasis in breast cancer, and represent a potential alternative procedure to SLNB.
Preoperative axillary ultrasound guided needle sampling in breast cancer: Comparing the sensitivity of fine needle aspiration cytology and core needle biopsy

Topps AR R, Barr SP P, Pritchard S and Maxwell AJ J. Nightingale Centre and Genesis Prevention Centre, University Hospital of South Manchester, Manchester, United Kingdom and Centre for Imaging Studies, University of Manchester, Manchester, United Kingdom.

Body: Background: Preoperative axillary ultrasound (US) combined with selective US-guided needle sampling (UNS) can be used to identify lymph node metastases. This can inform decisions about neoadjuvant chemotherapy and allow a patient to proceed immediately to axillary lymph node dissection (ALND) thus avoiding an extra sentinel node biopsy (SNB) procedure. We acknowledge the landmark ACOSOG Z0011 trial showing a subgroup of patients (T1-2) undergoing breast conserving surgery and whole-breast radiotherapy in which ALND can safely be omitted if they have minimal nodal disease burden. For these patients the utility of UNS may be limited if the surgeon has modified their practice according to the trial. For patients not fitting the Z0011 trial criteria, preoperative UNS remains important.

Previous studies comparing the sensitivity of axillary US-guided fine needle aspiration cytology (FNA) and core needle biopsy (CNB) have been small and a meta-analysis has not shown a difference in sensitivity\(^1\). Our aim was to directly compare the sensitivity of the two techniques.

Method: Patients with macrometastatic nodal involvement that were treated at a tertiary referral centre between January 2013 and December 2014 were retrospectively identified from pathology records. Preoperative UNS had been performed by one of eight Consultant Radiologists with the sampling method being according to each individual radiologist's preference. The result of the first UNS performed on each patient was compared to post-operative histopathology results. Patients who had undergone previous axillary surgery or any part of their investigations/treatment at another unit were excluded.

Results: A total of 101 CNBs and 181 FNAs were performed in 282 patients. There were 78 true positive CNBs and 96 true positive FNAs. US-guided CNB was therefore more sensitive than US-guided FNA (77.2\% vs. 53.0\%, \(p<0.001\)). Two non-diagnostic CNBs and eight non-diagnostic FNAs were performed. Five patients in the CNB group were correctly identified preoperatively as having isolated tumour cells (ITCs) or micrometastatic disease only in their axillary lymph nodes and were therefore triaged to SNB rather than ALND. A single haematoma requiring non-operative management was recorded in the CNB group.

Conclusion: US-guided CNB of the axilla is more sensitive than US-guided FNA and is a safe technique in experienced hands. We also highlight the additional potential benefit (whilst accepting the possibility of sampling error) of CNB over FNA in assisting the multidisciplinary planning of axillary surgery in patients who are found to have ITCs or micrometastatic disease only during their preoperative axillary staging.

The long term outcomes of Metasin RTqPCR intra-operative sentinel node analysis in early breast cancer

Background:
Axillary lymph node involvement is a prognostic factor in breast cancer and it is used to guide adjuvant therapy. Axillary clearance remains the standard of care in lymph node positive disease in most parts of the world. Usually this is performed as second procedure but immediate intra-operative node analysis allows clearance to be performed as part of the initial procedure where necessary.

The Metasin assay targets the breast epithelial cell markers CK19 and mammaglobin mRNA and detects the presence of breast tissue (metastatic disease) in the sentinel nodes. Evidence shows the Metasin assay to be fast (average assay time 41.2min) and accurate with a discordance rate below 4% compared with histology. The cost effectiveness of the assay has been reported in our previous studies.

Aim:
The aim of this study is to assess the risk of axillary recurrence following the use of the Metasin assay to guide axillary management.

Method:
This is a single centre retrospective study which included all patients presenting to a district general hospital with early clinically node negative breast cancer undergoing sentinel node biopsy between Oct 2011 and Dec 2014.

Alternate 2 mm slices of the node were examined intraoperatively using the Metasin assay and the remainder sent for histological examination. The results of the Metasin assay and histology were compared. The risk of axillary recurrence using the Metasin test to select patients for immediate axillary clearance was assessed.

Results:
1073 sentinel nodes from 545 patients were analysed during this three-year period. 2 patients were lost to follow up. 94 patients were node positive and underwent axillary clearance as part of their primary surgery. 449 patients had sentinel node biopsy with no further axillary procedure. There were 36 nodes (3.34%) with discordant results. Median follow up was 32 months (range 18 to 55 months).

Fourteen patients presented with recurrences (2.56%). The mean event free interval was 15 months. Of the 14 patients, 5 patients tested with Metasin had macrometastases and underwent immediate axillary clearance during the primary surgery. 7 patients were node negative and 2 patients were shown to have micrometastases. 11 patients recurred with distant metastases, 3 patients with local recurrence and 2 patients (0.36%) with axillary recurrences.

The two axillary recurrences occurred at 3 and 5 months after primary surgery. Both patients underwent Metasin intraoperative analyses of sentinel nodes which were negative. Subsequent histological examination confirmed no metastatic node involvement in one patient but micro-metastases in the other. Both of these patients had aggressive disease with local, axillary and distant metastasis and subsequently died of their disease.

Conclusions:
The Metasin assay is a reliable intraoperative test for sentinel node involvement and when used to guide surgical axillary management is associated with very low axillary recurrences (0.36% with a median follow up of 32 months).
Title: Long-term follow-up of persistent breast dermopigmentation after sentinel lymph node identification using superparamagnetic iron oxide particles (SIENNA+®)

Hannebicque K, Boulanger L, Bogart E, Giard S, Chauvet MP and Houpeau JL. Centre Oscar Lambret, Lille, France.

Body: Background
The French Sentimag study evaluated a non-invasive method for the localization of breast cancer sentinel lymph nodes (SLN) using SIENNA+®, a superparamagnetic iron oxide particles (SPIO), in addition to conventional techniques (radiotracer and blue dye). SIENNA+® was injected subcutaneously into the breast and detected by the SENTIMAG® handheld magnetometer probe. The results showed a good SLN identification performance but a skin discoloration was noted during this study after the SIENNA+® injection. This aim of this study was to assess the long-term duration and appearance of this dermopigmentation.

Methods:
56 patients had participated in Sentimag study in our Center, 6 patients who had undergone mastectomy were excluded. We selected 50 patients who had undergone breast conservative surgery. For these patients, SLN localization was performed by both the conventional method (radiotracer and/or blue dye) and magnetic tracer, SIENNA+®. 47 patients were reviewed retrospectively from January 2015 to April 2015, 1.5 to 2 years after surgery and were assessed for skin discoloration.

Results:
Of the 47 patients, a dermopigmentation, from grade 1 (light yellowing) to grade 3 (dark browning) remained visible at the site of injection of SIENNA+® after 20.2 months [14.4-25.9] in 36.1% of the patients (17/47). 6.4% of 47 patients seen had grade 3 skin discoloration and 29.7% had grade 1 or 2 skin discoloration. Interestingly, no patients reported that persistent staining was a cosmetic or psychological problem.

Conclusions:
The use of SIENNA+® appears as an alternative method to radioisotopes for SLN identification in early breast cancer, but it may result in a prolonged-dermopigmentation at the injection site. To avoid dermopigmentation, it would be interesting to compare different techniques of SIENNA+® injection into the breast (intra-tumoral injection or a deeper periareolar injection) through a randomized trial.
Title: Evaluating lymph node ratio (LNR) as a prognostic indicator in node-positive breast cancer

Kelliher A, Boyce M, Donnellan E, O Connor D, Murphy C and Bird B. University College Cork, Cork, Ireland and Bon Secours Hospital Cork, Cork, Ireland.

Body: Purpose: To determine whether LNR can provide additional prognostic information to pN staging in node-positive breast cancer patients.

Methods: We previously reported on the utility of LNR as a prognostic indicator in lymph node-positive early breast cancer. We present an updated analysis with a prolonged median follow-up of 85 months. A retrospective review of original histopathology reports was undertaken in a sample group of 214 patients diagnosed with node-positive breast cancer between January 2000 and January 2011. The LNR was defined as the number of positive lymph nodes divided by the total number of lymph nodes (LN) removed. LNR cut off points were divided into low (≤0.14), intermediate (0.15-0.39) and high (≥0.40) by trichotomy. Patients were also divided into three groups based on nodal status in accordance with the AJCC staging system. Those with 1-3 positive nodes were classified as pN1, those with 4-9 positive nodes were pN2 and those with 10 or more positive nodes were classified as pN3. Overall survival (OS) and invasive Disease Free Survival (iDFS) were calculated using the Kaplan Meier Method.

Results: The mean age at diagnosis was 58 (SD=12) years. The median follow-up time was 85 months. The 5-year OS and iDFS for node-positive patients were 80% and 70%, respectively. The mean number of lymph nodes examined was 15.2 (SD=6.6) and the mean number of positive nodes was 5.3 (SD=6.1).

When patients were stratified according to LNR groupings OS was 80% in the low LNR group, decreasing to 67% in the intermediate LNR group and 57% in the high LNR group (p<0.0001). Similarly, iDFS in the low LNR group was 71% decreasing to 57% in the intermediate LNR group and 42% in the high LNR group (p<0.0009).

Conclusions: These updated results from a cohort of patients with lymph node-positive early breast cancer at a median follow-up of over 7 years confirms the utility of LNR as a prognostic indicator. Univariate and multivariate analyses to assess the ability of LNR to discriminate risk in addition to AJCC nodal grouping will be presented.

Title: Abstract Withdrawn
Title: Validation of a Chinese nomogram with a Dutch breast cancer population: Excellent prediction of the probability of axillary lymph node metastasis

Qiu S-Q, Aarnink M, van Maaren MC C, Dorrius M, Koffijberg H, van Dam GM M and Siesling S. University of Groningen, University Medical Center Groningen, Groningen, Netherlands; The Breast Center, Cancer Hospital of Shantou University Medical College, Shantou, Guangdong, China; MIRA Institute for Biomedical Technology and Technical Medicine, University of Twente, Enschede, Overijssel, Netherlands; Netherlands Comprehensive Cancer Organisation, Utrecht, Netherlands; University of Groningen, University Medical Center Groningen, Groningen, Netherlands and University of Groningen, University Medical Center Groningen, Groningen, Netherlands.

Body: Background: In the era of precision medicine, the surgical management of axillary lymph nodes (ALN) should be patient-tailored. Omission of sentinel lymph node biopsy (SLNB) is possible in patients with early breast cancer and very low or very high probability of ALN metastasis. Recently, we developed a nomogram to predict the probability of ALN metastasis in breast cancer patients based on clinicopathological parameters including ultrasound using a Chinese patient dataset. In this study the nomogram performance was validated in an independent Dutch population from one hospital.

Methods: Data of 170 Dutch patients with a successful SLNB or axillary lymph node dissection were collected. A lymph node containing either micro- or macrometastatic disease was considered as a positive lymph node. Performance of the nomogram was assessed by calculating the area under the receiver-operator characteristic (ROC) curve (AUC). False-negative rates (FNRs) and false-positive rates (FPRs) at several different predictive cut-off points were calculated.

Results: There were 69 (40.6%) patients having a positive ALN. The AUC for the nomogram was 0.84 (95% confidence interval 0.78-0.90) compared with 0.86 in the Chinese validation population, showing excellent discrimination of the model. The FNR and FPR of the model were 10.2% and 0% for the predicted probability cut-off points of 14.5% and 90%, respectively.

ALN: axillary lymph node

This means that omission of SLNB is possible for patients with a predictive probability of less than 14.5% or higher than 90%, which accounts for 45.3% of all patients in this study.

Conclusions and future perspectives: In this study, the Chinese nomogram showed excellent performance in predicting the probability of ALN metastasis in an independent Dutch population. A multicentre validation of this nomogram in large Dutch patient population (>2500 patients) is ongoing.

Title: Sentinel lymph node biopsy by contrast-enhanced ultrasonography with sonazoid in patients with breast cancer - Prospective multicenter study

Shimazu K, Ito T, Uji K, Miyake T, Motomura K and Noguchi S. Osaka University Graduate School of Medicine, Suita, Osaka, Japan; Rinku General Medical Center, Izumisano, Osaka, Japan and Osaka General Medical Center, Osaka, Japan.

Body: Background: The aim of this prospective study is to evaluate feasibility of the periareolar injection of contrast agent (Sonazoid (SNZ)) followed by ultrasonography (US) for identification of sentinel lymph node (SLN) in breast cancer patients with clinically negative node.

Patients and Methods: Patients with T1-2N0M0 breast cancer were recruited in this study. They received the periareolar injection of SNZ followed by US to identify contrast-enhanced SLN. Fine needle aspiration biopsy (FNAB) was done for each CE-SLN. Then, they underwent SLN biopsy with the conventional method, blue dye and/or radiotracer (B/R).

Results: In almost all cases, contrast-enhanced lymphatic vessels were clearly visualized US soon after the periareolar injection of SNZ, and SLN, into which lymphatic flow was draining, was easily identified. The identification rate of SLN was 98% (98/100) by SNZ and 100% (100/100) by B/R. The number of SLNs identified by SNZ (mean per patient, 1.52) was significantly (P < 0.001) lower than that of those by B/R (2.22). Twenty-five patients had at least one metastasis in the SLNs identified by SNZ and/or B/R. In these patients, SLNs (n=39) identified by both SNZ and B/R showed a significantly (P < 0.0001) higher positivity (74.4%) for metastases than those (n=19) identified by B/R alone (21.1%).

Conclusion: Identification of SLN by periareolar injection of SNZ followed by US is a technically easy method and the identification rate of SLN was as high as 98%, being comparable to the conventional B/R. SLNs detected by SNZ seem to represent the true SLNs which first receive lymphatic flow from the tumor among the SLNs detected by B/R.

Title: Intraoperative assessment of the sentinel node (SN) in breast cancer by one step nucleic acid assay (OSNA): Experience of over 800 patients

Body: Introduction
The intra-operative assessment of the sentinel node in women with breast cancer enables an immediate axillary node clearance if the sentinel node is positive. This has significant benefits for the Patient, the Surgeon and the Health Care Provider. There are a variety of methods for the intra-operative assessment which include: Touch Imprint Cytology, Frozen Section Analysis and Polymerase Chain Reaction (PCR) based molecular assays. OSNA is a molecular assay using PCR, which detects the presence of cytokeratin 19 in the sentinel node. We report our experience of OSNA for the intraoperative assessment of the sentinel node in a single institution with 807 patients.

Methods
All patients with operable breast cancer who were found to be node negative on clinical and radiological assessment of the axilla, and who had their axilla staged by a sentinel node biopsy at the Breast Unit at Warwick Hospital, UK over a 5 year period were included in this study. Data was collected from a prospective database maintained at the Breast Unit. The axillary node positivity rate and the percentage of patients with macrometastatic and micrometastatic disease as detected by OSNA was collected and compared with a group of 411 patients who had the intraoperative assessment by Touch Imprint Cytology and final histology by conventional Haematoxylin &Eosin(H&E) assessment, prior to the introduction of OSNA. The Chi-square test were used for statistical significance.

Results
807 patients had their sentinel assessed intraoperatively using OSNA in this 5 year study period. The sentinel node was positive in 292 patients (36.5%). Of those who had a positive node, 138(17.3%) had macrometastatic disease and 154(19.2%) had micrometastatic disease. When compared to 411 patients in the preOSNA period, that were assessed by Touch Imprint Cytology and H&E sections, the node positivity rate increased from 24.6% to 36.5% (p 0.0001) with the introduction of OSNA. Whilst there was no significant increase in the rate of macrometastatic disease – 21.15% versus 17.3 % (p 0.052), there was a significant increase in the patients who had micrometases detected on OSNA - 3.5% versus 19.2 % (p 0.0009) as shown in the table.

Comparison of OSNA with conventional Touch Imprint Cytology and H&E

Conclusion
Our results prove that OSNA is a much more sensitive test for picking up metastatic disease, especially micrometastatic disease, in the sentinel node. Whilst this did cause some anxiety in the initial part of the study period, the results of recent trials like ACSOG Z-11 and IBCSG 23-01 have shown that small volume disease or micrometastases in the sentinel node do not always require an axillary node clearance. Intraoperative assessment of the sentinel node with OSNA significantly upstages the axillary nodal status, especially with regard to micrometastatic disease, but the ability to proceed to an axillary node clearance at the same operation as the sentinel node biopsy, still has significant advantages for the Patient, Surgeon and Health Care Providers.
Title: In the era of conservative surgery, can patients presenting with node positive breast cancer be spared axillary node dissection post neoadjuvant chemotherapy? A meta-analysis and review of literature

Body: Background: The use of sentinel lymph node biopsy (SLNB) following neoadjuvant chemotherapy (NAC) in patients presenting with clinically positive lymph nodes remains controversial.

Methods: A computer-aided search of the literature regarding SLNB in clinically node-positive breast cancer treated with NAC was carried out to identify the false negative rate (FNR), sentinel lymph node identification rate (IR), and axillary pathological complete response (pCR).

Results: Nineteen articles were used in the analysis yielding 3398 patients. The pooled estimate of the FNR was 13% and that of the IR was 91%. The adjusted pCR rate was 47%.

Conclusions: SLNB after NAC in biopsy-proven node positive patients results in reasonably acceptable FNR and IR making it a valid alternative management strategy to axillary dissection. Although the results are not matched with those in clinically node negative patients, a FNR of 13% is very unlikely to adversely affect overall survival. Its impact on locoregional recurrence should be evaluated in adequately powered future studies. More refined patient selection and optimal techniques can improve the FNR and IR in this patient population.
Limited effectiveness of patent blue dye in addition to isotope scanning for identification of sentinel lymph nodes: Cross-sectional real-life study in 1024 breast cancer patients

Merlin J-L, Rauch P, Leufflen L, Salleron J, Harlé A, Olivier P and Marchal F. Institut de Cancérologie de Lorraine, Nancy, France; Université de Lorraine, Nancy, France; CNRS UMR7039 CRAN, Vandoeuvre les Nancy, France and CHU, Nancy, France.

Body: Background. Reduced morbidity is associated with sentinel lymph node (SLN) biopsy performed with isotopic and blue dye identification. However, because its use has been associated with side effects including anaphylactic reactions, the effectiveness of adding blue dye to radioisotope for SLN mapping remains debated.

Patients and Methods. Using data from a prospectively maintained database, 1884 lymph node-negative breast cancer patients who underwent partial mastectomy with SLN mapping by a dual-tracer using patent blue dye and radioisotope, using the same subareolar injection technique, were prospectively studied in a real-life setting between January 2000 and July 2013. A total of 1024 with tumors <3 cm and with >1 node detected by one of the two techniques (N=1024) were included in this cross-sectional study. A lymph node was considered as an SLN when it was stained with patent blue (either partial or complete), had a blue lymphatic afferent, or had increased radioactivity. SLNs identified during these procedures were classified as containing both blue dye and radiotracer (“blue-hot” nodes), radiotracer alone (“hot-only” nodes), or blue dye alone (“blue-only” nodes).

Results. Among the 1024 patients analyzed for SLN mapping, 1010 patients (98.6%) had at least one hot SLN, and 880 (86.0%) had at least one blue SLN. A total of 866 patients (84.6%) had at least one blue-hot SLN. Only four patients had blue-only nodes involved and 26 patients had hot-only nodes. Therefore, the failure rate of the isotopic and the colorimetric method were 1.5% (4/274) and 9.5% (26/274), respectively. Among these four patients having no detectable radioactivity in the axilla, two had negative lymphoscintigraphy. Therefore, the contribution of blue dye to metastatic nodes was relevant for the identification of only 2/274 patients (0.8%). In the univariate analysis, age<60 (P=0.0089), tumor size (P<0.0001), tumor grade (P=0.0436), and blue SLNs (P=0.0109) were significantly associated with node involvement. In the multivariate analysis, after adjusting for the number of identified SLNs, blue SLNs remained significant (P=0.0210) but the discriminant power of this multivariate model was low (AUC=0.66). Three patients (0.3%) had an allergic reaction with patent blue dye, and anaphylactic shock occurred in two cases (0.2%).

Conclusions. The patent blue dye method is less sensitive than isotopic method to assess SLN involvement. Its added-value to reduce the false-negative rate is only limited to the rare cases in which no radioactivity is detectable in the axilla (<1%). When a radioisotope mapping agent is available, the use of patent blue dye should be avoided, because it can induce anaphylaxis. The results of this real-life cross-sectional study performed in a large number of patients, bring additional data that confirm the findings of previous studies. Highlighting the low interest of adding patent blue dye to isotopic detection for SLN mapping, these results led us to modify our procedures: when a radioisotope mapping agent is available, the use of blue dye is now avoided, because it can induce allergic reactions that can be life-threatening.
Title: Validation of novel diagnostic kits using the semi-dry dot-blot method for detecting metastatic lymph nodes in breast cancer; distinguishing macrometastases and micrometastases

Otsubo R, Hirakawa H, Oikawa M, Inamasu E, Baba M, Matsumoto M, Yano H, Kinoshita N, Abe K, Fukuoka J and Nagayasu T. Nagasaki University Hospital, Nagasaki, Japan; Chiba Aiyukai Memorial Hospital, Chiba, Japan and Nyuwakai Oikawa Hospital, Fukuoka, Japan.

Body: Background: The semi-dry dot-blot (SDB) method is a diagnostic procedure for detecting lymph node (LN) metastases. Metastases are confirmed by the presence of cytokeratin (CK) in lavage fluid of sectioned LNs that contain anti-pancytokeratin antibody, based on the theory that epithelial components such as CK are not found in normal LNs. We evaluated two novel SDB kits that use the newly developed anti-CK19 antibody for diagnosing LN metastases in breast cancer.

Methods: We obtained 159 LNs dissected from 93 breast cancer patients from July 2013 to December 2015 at Nagasaki University Hospital, including 38 dissected axillary LNs and 121 sentinel LNs, sliced at 2-mm intervals and washed with phosphate-buffered saline. The suspended cells in the lavage fluid of sliced LNs were centrifuged and lysed to extract protein. This extracted protein was used with a low-power and a high-power kit to diagnose LN metastasis. The washed LNs were blindly diagnosed by pathologists using hematoxylin and eosin (H&E) stain. Diagnoses based on the kit were compared with their H&E counterparts.

Results: Of the 159 LNs, 68 were assessed as positive and 91 as negative by permanent pathological examination with H&E. Sensitivity, specificity, and accuracy of the low-power kit for detecting LN metastases was 83.8%, 100%, and 93.1%, respectively. In 11 false-negative cases, there were nine micrometastases, producing a sensitivity of 96.4% for detecting macrometastases. Sensitivity, specificity, and accuracy of the high-power kit for detecting LN metastases was 92.6%, 92.3%, and 92.5%, respectively. Combining the low- and high-power kit results, sensitivity, specificity and accuracy for distinguishing macrometastases from micrometastases was 94.5%, 95.2%, and 95.0%, respectively. Diagnosis was achieved in approximately 20 min using the kits, at a cost of less than 25 USD.

Conclusions: The kits in our study were accurate, quick, and cost-effective in diagnosing LN metastases without the loss of LN tissue. The kits’ ability to distinguish macrometastases from micrometastases was excellent, which is important, clinically.

Title: Second sentinel lymph node biopsy for patients with local recurrence after breast cancer surgery

Park JY, Song JH, Choi JE and Lee SJ. Yeungnam University Medical Center, Daegu, Republic of Korea.

Body: Background: Sentinel lymph node biopsy (SLNB) has become standard procedure for primary breast cancer patients who have no tumor metastasis in sentinel lymph node (SLN). In this study, we evaluated feasibility and pathologic outcomes of second SLNB in patients with locally recurrent breast cancer and their follow-up results.

Methods: From January 2008 to December 2015, 114 patients underwent operation for locally recurrent breast cancer. In 42 patients of them, lymphatic mapping was performed for second SLNB. When SLN was visualized in lymphangiography, SLNB was performed. In the cases where SLN metastasis was confirmed, axillary lymph node dissection (ALND) was performed. Follow-up studies were performed every 6 months for 5 years and then annually.

Results: The mean interval to local recurrence from the initial surgery of breast cancer was 64.6±53.1 months. In 38 of 42 patients (90.5%), lymphatic mapping was successfully performed. There was no significant difference of success rate of lymphatic mapping according to previous operation method of breast and axilla or history of radiation therapy.

Aberrant lymphatic pathway was observed in 15 of 38 patients (39.5%). The rate of aberrant lymphatic pathway was higher in patients who underwent ALND previously then in patients who underwent SLNB only (81.8% vs 22.2%, p=0.001). In 6 patients who previously underwent ALND followed by radiation therapy, all their lymphatic pathway was altered. There was no significant difference of the rate of aberrant lymphatic pathway according to previous operation method of breast.

Of 38 patients in whom lymphatic mapping was successfully performed, 37 patients underwent SLNB. SLNs were identified in 31 patients (83.8%). There was no significant difference of success rate of SLNB according to previous operation method of breast and axilla or history of radiation therapy.

Of 31 patients whose SLNs were identified, 4 patients (12.9%) had tumor metastasis in their SLN. Among them, 3 patients underwent ALND but SLN was the only lymph node (LN) in which tumor metastasis was confirmed. The other patient underwent no further ALND because ipsilateral internal mammary LNs were only LNs in which tumor metastasis was confirmed in frozen section biopsy and micrometastasis was additionally confirmed in only one contralateral axillary LN in permanent biopsy.

The mean follow-up period after operation for local recurrence was 33.0±24.5 months. There were 10 cases (23.8%) of loco-regional recurrence or distant metastasis at 14 months of mean follow-up. Among them, one patient had ipsilateral axillary recurrence solitary at 11 months of follow-up. The patient underwent breast conserving surgery and SLNB for primary breast cancer which stage was I. Second SLNB for local recurrence was tried at 48 months after first operation but SLN was not identified. Because there was no evidence of axillary LN metastasis in preoperative image study, no further ALND was performed.

Conclusion: Second SLNB should be considered for patients with locally recurrent breast cancer because occult LN metastasis could be identified in the ipsilateral axilla or other site through aberrant lymphatic pathway. Further studies are needed to verify accuracy of axillary staging using second SLNB and also its oncologic safety.
Title: Non-sentinel lymph nodes involvement in early breast cancer patients: Performance of two predictive nomograms integrating the analysis of sentinel nodes by one step nucleic acid amplification in a cohort of 299 patients

Body: Backgrounds: Sentinel lymph node (SLN) biopsy is a highly accurate predictor of axillary status and has become the surgical axillary standard in breast cancer patients. About 50–70 % of patients with involved SLN have no additional non sentinel node (NSN) involved, suggesting that it be possible to avoid ALND in selected patients. Many tools have been developed to help surgeons in NSLN evaluation but they all need pathological data from tumor and SLN and can't be used during surgery. Developed for intraoperative detection of SLN macro or micrometastasis involvement, the semi-automated molecular one step nucleic acid amplification (OSNA), as accurate as pathology, is available. Two simple nomograms have been developed to predict NSN involvement based on the number of CK19 mRNA copy determined by OSNA:

· Nomogram developed by Peg V (Eur J Surg Oncol 2013): based on total tumoral load (TTL). TTL is defined as the addition of CK19 mRNA copies of each positive SLN (copies/µL). A TTL $\geq 1.2 \times 10^5$ copies/ml (specificity=85.3%, negative predictive value (NPV) = 80%) can predict NSN involvement.

· Nomogram developed by Di Filippo F (Journal of Experimental & Clinical Cancer Research 2015): based on the number of CK19 mRNA copies and ultrasound tumor size. These two variables are categorized using quartiles with a score for each and the addition of both corresponds to a probability of NSN involvement (sensitivity = 98.1%, NPV = 92.5 %).

Patients and Methods: this is a retrospective study of 299 patients. Each patient had SLN involvement (macro or micrometastasis) and underwent a complementary ALND. The main objective was to evaluate the performance of each nomogram using a discrimination ability model, assessed by ROC analysis. Predictive accuracy was measured by the area under ROC curves (AUC) reported with its 95 % confidence interval. The second objective was to compare the two nomograms using Hanley & McNeil method, to test the statistical significance of the difference between the AUC. Analysis was performed using stata 13.1 SE.

Results: The mean age was 59, 1 year. Most patients were treated for an infiltrating ductal carcinoma (80.3%, 240/299). The mean ultrasound tumor size was 13 mm and the mean pathological tumor size was 15 mm. The median number of examined SLN was 2 with a macro-metastasis in 67, 6%, 202/299). 70 patients had involved nodes in ALND (23%). The discrimination of N Peg, quantified with AUC was 0.685 (p<0, 00001). The discrimination of N Di Filippo, quantified with AUC was 0.72 (p<0, 00001).

Hanley & McNeil method shows that Di Filippo nomogram is significantly superior to Peg nomogram (p=0,048).

Conclusion: The current study shows that these two nomograms are reliable and can be used to predict NSLN involvement. The combination of molecular data and ultrasound tumor size seems to be more efficient than molecular data alone. These results are similar to results of nomogram studies based on pathological analysis but only these nomograms integrating molecular data can be used during the surgery.
Title: Abstract Withdrawn
Title: A one-day protocol with activities lower than 20 MBq for the detection of sentinel lymph nodes - Experience after 150 cases

Body: Introduction:
Common protocols for the detection of sentinel lymph nodes (SLN) in early breast cancer often include injection of the tracer one day before surgery. In order to detect enough activity on the day of surgery, the applied activity in many protocols is as high as several hundred MBq. Even in common one-day protocols the activity applied is often up to 50 MBq. We developed a one-day protocol with a mean activity lower than 20 MBq in order to reduce radiation exposure for patients and staff. Here we are presenting our experience after 150 cases.

Material and methods:
150 patients with clinically and sonographically negative axilla (cN0) and no multicentricity underwent a SLN biopsy using a low-dose protocol performed on the day of surgery. After ultrasound-guided injection of the tracer (Technetium99) lymphoscintigraphy was performed in all cases. 7 minutes before the first cut 5 ml blue dye was injected in the region of the areola. Fresh-frozen sections of the SLN(s) were not performed.

Results:
In 149 of 150 patients (99.3%) at least one SLN could be identified by lymphoscintigraphy. The detection rate during surgery with combined tracers Technetium99 and blue dye was 100%. The mean applied activity was 17.8 MBq (9-20). A mean number of 1.3 (0-5) SLNs were identified by lymphoscintigraphy, a mean number of 1.7 (1-5) SLNs were removed during sentinel lymph node biopsy. 36 patients received a secondary axillary dissection according to the historical standard because of involved SLNs. In 11 cases (30.6%) additional involved lymph nodes were found.

Conclusion:
One-day protocols with an activity lower than 20 MBq are a safe alternative to two-day protocols with significantly higher radiation doses. Using Technetium99 and blue dye in a dual tracer approach, detection rates of 100% are possible in clinical routine with minimal radiation exposure for patients and staff. The number of removed lymph nodes, the rate of secondary axillary dissections and the number of cases with additional involved lymph nodes is not higher than in published trials.
**Title:** Ex vivo shear-wave elastography of axillary lymph nodes predicting nodal metastasis in patients with primary breast cancer: A pilot study

Lim JW, Lee HW, Park JT, Ahn SG and Jung J. Gangnam Severance Hospital, Yonsei University College of Medicine, Seoul, Republic of Korea.

**Body:**

**Objective:** To evaluate the feasibility of shear-wave elastography using breast ultrasonography in identifying metastasis of removed sentinel lymph nodes during the operation for treatment of breast cancer.

**Background:** Conventional method for identification of sentinel nodal metastasis is time and cost consuming. The optimal method for identification of nodal status is important.

**Methods:** Excised sentinel lymph nodes during the operation were prospectively examined with the elastography. Metastatic status of lymph nodes was confirmed with permanent histology. Only macrometastasis was regarded as positive. Elastic values measured by the ex vivo elastography and nodal characteristics were analyzed to correlate with nodal metastasis.

**Results:** A total of 274 lymph nodes harvested from 68 breast cancer patients at Gangnam Severance Hospital from May 2014 to April 2015 were included this study. There was the difference of elastic values between nodes with and without metastasis (mean stiffness, 41.6 kPa and 17.4 kPa, \(P < 0.001\)). Mean sizes of metastatic nodes (range 0.36-2.59 cm) were significantly larger than that of non-metastatic nodes (1.0 cm versus 0.75 cm, \(P < 0.001\)). Moreover, there was a correlation between the size of metastatic nodes which ranged from 0.7 to 21.5 mm with a median of 7 mm and nodal stiffness (correlation coefficient of mean stiffness, \(r = 0.431\)). The area under the receiver operating characteristic curve (AUC) by the mean stiffness was 0.794. The combination of size of nodes, mean stiffness and ratio made AUC of 0.856.

**Conclusions:** In our study, ex vivo shear-wave elastography of sentinel lymph nodes was a feasible method to predict metastasis. Through the validation study, ex vivo elastography could be helpful to determine metastasis of sentinel lymph nodes during the operation.

**Keywords** Breast cancer; Elastography; Lymph node metastasis.
Title: Technical feasibility and validity of sentinel lymph node biopsy in patients with ipsilateral breast tumor recurrence

Matsumoto A, Jinno H, Yanagisawa T, Yoshikawa M, Takahashi Y, Seki T, Takahashi M, Hayashida T, Ikeda T and Kitagawa Y. Teikyo University School of Medicine, Tokyo, Japan; Keio University School of Medicine, Tokyo, Japan and Kitasato University Kitasato Institute Hospital, Tokyo, Japan.

Body: Background: The incidence of ipsilateral breast tumor recurrence (IBTR) was reported to be approximately 5-10% of breast cancer patients who had breast-conserving surgery. However, the role of sentinel lymph node biopsy (SLNB) in patients with IBTR still remains to be elucidated. The aim of this study was to evaluate feasibility and validity of sentinel lymph node biopsy for ipsilateral breast tumor recurrence (second SLNB).

Patients and methods: A prospective database of 1607 patients with clinically node-negative breast cancer who underwent SLNB from January 2005 to May 2015 was analyzed and 46 patients with IBTR underwent SLNB. Lymphatic mapping was performed using a combined method of blue dye and radioisotope. ICG fluorescence imaging was performed in cases with failure of identification by blue dye and radioisotope.

Results: The median age was 52 (range: 36-82) years at the time of second SLNB and the mean size of recurrent tumor was 1.39 ± 0.63 cm. Thirty-one (67.4%) and 10 (21.7%) patients had a history of previous SLNB and axillary lymph node dissection (ALND), respectively. Another five (10.9%) patients had no previous axillary surgery for primary tumors. Preoperative lymphatic mapping by lymphoscintigraphy was successfully performed in 24 of 36 patients (66.7%). The identification rate by lymphoscintigraphy among patients with previous SLNB, ALND, and no axillary surgery was 64.0% (16/25), 66.6% (6/9) and 100% (2/2), respectively (P= 0.583). Overall, sentinel lymph nodes (SLNs) were successfully identified in 37 (80.4%) of 46 patients during surgery. The identification rate in patients with previous SLNB, ALND and no axillary surgery was 80.6% (25/31), 80.0% (8/10) and 80.0% (4/5), respectively (P=0.990). The aberrant lymphatic drainage to extra-ipsilateral axilla was found more frequently in patients with previous ALND compared with previous SLNB and no axillary surgery (40.0% vs. 6.5% vs. 0%, P=0.015). Among three (6.5%) patients with SLN metastases, one patient with previous SLNB had macrometastasis at the ipsilateral axilla and ALND found a positive non-SLN (1/21). The remaining two patients with previous SLNB and ALND had micrometastases at ipsilateral and contralateral axilla, respectively and both patients underwent no further axillary treatment. After second SLNB, systemic treatment including chemotherapy, endocrine therapy and trastuzumab was performed in 17 (37.0%), 36 (78.3%) and seven (15.2%) patients, respectively. No axillary recurrence was observed after a median follow-up time of 37.2 months from surgery for IBTR.

Conclusions: Second SLNB is technically feasible regardless of types of previous axillary surgery and may avoid complications from unnecessary ALND for IBTR. Furthermore, it could improve risk prediction for IBTR and provide valid information for deciding adjuvant therapy.
Factors that can be used to guide further axillary treatment following positive sentinel lymph node biopsy

McIntyre N, Murray J, FitzGerald SC C, Murphy DS S and Lannigan AK K. Lanarkshire Breast Unit, Wishaw, Lanarkshire, United Kingdom.

**Aims:** Sentinel lymph node biopsy (SLNB) is used to stage the axilla in breast cancer patients with clinically and radiologically normal lymph nodes. The burden of involved lymph nodes in a SLNB sample can be calculated using the formula: Total number of positive sentinel nodes / Total number of sentinel nodes = Positive SLN Ratio (PSLRN). This study looked at the value of using PSLNR to select those patients who may benefit most from further axillary treatment.

**Methods:** Data from all patients who underwent axillary ultrasound and SLNB in NHS Lanarkshire under the care of four consultant surgeons from January 2010-June 2015 was collected and recorded prospectively.

**Results:** 799 patients were identified and those who had an upfront sentinel node biopsy before neoadjuvant chemotherapy were excluded leaving a sample group of 748 patients. 182 patients had a positive SLNB (24%). Of the 114 patients who had an axillary lymph node clearance (ALNC) following positive SLNB, 46 had further involved lymph nodes (40%). 70% of patients with further involved nodes on ALNC had a high PSLR ratio of >0.5 on initial SLNB, but only 47% of patients who had no further positive nodes on ALNC, had a high PSLR ratio of >0.5 (p=0.014). 21% of non-surgically managed patients (who had either radiotherapy or no further axillary treatment) had a ratio >0.5. Of those patients who had a positive SLNB, 9.9% had an abnormal axillary US with a normal pre-operative biopsy compared to 7.7% of abnormal scans in patients with a negative SLNB.

**Conclusions:** The majority of patients who underwent ALNC following a positive SLNB did not have any further nodal disease and could have been managed without further surgery. The PSLN ratio can be useful together with other pathological factors to help select those who could potentially be spared further axillary treatment.
Title: Axillary reverse mapping using fluorescence imaging in the surgical treatment for breast cancer patients

Liu J, Li J, Zhou J, Cui H, Xiang J, Jia P, Xiang A and Chen H. Affiliated Hangzhou Hospital of Nanjing Medical University, Hangzhou, Zhejiang, China.

Body: Background: Axillary lymph node dissection (ALND) is the standard surgical treatment for breast cancer patients who have axillary nodal metastasis but do not meet the criteria of Z0011 trial. Arm lymphedema is one of the most common and serious complications of ALND. Based on the hypothesis that the lymphatic system of the upper extremity may be separate from that of the breast, the axillary reverse mapping (ARM) technique has been developed to identify the axillary lymph nodes and lymphatics that receive the lymph from the upper limb, and to preserve them during ALND in order to prevent arm lymphedema. However, it is difficult to keep the arm lymphatic system intact because of the lack of full understanding of anatomical variations of the ARM nodes and lymphatics in the axilla, the inconsistency of different ARM techniques in identifying the axillary ARM nodes, and the potentially high rate of ARM nodal metastases in breast cancer patients. The aims of this study was to know (1) the identification rate of ARM with fluorescence imaging (2) the distribution of these ARM nodes and (3) whether it's safe to spare the ARM nodes in breast cancer patients during SLNB or ALND.

Method: Forty female patients of primary invasive breast cancer between 28 to 69 years old were included in the prospective study. Patients who had bilateral breast cancer, the history of axillary surgery, or the history of neoadjuvant chemotherapy were excluded. Methylene blue dye was used in the SLNB procedure. The ARM procedure was carried out to all the patients with a subcutaneous injection of the fluorescent dye indocyanine green into the medial bicipital sulcus in the upper arm about 15 minutes before SLNB or ALND. During surgery, photodynamic eye was used to detect the fluorescent nodes in the axilla. The fluorescent ARM nodes in the surgical region were removed and sent for pathological examination of node metastasis.

Results: ARM was successful in 8 out of the 35 patients who underwent SLNB + ARM, in 3 out of the 5 patients who underwent ALND + ARM and in 25 out of the 35 patients who underwent ALND following SLNB + ARM. The ARM identification rate was 22.9%(8/35) in SLNB, and was 93.3%(28/30) in ALND. Totally, 119 fluorescent ARM nodes were detected, and 57.1 % (68/119) of them were located under the axillary vein, above the 2nd intercostobrachial nerve, and in the lateral of thoracic dorsal neurovascular bundle. Six out of 35 patients were found to have ARM-SLN crossover during SLNB+ARM procedure. Two out of 24 patients were found to have the ARM nodal metastases, with the pathological node stage being pN2, pN3 respectively.

Conclusion: ARM with fluorescence imaging using indocyanine green was sensitive for identification of ARM nodes in ALND with a high success rate; ARM nodes had a certain distribution pattern in the axilla; ARM should not be performed to the patients with multiple nodal metastases in the axilla.
Identifying the missing hereditary factors of familial breast cancer could have a major and immediate impact on reducing breast cancer risk in these family members.

Up to 1,325 candidate breast cancer predisposition genes, identified through exome sequencing of BRCAx families, were sequenced in index cases of up to 4,000 BRCAx families and 4,000 cancer free women from the LifePool study in Australia. Interrogation of the data to refine the highest priority candidates is ongoing, but it is noteworthy that known (PALB2) or suspected (MRE11A) moderately penetrant breast cancer genes showed enrichment of loss of function (LoF) mutations in this dataset. Conversely, some other recently proposed breast cancer genes (BRIP1 and RINT1) did not show a significantly higher LoF mutation frequency in the cases compared to controls. Based on the number of LoF mutations leading candidates include NTHL1 (12 cases versus 4 controls) and ALKBH1 (7 cases versus 2 controls) which are each important members of the base excision repair and direct nucleotide repair pathways. We examined other genes in the base excision and direct repair pathways that were on our sequencing capture design and observed a significant enrichment of potentially deleterious mutations in 12 genes (NTHL1, OGG1, APEX1, APEX2, NEIL1, NEIL2, NEIL3, MUTYH, MPG, ALKBH1, ALKBH2, ALKBH3): Among the 1,638 cases and 1,654 controls analysed to date, 76 LoF variants were detected in these genes among the cases versus 47 LoF variants among the controls ($p=0.007$). Based on the overall distribution of variants between cases and controls the probability of selecting 12 genes with such enrichment from the 1,325 genes screened was less than 1 in 200.

Our data implicates rare mutations in base excision and direct DNA repair pathways genes as moderate-penetrance breast cancer susceptibility alleles.
Body: **Background:** Mosaic findings (mutations outside of the expected 50:50 allele ratio) are often detected in the course of routine constitutional genetic testing due to the high sensitivity of next-generation sequencing (NGS) technologies. The significance of these findings is however often unclear. They can result from constitutional mosaicism secondary to an early embryological event, an acquired somatic mutation in hematopoietic cells, a technical artifact, or (less likely) a reversion event. Studies have shown that clonal hematopoiotesis increases with age, seen in up to 10% and 25% of individuals 65 and 90 years of age, respectively. Additional studies have demonstrated expansion of TP53 mutations in peripheral blood cells following chemotherapy administration. We therefore wanted to investigate the potential clinical significance of mosaic mutations found in the peripheral blood in samples submitted for hereditary cancer testing with a focus on TP53.

**Methods:** We examined high-depth NGS data from blood cell-derived DNA for mutations with pathogenic potential suggestive of mosaicism (5-30% allele frequency) in known hereditary cancer genes. For each gene, we determined the average ages of patients tested and compared these distributions to the distribution of ages of patients found to have mosaic mutations. For the mosaic TP53 mutations, we further characterized the mutations found as well as described the clinical scenarios in which the mosaic findings occurred.

**Results:** To date, 101 patients were found to have possibly mosaic mutations with pathogenic potential, including 26 cases with TP53 mutations (0.07% of patients tested), 16 with CHEK2 mutations (0.05%), and 16 with ATM mutations (0.05%). Significant bias towards older ages is seen in patients with ATM (p= 0.0026) and CHEK2 (p=4.2x10-6) mosaic findings. Mosaic TP53 and NF1 mutations were also enriched in older patients , although not as significantly as CHEK2 and ATM mosaic patients. 24/25 patients with TP53 mosaic mutations with a known history were cancer affected. In the COSMIC database, 20/20 of the TP53 mosaic mutations are associated with neoplastic conditions and 13/20 are associated with hematolymphoid neoplasms. 15/20 of the pathogenic mosaic TP53 findings were seen previously in our lab at a ratio corresponding to germline, thereby significantly lessening the possibility of technical artifact.

**Conclusion:** The statistically significant older ages of patients with ATM and CHEK2 mosaic variants suggests that many of these are acquired changes in hematopoietic stem cells rather than constitutional mosaicism per se. Although NF1 is known to be associated with constitutional mosaicism, the bias towards older patients of the NF1 mosaics we saw similarly suggests that most are acquired changes in the hematopoietic stem cells. The less significant age bias in the TP53 events suggests that chemotherapy administration may be leading to enrichment of TP53 mutated clones, although an increased rate of constitutional mosaicism cannot be ruled out.
Title: Optimized prediction of deleterious missense mutations in BRCA1 and BRCA2 genes

Hart SN N, Hoskin T, Shimelis H, Feng B, Lindor NM M, Monteiro A, Iversen E, Goldgar DE E, Suman V and Couch FJ J. Mayo Clinic, Rochester, MN; University of Utah, Salt Lake City, UT; Mayo Clinic, Jacksonville, FL; Moffit Cancer Center, Tampa, FL and Duke, Durham, NC.

Body: Approximately 15% of genetic screens for mutations in BRCA1 and BRCA2 identify Variants of Uncertain Significance (VUS). Primarily missense mutations, VUS are often difficult to interpret, leading to either uncertainty in how to properly counsel a patient or an unnecessary prophylactic surgery. Given the paucity of data for which missenses are classified as truly pathogenic, computational deleterious missense prediction (DMP) algorithms are used to predict whether a mutation is likely deleterious or neutral. Accuracy of DMPs can vary considerably and have only been calibrated on a relatively small number of missense mutations of demonstrable effect on protein function. In this study, the performance of 41 different DMPs was compared to functional data from 455 functionally characterized missense variants in BRCA1 and BRCA2. New optimized thresholds for classifying missense mutations as deleterious are presented for several existing models as well as a newly derived naïve voting method (NVM). The areas under the curve estimates for the NVM approach are between 0.889-0.922, much higher than previous methods. We estimate that the overall pathogenic potential of missense variants to be 6.8% for BRCA1 and 3.2% of BRCA2, but can be as high as 50% depending on protein location. Overall these results provide key insights into how to predict deleterious missense mutations in BRCA1 and BRCA2.
Title: Li-Fraumeni syndrome in females with early onset breast cancer in a Mexican population

Gallardo-Alvarado LN, Cantu-De Leon DF, Tusie-Luna T, Tusie-Luna I, Diaz-Chavez J, Herrera EM M, Chavez-MacGregor M, Bargallo-Rocha E, Villarreal C, Herrera.Montalvo LA A and Segura-Kato YX X. Instituto Nacional de Cancerologia, Mexico, Mexico; Instituto Nacional de Ciencias Médicas y Nutrición “Salvador Zubirán”/UNAM, Mexico, Mexico; University of Texas MD Anderson Cancer Center, Houston, TX and Genyka Diagnostico S.A.P.I de C.V, Mexico, Mexico.

Body: Background: Breast cancer in Mexican patients presents in average 10 year earlier compared to other populations. Among patients with $TP53$ mutations, breast cancer is the most common malignancy. In this study we aim to determine the rate of $TP53$ mutations among young Mexican breast cancer patients. Methods: Breast cancer patients younger that 45 were retrospectively identified, only patients without BRCA1/2 mutations were included. Clinical records and pedigrees were reviewed. Next generation sequencing test for $TP53$ was performed from blood specimens. All pathogenic mutations were confirmed by Sanger sequencing and verified if were included in the IACR TP53 database. Results: Among the 78 patients younger than 45yo evaluated and tested with next generation sequencing, we identified 5 patients with a $TP53$ mutation (6.4%). All were younger than 36 corresponding to a rate of 9.4% of mutations in this group of individuals ($n = 53$). Two, not previously described, frameshift mutations were found (c.291delC and c.273dupG) and three missense mutations (c.844C>T, c.517G>A, c.604C>T). A VUS c.672G>A that causes a silent mutation in a splicing-donor site was identified. All patients with a $TP53$ mutation had locally advanced disease and tumors were high grade and Her2 positive. Conclusions: Among Mexican women younger than 45yo, the rate of $TP53$ mutations was higher than in other populations where it's estimated to be 1%. Among patients younger than 36 the proportion was even higher. All patients had a family history suggestive of Li-Fraumeni syndrome. The VUS found in our series needs a deeper analysis (family segregation, structure and function of the resulting protein). Our results support the international recommendation of performing molecular testing for $TP53$ in breast cancer patients younger than 35 years. Identification of patients with $TP53$ mutation has important prognostic, therapeutic and quality of life implications for the proband in addition of the risk reduction strategies and intensive surveillance recommended in their families.
Title: Comparison of non-breast and ovarian cancer phenotypes of BRCA1/2 mutation carriers across multi-gene panels

Body: Background: BRCA1/2 germline mutations account for the majority of hereditary breast and ovarian cancers. Until 2013, the only way to identify individuals with BRCA mutations was through single gene testing. With multi-gene panel testing (MGPT) including BRCA1/2, BRCA mutations are being identified at an increased rate. To date, the phenotype of BRCA1/2 mutation carriers includes an increased prevalence of breast, ovarian, prostate, and pancreatic cancer, as well as melanoma. The phenotype, however, of mutation carriers identified by panel testing is not well understood.

Methods: All sequential cases submitted to our laboratory for MGPT including BRCA1/2 between June 2013 and June 2015 and BRCA1/2 single gene testing between June 2013 and February 2015 were retrospectively reviewed. Data from 77,345 test request forms were reviewed; probands with a BRCA1 or BRCA2 mutation were selected and analyzed. Probands with no personal history of cancer/not provided (n=528) were excluded.

Results: Of 2,967 BRCA1/2 positive probands, 2,439 (82.2%) had a personal history of cancer, with 2,794 cancers reported. On all tests completed, with the exception of a pancreatic cancer focused panel, breast and/or ovarian cancer were the most commonly observed cancer types (n=2,364, 84.6%). On single gene testing (n=739), prostate (n=16, 2.2%), colorectal (n=8, 1.1%), and pancreatic (n=7, 0.9%) cancers were the other most frequent cancers reported. Across all MGPT cases (n=1,700), additional observed cancers included uterine (n=48, 2.8%), colorectal (n=46, 2.7%), pancreatic (n=37, 2.2%), melanoma (n=29, 1.7%), and thyroid (n=27, 1.6%). For breast cancer-specific gene panel cases (n=934), additional cancers included thyroid (n=12, 1.3%) and uterine cancer (n=10, 1.1%). For gynecologic cancer gene panel cases (n= 482), additional cancers included uterine (n=21, 4.4%), colorectal (n=11, 2.3%), and melanoma (n=11, 2.3%). Cases tested via a pancreatic cancer gene panel (n=25,) had pancreatic cancer (n=17, 68%) reported most frequently, followed by breast (n=6, 24%), colorectal (n=3, 12%), and melanoma (n=3, 12%). For comprehensive cancer gene panel cases (n=254), colorectal (n=28, 11.0%), uterine (n=17, 6.7%), pancreatic (n=14, 5.5%), prostate (n=10, 3.9%), thyroid (n=10, 3.9%), and a variety of rare tumor types (n=15, 5.9%) were among the additional cancers reported.

Discussion: As expected, the majority of cancers reported on almost all tests were breast and/or ovarian cancer. More specifically, the observed cancers for tumor specific cancer panels, matched the relevant cancer type (i.e. pancreatic cancer most commonly reported in those tested via a pancreatic cancer panel). However, on the comprehensive cancer panels, other than breast and ovarian cancer, there appears to be a more even distribution of various cancer types, including rare tumors, in probands who have a BRCA1 or BRCA2 mutation. Further studies should be conducted to examine the phenotypes of BRCA mutation carriers identified via comprehensive cancer panels to determine the association and prevalence of unexpected cancer types with BRCA1/2 mutations. This could have important implications for determining the most appropriate genetic test and management of BRCA mutation carriers.
Body: The surge in *BRCA1/2* and multiple-gene panel testing after a diagnosis of breast cancer has fueled concerns about how genetic testing results will be integrated into patient management. However, there is virtually no research about the timing or extent of genetic counseling before or after testing or the impact of genetic results on bilateral mastectomy (BLM) use since the advent of more widespread testing. **Methods:** A population-based sample of 3600 patients newly diagnosed with breast cancer identified by two SEER registries (Georgia and Los Angeles County) were sent surveys two months after surgery (Dx dates 2014-15) about their genetic testing and treatment experiences. Survey information was merged with SEER data. We examined patterns and correlates of counseling and genetic testing and the impact of results on patient preferences for BLM and receipt of BLM. **Results:** Among 2388 patients with unilateral breast cancer (response 70%), 697 (29.2%) had elevated pre-test risk of a germline mutation (based on age, family cancer history, ancestry, and tumor subtype). One-quarter of these higher risk patients (25.6%) did not discuss whether to have testing with any provider, 26.1% discussed it with clinicians only, and 48.3% had a visit with a genetic counselor. Half of patients with elevated pre-test risk (51.2%) were tested: 6.6% before diagnosis, 65.4% after diagnosis but before surgery and 28.0% after surgery. Higher risk patients who underwent testing were younger (p<.001) and had higher income (p=.029) but rates did not differ significantly by race, education, insurance, marital status, cancer stage, comorbidities, or geographic site after controlling for all covariates. There was wide variation in the type of professional who discussed test results with patients: discussed with surgeon only (17.8%), medical oncologist only (19.7%), both physicians but no counselor (4.8%), or genetic counselors (56.8%). Among all testers in the total sample (n=667), 54 (9.4%) reported a pathogenic mutation (12.1% of higher risk patients vs 5.7% of low risk patients) and 59 (10.0%) reported a variant of unknown significance (VUS) (10.2% of higher risk patients vs 9.9% of lower risk patients), p=.027 for differences between groups. Two-thirds (60.4%) of patients with pathogenic mutations reported that the test made them more interested in BLM vs 8.8% of those with a VUS, and 11.4% of those with negative tests, p<.001. Two-thirds (69.2%) of those with pathogenic mutations received BLM vs 21.9% of those with VUS and 27.9% of those with negative tests, p<.001. **Conclusions:** Many patients newly diagnosed with breast cancer at higher risk of carrying a pathogenic mutation do not receive pre-test counseling or genetic testing and disparities are observed. There is wide variability in the timing of genetic testing after diagnosis and with which clinician the findings are discussed. Taken together, these results suggest that germline genetic testing after a diagnosis of breast cancer is poorly integrated into practice. However, the impact of genetic test results on patient attitudes and receipt of bilateral mastectomy suggests that genetic testing does help target prevention to a patient's future risk for a new primary breast cancer.
Title: Predicting germline mutations in BRCA1/2 and beyond: A comparison of women with single and multiple breast primaries

Body: Synchronous or metachronous breast primaries are a well-known indication of hereditary breast cancer, particularly within BRCA1/2 mutation carriers. However, the frequency of gene mutations within this patient group has not been well defined, especially in the setting of multi-gene panel testing (MGPT). We conducted a retrospective review of mutation carrier status in a population of females with breast cancer(s), but no other reported cancer diagnoses, and who had MGPT at a single diagnostic laboratory. Among 31,864 females tested, the following were excluded from analysis: 5389 (17%) had variants of unknown significance (VUS), 133 (0.4%) had moderate risk mutations and 316 (1.0%) had MUTYH monoallelic mutations. For the remaining 26,026 females, we evaluated whether mutation status is associated with risk of multiple breast primaries using Fisher's exact test and logistic regression analysis adjusting for age at testing, age at first breast cancer diagnosis, and mutations in other genes. The number of genes analyzed ranged from 5-49, depending on the panel ordered. Gene-specific analyses were limited to with 10 or more mutations in this cohort (ATM, BARD1, BRCA1, BRCA2, BRIP1, CDH1, CDKN2A, CHEK2, MRE11A, MUTYH, MSH6, NBN, NF1, PALB2, PMS2, PTEN, RAD50, RAD51C, RAD51D, and TP53).

In this cohort the average age of first breast cancer diagnosis was 47.7 (range 12-95) and the average age of second diagnosis was 56 years (range 17-89). A positive result (pathogenic mutation or variant, likely pathogenic) in any gene was more likely for women with three or more breast cancer primaries (p=0.007) and two or more primaries (p=1.2e-08) than those with one breast primary.

Overall, women with a mutation in any gene were more likely to have multiple primary breast cancers than those without mutations. Specifically, women with mutations in ATM, BRCA1, CDH1, PALB2, PTEN, and TP53 mutations were more likely to have multiple breast primaries than non-carriers of mutations in those genes (table 1).

Our results show that women with multiple breast primaries are more likely to have mutations in some genes than others. Interestingly, all genes with significant odds ratios are well-described and most are known to cause high risk for breast cancer, with the exception of ATM. Additional studies are needed to confirm these results and quantify risks for second primary breast cancers. With further work defining the risks of multiple primary breast cancers, this information could be implemented into clinical practice to aid women in risk management following a positive result.
Title: Mutational landscape of breast cancers from PALB2 germline mutation carriers

Body: Background: The PALB2 gene encodes the partner and localizer of the BRCA2 protein, which participates in homologous recombination during DNA repair via an interaction with BRCA1 and BRCA2. Germline mutations in PALB2 are associated with an increased risk of breast cancer, with a cumulative risk of 35% by age 70 in female PALB2 mutant carriers. The aims of this project were to characterize the genomic landscape of PALB2 breast cancers and define the differences in the repertoire of somatic genetic alterations and mutational signatures between PALB2, BRCA1 and BRCA2 breast cancers.

Methods: Representative samples from fourteen breast cancers from patients with known PALB2 germline mutations (seven frame-shift (2 H1170fs, 3 K346fs, 1 T841fs and 1 L531fs), five truncating (3 W1038* and 2 Q775*) and two missense (W1140G and L35P)) were microdissected to ensure a tumor cell content of >70%. DNA samples from microdissected tumors and their matched normal counterparts were subjected to whole exome sequencing on an Illumina HiSeq2000 to a median depth of 118x (range 33-193x). Somatic single nucleotide variations were detected using MuTect, and small insertions and deletions were identified using Strelka and Varscan2. Using ABSOLUTE and FACETS, we investigated the presence of loss of heterozygosity (LOH) of the PALB2 wild-type allele in these tumors. In addition, the mutational signatures and large scale state transitions (LSTs) were defined. The repertoire of somatic mutations identified in PALB2 breast cancers was compared to that of breast cancers from BRCA1 (n=11) and BRCA2 (n=10) germline mutation carriers from The Cancer Genome Atlas study.

Results: PALB2 breast cancers were found to harbor a median of 80 somatic mutations (range 22-286) and one somatic mutation (range 0-13) affecting known cancer genes. Somatic loss of the PALB2 wild-type allele was found in five cases, and in three additional cases, a second PALB2 somatic mutation likely constituted the second 'hit' (two with truncating mutations, Q479* and Q61*, and one with a Q921fs frameshift mutation). Six PALB2 breast cancers displayed the BRCA mutations signature; of these, five had PALB2 bi-allelic inactivation (three LOH of the wild-type allele and two a second PALB2 somatic mutation). 71% of the samples were found to have LSTs, including all cases with a BRCA mutational signature. A significant association between PALB2 bi-allelic inactivation and concurrent BRCA signature and high LST was observed (p=0.015). Breast cancers from PALB2 mutation carriers had fewer somatic TP53 mutations than BRCA1 breast cancers (3/14, 21% vs 9/11, 82%, p=0.004), but no difference in the repertoire of somatic mutations compared to that of BRCA2 breast cancers.

Conclusions: PALB2 breast cancers were found to harbor pathogenic mutations in driver genes, including TP53, PIK3CA, NF1 and NCOR1, however lacked highly recurrent somatic mutations. Unlike BRCA1/2 breast cancers, the majority of breast cancers from PALB2 germline mutation carriers lacked LOH of the PALB2 wild-type allele. Importantly, however, an association between PALB2 bi-allelic inactivation and the BRCA mutational signature and LSTs was observed, providing additional evidence for a homologous recombination-deficient phenotype at least in a subset of PALB2 cancers.
Title: Differential mutation pattern between neoadjuvant and metastatic settings in breast cancer patients

Body: Background: Dysregulated signaling pathways occur in human cancers including breast cancer, making it a rational target for novel genome guided combinatorial personalized therapies. The aim of the present study was to investigate the different genetic mutation pattern between neoadjuvant and metastatic settings in breast cancer patients to guide research and clinical treatment.

Material and Methods: 150 breast cancer patients were involved in this study. 38 patients were receiving neoadjuvant treatment and 112 patients were in the metastatic setting. Tumor specimens obtained from the 150 patients were subjected to genetic mutation testing by FoundationOne. Genetic alterations detected by FoundationOne test were collected and analyzed.

Results: 96 and 149 different genes were reported by FoundationOne in neoadjuvant and metastatic setting respectively. The average number of non-synonymous mutation was five per case in the neoadjuvant setting and six per case in the metastatic setting. TP53 (58%), MYC (32%), PIK3CA (29%), PTEN (16%), CDH1 (13%), CCND1 (11%), EMSY (11%), LYN (11%) and ZNF703 (11%) were the most seen mutations in neoadjuvant setting. TP53 (40%), PIK3CA (39%), MYC (22%), CCND1 (21%), FGF19 (21%), FGF4 (21%), CDH1 (20%), FGF3 (19%), ERBB2 (17%), ESR1 (14%), FGFR1 (14%), ZNF703 (14%), GATA3 (13%), MYST3 (11%), PTEN (11%), EMSY (10%), NF1 (10%) and ZNF217 (10%) were the most seen mutations in metastatic setting. ESR1 and GATA3, which are seen in 14% and 13% of metastatic breast cancer patients, were not reported in neoadjuvant breast patients. Moreover, among the 16 metastatic breast cancer patients who has ESR1 mutation, 9 (56%) of them presented with PIK3CA or other genetic mutations which are directly involved in the phosphoinositide 3-kinase (PI3K)/AKT pathway.

Conclusion: A significantly more mutation in Receptor Tyrosine Kinases (RTKs)/Growth Factor Signaling (especially ERBB and FGFR pathways) was reported in the metastatic setting compare to the neoadjuvant setting, suggesting a critical role of the RTKs in metastatic breast cancer patients. The coexisting of ESR1 and PI3K/AKT pathway alteration and the absence of ESR1 in neoadjuvant setting also suggested that in early stage breast cancer patients who have a PI3K pathway alterations; there is a higher chance to develop ESR1 mutation with disease progression.
Title: Molecular differences between screen-detected and interval breast cancers are largely explained by PAM50 subtypes

Body: Purpose: Interval breast cancer is of clinical interest as it exhibits an aggressive phenotype and evades detection by screening mammography. A comprehensive picture of somatic changes that drive tumors to become symptomatic in the screening interval can improve understanding of the biology underlying these aggressive tumors.

Experimental design: Initiated in April 2013, Clinical Sequencing of Cancer in Sweden (Clinseq) is a scientific and clinical platform for the genomic profiling of cancer. The breast cancer pilot study consisted of women diagnosed with breast cancer between 2001-2012 in the Stockholm/Gotland regions. A subset of 318 breast tumors were sequenced, of which 113 were screen-detected and were 60 interval cancers. We applied targeted deep-sequencing of cancer-related genes, low-pass whole-genome sequencing and RNA-sequencing technology to characterize somatic differences in the genomic and transcriptomic architecture by interval cancer status. Mammographic density and PAM50 molecular subtypes were considered.

Results: In the crude analyses, TP53, PPP1R3A, and KMT2B were significantly more frequently mutated in interval cancers than in screen-detected cancers. Acquired somatic copy number aberrations with a frequency difference of at least 15% between the two groups included gains in 17q23-q25.3 and losses in 16q24.2. Gene expression analysis identified 447 significantly differentially expressed genes, of which 120 were replicated in an independent microarray dataset. After adjusting for PAM50, most differences were no longer significant.

Conclusions: Molecular differences by interval cancer status were observed, but they were largely explained by PAM50 subtypes. This work offer new insights into the biological differences between the two tumor groups. Translational relevance: Although screen-detected cancers are biologically distinct from interval cancers in terms of somatic mutations, copy number aberrations and gene expression, most of the differences are no longer significant after adjusting for breast cancer intrinsic subtypes (PAM50). We also show that the molecular differences appear to form a spectrum from less aggressive (screen-detected) to more aggressive (interval) manifestations of the disease, which can be characterized by PAM50 subtypes, namely, luminal A, luminal B, HER2-enriched and basal-like, in that order. This work clarifies the picture on what type of breast cancer we are likely to identify through population-based screening, and what type of cancer we are likely to miss. Current knowledge of PAM50 subtype-specific risk factors need to be expanded as our findings might influence how we screen women with a higher risk of basal-like breast cancer for example, beyond known risk groups BRCA1 mutation carriers and women of African-American descent.

Title: Application of digital-PCR technology to determine c-MET copy number variation in paired primary breast cancer and brain metastases

Giannoudis A, Zakaria R, Platt-Higgins A, Syed KAR AR, Ashton K, Dawson T, Rudland PS S, Holcombe C, Jenkinson MD D and Palmieri C. University of Liverpool, ITM, Liverpool, Merseyside, United Kingdom; University of Liverpool, The Walton Centre, Liverpool, Merseyside, United Kingdom; University of Liverpool, IIB, Liverpool, Merseyside, United Kingdom; Royal Preston Hospital, Fulwood, Preston, Lancashire, United Kingdom and The Royal Liverpool University Hospital, Liverpool, Merseyside, United Kingdom.

Body: INTRODUCTION:
c-MET amplification/overexpression has been associated with treatment failure and progression in many cancers, including breast cancer (BC). c-MET showed amplification by fluorescent in situ hybridization (FISH) in 27% of trastuzumab-treated HER2-positive patients. These patients had a high trastuzumab failure rate and a shorter time to progression. Up to 50% of patients with metastatic HER2-positive disease will develop brain metastases (BM) during their disease course and in approximately one third, brain is the first site of progression. Amplification/copy number variations (CNVs) are mainly assessed by FISH whereas overexpression is assessed by immunohistochemistry (IHC). We present a PCR-based assay (digital-PCR) able to determine CNV in c-MET and HER2 in a cohort of patients with metastatic BC to the brain and demonstrate the correlation of CNV to protein expression.

METHODS:
DNA was isolated from paraffin-embedded tissues of 23 paired primary BC-BM cases. CNV was analysed by the QuantStudio™ 3D-Digital-PCR (QS3D) and real-time qPCR (both from ThermoFisher Scientific). The breast MCF7, T47D, BT474, AU565, SKBR3 and the gastric MKN45 cell lines were used as controls for the HER2 and c-MET CNV assays. Copy number per diploid genome was calculated using the absolute quantification number of FAM-labelled target and VIC-labelled RNaseP reference multiplied by 2. Cases with \( \leq 2 \) copies are classified as normal whereas cases with >2 were classified as amplified. The HER2 positivity of the primary BC cases was routinely assessed by IHC. The c-MET protein expression was assessed by IHC using the c-MET(3D4) monoclonal antibody (ThermoFisher Scientific).

RESULTS:
CNV in c-MET by QS3D digital-PCR was detected in 69.6% of primary BC (ER-/HER2+:2, ER+/HER2+:5, ER+/HER2-:8, Triple-negatives:5, unknown:3) as well as 69.6% of BM, whereas HER2 CNV was observed in 39.1% primary BC and 52.2% BM. In the HER2-positive cases, the prevalence of HER2 CNV was 100% in both primary BC and BM. Within these cases, c-MET CNV was 85.7% in the primary BC and 71.43% in BM. CNVs in both genes were observed in 30.4% of all primary and 39.1% of BM. The CNV data are presented in Table 1.

There was a high concordance between the QS3D and qPCR data with Pearson's R=0.74 (p<0.00001).
A significant correlation between HER2 protein expression and CNV was observed (Fisher's exact test p=0.0005). Data will be presented on c-MET protein expression in the pair samples.

CONCLUSIONS:
The prevalence of CNV is much higher than that reported by immunohistochemistry and FISH in the literature to date, possibly
due to the sensitivity of the digital-PCR technology. The high level of c-MET CNV in primary and metastatic BC, and the concurrent CNV in both genes warrants further investigation. It also highlights the potential to use c-MET directed therapy particularly in HER2+ BC and reinforces the potential importance of precise detection methods in both the primary and metastatic setting. Analysis of a larger series is currently on-going.

**Title:** Identification, clinical characteristics and treatment outcomes of somatic human epidermal growth factor receptor 2 (ERBB2) mutations in metastatic breast cancer patients

**Body: Background**
Metastatic breast cancer (MBC) is seen as incurable and advances in new therapies or targets are necessary. Targeted therapies against human epidermal growth factor receptor 2 (ERBB2) (also known as HER2) in tumors with ERBB2 overexpression due to gene amplification have improved patients outcomes. Besides ERBB2 amplification, this receptor can also be altered by somatic mutations (without ERRB2 amplification) that likely drive tumorigenesis. Neratinib, an irreversible pan-HER tyrosine kinase inhibitor, has recently been demonstrated to potently inhibit breast cancers that have amplification or activating mutations in ERBB2. This is the first study that thoroughly investigates the natural history of ERBB2 mutations in MBC patients. The primary study objectives are to 1) evaluate the frequency of ERBB2 mutations in a large MBC cohort, 2) understand standard clinical, pathological and patient characteristics associated with ERBB2 mutations, 3) identify other gene mutations/aberrations that may co-occur with ERRB2 mutations, 4) characterize treatment responses and outcomes to standard therapies in patients with ERBB2 mutant vs. wild-type tumors, and 5) determine if ERBB2 mutations can be detected from plasma ctDNA samples collected at baseline (not reported here).

**Patients and Methods**
This retrospective study included all MBC patients (primary metastatic or developed metastases during follow-up), independent of hormone receptor or HER2 amplification status, diagnosed between January 1st 2000 and July 31st 2015 at the Multidisciplinary Breast Center of University Hospitals Leuven, and for whom sufficient tumor material was available for DNA extraction. Extracted DNA from primary breast cancer tissues were subject to targeted NGS-based sequencing, to identify single nucleotide variants, insertion, deletion, and indels within exons 8, 17, 19, 20 and 21 of the ERBB2 gene.

**Results**
We established and validated a research use only next-generation sequencing assay across five exons of the ERBB2 gene. 1062 MBC patients were included and so far 177 patients were successfully screened for ERBB2 mutations resulting in an occurrence of n=10 (5.6%) in this population. The remaining patients are currently being screened for ERBB2 mutations and the overall results on all described endpoints will be available at the meeting.

**Conclusion**
ERBB2 mutations seem more frequent in MBC than previously thought based on the general early breast cancer population. In depth analysis of this large MBC cohort evaluating clinical characteristics and standard treatment outcomes of ERBB2 mutant MBC may provide further knowledge on this breast cancer subtype that may benefit from HER2-directed therapies which are currently under investigation in clinical trials.
Body: Background: We studied the associations between cancer gene alterations with clinical parameters in primary breast cancer (BC) samples of patients treated in either the FinHer or the FinXX adjuvant trial. These randomized trials accrued patients using similar inclusion criteria (node-positive, or node-negative with size >20 mm and PgR-) from the same centers, and had a similar control arm (3 cycles of docetaxel (T) followed by 3 cycles of CEF; T+CEF).

Methods: Mutations of 371 cancer-associated genes and copy number alterations (CNAs) of 86 genes or chromosomal regions were analyzed using next generation sequencing from the DNA extracted from formalin-fixed BCs. In FinHer, the comparator arm to T+CEF consisted of 3 cycles wkly vinorelbine (V) followed by 3 cycles of CEF (V+CEF), and in FinXX of docetaxel plus capecitabine (TX) followed by 3 cycles of cyclophosphamide, epirubicin and capecitabine (CEX; TX+CEX). Adjuvant trastuzumab was administered to patients with HER2+ BC in FinHer based on random allocation for 9 weeks with either T or V, and in FinXX to all patients after May 2005, usually for 1 yr.

Results: 1,014 BCs were analyzed for mutations and CNA alterations; 992 and 915 analyses were successful, respectively. 73.7% of the BCs were ER and/or PgR+ (cut-off 10%), 11.9% ER/PgR-/HER2+, and 14.7% triple-negative. 32 genes were mutated in ≥10 cancers, most commonly TP53 (38%), PIK3CA (33%) and GATA3 (10%); ErbB2 was mutated in 2.0% and ErbB3 in 1.3%. Mutations of genes associated with hereditary BC were frequent, CHEK2 4.8%, BRCA2 3.1%, PALB2 2.3%, BRCA1 1.7%. All 101 GATA3 mutations were found in ER/PgR+ BCs, whereas BRCA1, ErbB3, PREX2 and PIK3R1 mutations showed the strongest associations with ER/PgR- BC. TP53 and ErbB3 mutations were associated with HER2-positivity, whereas no AKT1, BRCA1 or SF3B1 mutations were detected in HER2+ BC. RB1, BRCA1, PALB2 and TP53 mutations were associated with high Ki-67%; MAP3K1, CDH1 and CBFB mutations with low Ki-67%. 70% of lobular cancers harbored mutated CDH1, whereas TP53 mutations were rare (4.5%). Presence of RAD50, PALB2, CHEK2 and TP53 were significantly associated with poor recurrence-free survival (RFS) with a hazard ratio (HR) of 4.11, 2.34, 2.22 and 1.56, respectively, whereas PIK3CA and GATA3 mutations with favorable RFS (HR 0.68 and 0.55). Lobular cancers with or without CDH1 mutation had similar RFS. The most frequently amplified genes were ErbB2 (26%), CCND1 (17%), RAD21 (14%) and c-MYC (14%). HER2+ BCs (defined by CISH or immunohistochemistry) frequently harbored amplified ErbB2 (88%), but also amplifications of ErbB3, MYB, WT1, FOXA1 and PIK3CA were associated with HER2+ BC. Amplifications of several genes significantly correlated with a negative ER/PgR-status, the ductal histological type or high Ki-67%. In the FinXX trial subset patients with mutated TP53 had unfavorable outcome when treated with T+CEF but not when treated with TX+CEX, whereas patients with mutation in one of the 11 genes involved in DNA repair had poor outcome when treated with TX-CEX, but not when treated with T-CEF.

Conclusions: Cancer gene aberrations show varying associations with the clinical and histopathological features of BC. Such molecular variations may explain in part the variations found in the efficacy of cancer drugs between clinical trials.
Title: Exome sequencing of human breast cancer tissues resistant to taxanes

Endo Y, Dong Y, Kondo N, Hato Y, Hisada T, Nishimoto M, Nishikawa S, Takahashi S and Toyama T. Nagoya City University Graduate School of Medical Sciences, Nagoya, Aichi, Japan and Nagoya City University Graduate School of Medical Sciences, Nagoya, Aichi, Japan.

Body: Background: Although taxanes are a mainstay of breast cancer treatment, some cases are resistant to these drugs. This is a crucial issue in breast cancer therapy. In the emerging era of next-generation sequencing, it is possible to obtain extensive genomic information on individual tumors in a very short time. Using this technology, it was reported that specific mutations might affect therapeutic efficacy and induce resistance to specific treatment.

Objective: The aim of this study was to investigate the mechanisms of taxane resistance using whole exon sequencing and expression analyses in human breast cancer tissues.

Materials and Methods: We selected six breast cancer patients whose tumors responded well to anthracycline treatment but suffered disease progression on taxane treatment. We then performed whole exon sequencing on these samples using HiSeq (Illumia). In this way, we identified somatic mutations of candidate genes considered to be instrumental for mediating resistance to taxanes. Next, we performed mRNA expression analyses of these candidate genes in a further 122 breast cancers treated with taxanes at our institute. Finally, we correlated mRNA expression levels of these genes with clinicopathological factors and prognosis.

Results: We identified 9 mutations common to all 6 patients analyzed in this study, and a further 16 mutations shared by 5 of them. Kaplan-Meier analyses showed that high level mRNA expression of 3 of these 25 genes was significantly associated with poorer disease-free survival. Moreover, high level mRNA expression of one of these three genes was significantly associated with worse overall survival. However, there were no significant correlations between expression levels of these three genes and any clinicopathological features.

Conclusion: Using next-generation sequencing, we have identified three candidate genes involved in resistance to taxane treatment in breast cancer. We are now analyzing the functional attributes of these three genes.

Title: Influence of mutagen exposure on molecular profile in breast cancer

Knepper TC C, Grabska J, Teer JK K, McLeod HL L and Solliman HH H. H. Lee Moffitt Cancer Center & Research Institute, Tampa, FL.

Body: Background: Molecular profiling of tumor DNA has changed the management of many cancers. For example, differences in mutations have been observed in lung adenocarcinoma between smokers and non-smokers, with the latter harboring more EGFR mutations. However, there is a paucity of information the influence of mutagen exposure on molecular profile in other cancers. This is a pilot analysis to determine if smoking history or prior adjuvant radiation has an influence on the molecular profiles of women with breast cancer.

Methods: Moffitt's Clinical Genomic Action Committee (CGAC) database was used to assess 62 patients with breast cancer treated at Moffitt with targeted deep sequencing of 315 genes as part of clinical care between 4/1/2013 and 12/31/2015. Smoking history was determined by self-report and history of adjuvant radiation therapy was abstracted from the medical record. Tumor sequencing results were analyzed for differential mutational burden (any alteration other than amplifications) and the presence of differentially altered genes between the groups of interest. The groups were similar with regards to percentage of triple negative patients (35.3% vs. 33.3%) between active/prior smokers and never smokers respectively.

Results: The most frequently mutated genes across the cohort were TP53 (54.2%), PIK3CA (40.7%), MLL3 (25.4%), CDH1, PTEN, and MLL2 (18.6%), BRCA2 and NF1 (15.3%), BARD1, ESR1, CDKN2A/B, and SPEN (13.6%). There was no difference in the mutational burden between 17 smokers (mean 10.2 alterations; range 1-21) and 42 never smokers (mean 11.5 alterations; range 4-30); p=0.35, with a trend towards more mutations in never smokers. Amongst genes with at least 10 total alterations, breast cancers of smokers contained a higher frequency of alterations in APC, BLM, and RAD50 (17.6% vs. 2.4%), PIK3CA (58.8% vs. 33.3%), MAP3K1 (23.5% vs. 7.1%), GPR124 (17.6% vs. 4.8%), and TP53 (70.6% vs. 47.6%); although none met statistical significance for multiple comparisons. On the other hand, non-smokers contained increased alterations in MLL2 (5.9% vs. 23.8%), ATM (0.0% vs. 14.3%), as well as FAT1, ATR, AR, and KDM5C (0.0% vs. 11.9%); but also did not differ to a statistically significant degree. There was no difference in the mutational burden between 26 patients without prior radiation and the 34 with prior radiation, each group had a mean of 11.1 alterations.

Conclusions: There was no difference in the mutational burden between smokers and never smokers in breast cancer or between breast cancer patients who received prior radiation therapy and those who did not.

Title: Comparison of the mutational landscape of breast cancer during pregnancy and non-pregnant controls

Loibl S, Pfarr N, Weber K, Neunhöffer T, Villegas S, Stenzinger A, Furlanetto J, Aktas B, Budczies J, Marmé F, Kahmann L, Denkert C and Weichert W. German Breast Group, Neu-Isenburg; Institute of Pathology, Technical University Munich; Helios Kliniken Wiesbaden, Wiesbaden; Institute of Pathology, Charité Berlin; Institute of Pathology, University Hospital Heidelberg; University Women’s Hospital, Essen; NCT, Section Translational Gynaecologic Oncology, Heidelberg and Klinikum Landkreis Neumarkt.

Body: Background: Currently, breast cancer during pregnancy (BCP) is not believed to be biologically different from breast cancer unrelated to pregnancy based on limited datasets mainly obtained by immunohistochemistry. However, some groups report that BCP patients have an inferior survival compared to young non-pregnant breast cancer patients. The largest analysis based on the BCP registry by the German Breast Group (GBG) revealed however, no difference between pregnant and non-pregnant breast cancer patients, indicating that treatment rather than biology might be the reason for the inferior survival reported by others.

Methods: The BCP study (GBG 29/BIG 03-02) is a multicentre observational study for breast cancer during pregnancy. In tumour tissue collected within this study from pregnant M0 patients we investigated the following genes: AKT1, ATM, BRAF, CBFB, CCND1, CDH1, CDKN2A, CTCF, EGFR, ERBB2, ESR1, FGFR2, GATA3, KRAS, MAP2K4, MAP3K1, MDM2, MED12, MYC, PIK3CA, PIK3R1, PTEN, RB1, RUNX1, and TP53 by massive parallel sequencing (MPS). This included patients with all molecular subtypes: HR+/-, HER2+-. Sequencing was done on an IonTorrent Proton using a custom designed Breast Cancer Panel (BCPv2). This panel comprises 236 amplicons split into two primer pools and covers hotspot regions of 138 exons of the 25 genes.

To test the hypothesis that breast cancer diagnosed during pregnancy is biologically not different from breast cancer diagnosed in young non-pregnant women, we compared the molecular profiles obtained, with genetic data from M0 patients not known to be pregnant from TCGA with age <= 45. TCGA data were pre-processed to be compatible to the targeted MPS datasets from pregnant patient.

Results: Material from 141 patients from the BCP study was available from which ultimately 109 fully evaluable MPS datasets could be obtained. In the TCGA data set 114 breast cancer patients <= 45 years could be identified. Pregnant patients with breast cancer were significantly younger, had more often HR- tumours (59.6% vs 30.1%) but had less frequently grade 3 tumours (30.6% vs 48.2%). All other clinical variables showed no significant differences between pregnant and non-pregnant patients. In the BCP data, overall 106 mutations could be found. The most frequent mutations were detected in TP53 (62%) and in PIK3CA (11.1%). In non-pregnant patients the mutation rates were different with 32.5% in TP53 and 21.1% in PIK3CA.

Exact matching by variables age, HR, HER2 and grade yielded 40 patients from both datasets. In these subcohorts, still divergent mutational rates for TP53 and PIK3CA between pregnant and non-pregnant women were noted, however, the differences failed to reach statistical significance.

Conclusions: Overall the mutational landscapes do not seem to be overtly different between pregnant patients and no-pregnant controls, although slight imbalances in mutational rates occurred, which might be partly explained by a selection bias and a small sample size after matching. Further comparisons using other datasets, looking into survival and regarding copy number variation are currently conducted.

This research is been funded by the German Cancer Consortium-DKTK and the BANSS Foundation.
Title: A fit-for-purpose NGS system that reports ERBB2 (HER2) mutations and copy number variants for clinical trials research and drug development

Body: Introduction: HER2-positive breast cancers comprise 20-30% by subtype and represent the second poorest prognosis. In addition to HER2 signaling activation via protein overexpression or gene amplification (measured by IHC or ISH), somatic mutations in the ERBB2 (HER2) gene have been identified in 2-4% of breast cancers and reported to drive HER2 pathway signaling and tumorigenesis. Irreversible HER2 tyrosine kinase inhibitors such as neratinib have been shown to potently inhibit breast tumors harboring somatic HER2 activating mutations and are under active clinical investigation. A targeted molecular characterization strategy is thus needed to support clinical trial research. Here, we present an integrated NGS system that identifies multiple classes of ERBB2 aberrations, including single nucleotide variants, insertion/deletion mutations, and copy number variations (CNVs).

Methods: Genomic DNA was isolated from FFPE human tumor tissues or FFPE-embedded engineered cell lines expressing ERBB2 mutations. Pre-analytical sample QC was performed by a novel qPCR assay that quantifies amplifiable DNA templates suitable for library preparation. NGS libraries were prepared using the QuantideX® NGS ERBB2 Mutations assay, with two-pool PCR-based enrichment to detect multiple types of ERBB2 genomic alterations. Libraries were sequenced (Illumina MiSeq®) and analyzed using QuantideX® Reporter software, directly incorporating the pre-analytical QC data from each DNA sample to improve variant call accuracy.

Results: The QuantideX® NGS ERBB2 Mutations system targets 28% of ERBB2 coding bases covering exons 8 and 17 - 24, including codons 713-989 of the tyrosine kinase domain. The assay also detects focal, whole-arm and polysomy-induced HER2 amplification using sentinel flanking amplicons, and amplicons covering CEN17 and copy number-neutral chromosomal regions identified in the TCGA breast cancer cohort. The assay was analytically validated in a CLIA-laboratory which included an analysis of 6 mixtures and titrations of synthesized DNA bearing 31 ERBB2 mutations, 17 engineered cell lines and FFPE cell-line blocks, and 12 surgically-resected FFPE carcinomas. A multi-day/operator study revealed 100% sensitivity and PPV for detection of ERBB2 SNVs, indels and complex variants down to 5% mutation positive in wild-type DNA. The NGS system was also used to profile ERBB2 variants in 473 FFPE human tumor tissues, including 280 breast carcinomas. Mutation-positive samples were confirmed by an orthogonal NGS method. A subset of 46 FFPE tissue samples were assessed for CNVs by NGS and compared with matched droplet digital PCR (ddPCR) analysis. A correlation of $R^2 > 0.91$ between NGS and ddPCR underscores the potential of the assay to reveal both ERBB2 mutations and copy number changes.

Conclusions: The QuantideX® NGS ERBB2 system integrates optimized wet- and dry-bench elements to achieve broad and accurate detection of ERBB2 mutations and copy number variants from challenging FFPE specimens. The technology has the potential to advance breast cancer clinical research and aid in the selection of patients for clinical trials, particularly those that assess HER2-directed therapies such as afatinib, lapatinib, and neratinib.
Title: Genomic pattern of breast carcinomas carrying mutations of non-\textit{BRCA} homologous recombination genes

Lin P-H, Kuo W-H, Wang M-Y, Lo C, Lin C-H, Lu Y-S, Chiu C-F and Huang C-S. National Taiwan University Hospital, Taipei, Taiwan and China Medical University Hospital, Taichung, Taiwan.

Body: Background

\textit{BRCA1} and \textit{BRCA2} are involved in the homologous recombination (HR) double-strand DNA break repair and genomic patterns of breast tumors with defective \textit{BRCA} are characterized by increased genomic instability. The pre-clinical and clinical studies show that tumors with defective \textit{BRCA} or other HR genes can response to platinum and PARP inhibitors. However, the genomic pattern of tumors carrying mutations of non-\textit{BRCA} HR genes are not investigated.

Methods

Genomic patterns of breast carcinomas were performed by comparative genomic hybridization (CGH) array containing 60000 probes covering the whole genome with an average spacing of 40kb. The frequency of gains and losses for each regions detected by probes was calculated by ratio thresholds of 0.25 and -0.25, respectively. Large-scale genomic structural aberration was defined as the region of gains and losses of at least 10Mb. We analyzed the difference of large-scale aberration, including numbers, length and specific regions, between tumors with \textit{BRCA} mutation (mt\textit{BRCA}), non-\textit{BRCA} HR mutation (mtHR) and wild type.

Results

We examined 41 breast carcinomas, including 15 cases with \textit{BRCA} mutations, 14 with non-BRCA HR gene mutations and 12 without mutations (control). The 14 non-\textit{BRCA} HR gene were 1 \textit{ATM}, 1 \textit{BRIPI}, 1 \textit{BARD1}, 1 \textit{FANCA}, 2 \textit{FANCB}, 1 \textit{FANCI}, 1 \textit{PALB2}, 2 \textit{RAD50}, 2 \textit{RAD51C} and 2 \textit{RAD51D}. The number and length of large-scale genomic structural aberration of mt\textit{BRCA} tumors were significantly higher than wild type tumors (number $p=0.005$; length $p=0.005$), indicating CGH can distinguish the mt\textit{BRCA} from control tumors. We then checked the mtHR tumors, which also revealed significantly increased number and longer length of structural aberrations compared to wild type tumors (number $p=0.035$; length $p=0.022$), but were not different from mt\textit{BRCA} tumors (number $p=0.204$; length $p=0.425$). Among the specific regions on chromosomes, mt\textit{BRCA} and mtHR tumors contained similar genomic aberration regions but different from wild type tumors. The most frequent aberration regions of mt\textit{BRCA} and mtHR tumors are chromosome 6p22.1-p25, 6q21-q27, 8q11.1-q24, 11p11.2-p14.1, 11q, 12p and 19p, which are less revealed in the wild type (all $p$ value $<0.05$).

Conclusions

Our study demonstrated a direct evidence that increased genomic instability were the common characteristics of mt\textit{BRCA} and non-\textit{BRCA} mtHR tumors. In addition, we identify the specific genomic patterns of mt\textit{BRCA} and mtHR tumors, which can be a biomarker indicating HR deficiency and response to platinum and PARP inhibitors.
Title: Increased stromal lymphocytes in breast cancer patients with autologous dendritic cell vaccination plus neoadjuvant chemotherapy

Body: Introduction: Higher levels of TILs after neoadjuvant chemotherapy (NAC) in the residual tumor have been related to a better outcome in BC patients. According to International TILs working group (2014), we have quantified stromal TILs in a cohort of patients treated with NAC plus dendritic cell vaccines (cohort V) (NCT01431196 plus an expanded cohort) and in an historic cohort of patients treated with the same NAC without V (cohort C) in order to assess if the addition autologous dendritic cell vaccination pulsed with patient’s tumor lysates helps to increase TILs in the residual BC specimen. Our previous data with these cohorts of patients have shown an improved pCR and the stimulation of lymphocytes population in the peripheral blood from cohort V.

Methods: Classification of molecular subtypes was performed by IHC. We evaluated percentage of TILs by three different pathologists using stained HE core biopsy sections in paired samples taken at diagnosis (preNAC) and after surgery (postNAC) in a prospectively defined retrospective analysis.

Results: 79 patients were evaluated (cohort C 42; cohort V 37). Patients from V cohort were younger (p=0.01). Cohorts were well balanced for AJCC staging, molecular subtypes (cohort C: LA 26%, LB 45%, TN 29%; cohort V: LA 24%, LB 40%, TN 35%), stromal TILs preNAC [cohort C: median 9 (range, 1-24); cohort V: 6 (1-34); p=0.38] and stromal TILs postNAC [cohort C: 9 (2-52); cohort V 8 (4-50); p=0.94]. Seventy-seven patients (97%) underwent surgery (cohort C 41; cohort V 36). Pathologic CR was higher in Cohort V (27% vs 7%; p=0.02). However a superior pCR rate was detected in TNBC subtype (cohort C 27%; cohort V 58%; p=0.15). Patients from Cohort V experienced an increment of stromal TILs after NAC plus autologous dendritic cell vaccination (preNAC: 6 (1-34); postNAC 8 (4-50); p=0.03), especially in TNBC [preNAC 14 (1-34); postNAC 30 (10-50); p=0.2]. A correlation analysis by Pearson’s R coefficient stated a strong association in V cohort between stromal TILs preNAC and postNAC (R=0.83) as well as a moderate correlation between stromal TILs postNAC and and molecular subtypes (R=0.6).

Conclusion: Pathological complete responses were higher in BC patients treated with neoadjuvant chemotherapy plus active immunotherapy. The addition of autologous dendritic cell vaccines to NAC increases significantly stromal TILs in breast cancer patients.
Title: Recognition of autologous neoantigens by tumor infiltrating lymphocytes derived from breast cancer metastases

Body: Background & Translational Relevance: Adoptive transfer of tumor infiltrating lymphocytes (TIL) can effect long-term durable regression in patients with metastatic melanoma but has not been widely tested in common epithelial cancers. When examining the TIL of successfully treated patients with melanoma, a heterogeneous T cell population can be identified with reactivity against melanoma differentiation antigens, cancer germline antigens, and personalized non-synonymous somatic mutations. Common epithelial cancers, including breast cancer, express far fewer somatic mutations than melanoma, however, a patient with metastatic cholangiocarcinoma was treated with autologous CD4+ TIL enriched for neoantigen specificity and has experienced an ongoing partial response (>2 years). It is known that the presence of TIL on pathologic examination of triple-negative breast cancers is a positive prognostic marker for disease-free survival and overall survival. The identification of enriched populations of neoantigen-specific TIL could form the basis for personalized cell therapy for patients with metastatic breast cancer. This pilot study investigates the ability to grow TIL from breast cancer metastases, to identify personalized non-synonymous somatic mutations and potential neoantigens, and to adoptively transfer TIL into patients with breast cancer.

Methods: Eligible patients were evaluated and treated under IRB-approved protocols for tissue procurement, genomic testing, and adoptive cell transfer. Portions of resected tumors were placed in culture under standard TIL conditions. DNA was extracted from tumor and matched normal peripheral blood samples for whole exome sequencing (WES). Non-synonymous somatic mutations were identified and tested for potential immunogenicity.

Results: Nine patients have undergone surgical resection in this ongoing pilot study, and TIL was successfully grown from the tumors of all patients. All were primarily CD3+ (median 79%) with a small population of natural killer cells. Of the CD3+ cells, 7 of 9 patients had a predominantly CD4+ population (median CD4:CD8 ratio 2.2, range 0.4-5.8). With the exception of a single patient with inflammatory breast cancer, tumor purity allowed for WES of the tumors of eight patients, and non-synonymous somatic mutations were identified as potential neoantigens (median 96.5, range 71-148). Autologous T cell reactivity has been identified against tumor-specific mutations in 4 of 6 patients studied. The TIL of one patient demonstrated in vitro reactivity to a mutated form of RBPJ, a DNA-binding protein involved in Notch1 signaling. In addition, specimens obtained from this patient at autopsy contained the specific RBPJ mutation (RBPJ c.A611T) in every sampled tumor (n=16). Other patient-specific neoantigens identified by autologous reactivity include SLC3A2, KIAA0368, and a mutated TCRBV domain.

Conclusions: Tumor-infiltrating lymphocytes derived from metastatic breast cancer can react to tumor-specific non-synonymous somatic mutations in vitro. TIL grown from breast cancers are predominantly CD4+ and can form the basis of an adoptive cell transfer experimental approach to patients with metastatic breast cancer.
Title: Differential effect of chemotherapy on immune gene expression signatures based on molecular subtype of breast cancer

Hicks MJ J, Estrada MV, Sanders ME E, Salgado R, Cook RS S, Arteaga CL L and Balko JM M. Vanderbilt University, Nashville, TN; Vanderbilt University Medical Center, Nashville, TN; Vanderbilt University Medical Center, Nashville, TN; Vanderbilt University Medical Center, Nashville, TN and Jules Bordet Institute, Brussels, Belgium.

Body: Background: Neoadjuvant chemotherapy (NAC) is frequently used in triple negative breast cancers (TNBC), and patients who achieve pathological complete response (pCR) following NAC have improved outcomes over those with residual disease (non-pCR). Unfortunately only 30% of TNBC patients achieve pCR, with no good treatment options for other 70% with non-pCR. Tumor infiltrating lymphocytes (TILs) in TNBC are predictive of pCR to NAC, and TILs found in the residual disease further prognosticate patients with residual disease into an improved prognosis subset. These data suggest there is an immune component to TNBC that might be affected by chemotherapy. Given the advent of immunotherapy trials in breast cancer, specifically in combination with NAC, there is an unmet need to gain a better understanding of the immune microenvironment in TNBC.

Objective: We investigated the role of NAC on the immune microenvironment by examining breast cancer samples before (diagnostic biopsy) and after (residual disease) NAC, as these data are pertinent to the design and analysis of ongoing clinical trials in breast cancer combining immunotherapy with concurrent chemotherapy.

Methods: RNA was extracted from 51 paired (pre- and post-NAC) breast cancer specimens with extensive residual disease, and analyzed by nCounter analysis for expression of >750 immune-related genes. Functional immune signature scores were generated, compared between matched pre- and post-NAC, and stratified by breast cancer molecular subtype (luminal (n=4), Her2-enriched (n=5), basal-like (n=17)). DNA extracted from a subset of these samples was utilized for T cell receptor sequencing to explore changes in T cell clonality following NAC in each subtype.

Results: Across all subtypes of breast cancer, immune scores decreased after NAC consistent with a broad decrease in TILs observed histologically. When samples were stratified by molecular subtype using the PAM50 analysis, luminal A/B and basal-like patients demonstrated a decrease in immune signatures after NAC, while Her2-enriched patients exhibited a global increase in immune scores. Importantly, basal-like patients had the greatest immune signature changes, including decreases in T cell functions and CD8+ T cell, T helper and T regulatory signatures (p>0.05). Conversely, these signatures were increased after NAC in the Her2-enriched molecular subtype. Analyses of T-cell clonality are ongoing, but should yield insight into the effect of NAC on the landscape of effector T-cells in the micro-environment.

Conclusions: Our work suggests that NAC decreases immune infiltrate signatures, specifically related to effector T cells in patients who do not achieve pCR. However, we observed an increase after NAC in the same signatures in Her2-enriched patients, suggesting that these patients’ tumors may respond differently to chemotherapy on the immune-molecular level. As clinical trials progress in TNBC with the combination of chemotherapy and immune therapy, more work is needed to understand who might benefit from these therapy regimens.
Title: BRCA gene mutations do not shape the extent and organization of tumor infiltrating lymphocytes in triple negative breast cancer

Body: The remarkable responses observed in metastatic cancer patients treated with immunotherapies, including inhibitors directed to the PD-1 and PD-L1 checkpoint molecules, makes it a priority to identify critical variations in pro- and anti-tumor immune responses in breast cancer (BC). In patients with triple negative (TN) BC, an increased presence of tumor infiltrating lymphocytes (TIL) and tertiary lymphoid structures (TLS) have been associated with good clinical outcomes. However, the frequency of specific lymphocyte subpopulations, PD-1 and/or PD-L1 expression and their prognostic significance remains an open question. Our recent work found that PD-1 and PD-L1 expression are specifically associated with higher TIL densities and an increased number of TLS in BC. We further demonstrated that TIL density, TLS and PD-L1 expression were correlated with more aggressive breast tumor characteristics, including higher proliferation and hormone receptor negativity. In this project, we examined the prevalence of TIL, TLS, PD-1 and PD-L1 expression in TNBC and further compared these immune parameters between TNBC patients harboring BRCA1 or BRCA2 germline gene mutations with those carrying the wild-type (wt) genes. A total of 1402 BC patients whose blood was genetically tested for germline BRCA1 and BRCA2 mutations were examined for inclusion in this study. Ninety-eight chemotherapy-naïve patients with primary invasive ER−, PR− and HER2− BC and demonstrated germline BRCA1 or BRCA2 wt or mutated-gene status were included in this study. Ninety-four tumors were determined to be suitable for evaluating immune cell infiltration (51 BRCA wt and 43 BRCA-mutated). FFPE tumor tissue from the surgical specimens was analyzed by immunohistochemistry (IHC) staining of full-face tissue sections. IHC was performed as a dual label using CD3 plus CD20 for T and B cells, CD4 plus CD8 for the major T cell subpopulations and PD-1 plus PD-L1 for individual or paired expression of these receptors. The stained slides were independently scored by two experienced pathologists for TIL, TIL subpopulations, TLS and checkpoint molecule expression.

These analyses revealed that 87% of our TNBC cohort was TIL-positive (≥10% TIL) with 35% classified as lymphocyte predominant BC (LPBC; ≥50% TIL). T cells were the principal component of the lymphocytic infiltrate with no significant differences between the BRCA wt and BRCA-mutated groups detected in total T cells (CD3+), helper T cells (CD4+), cytotoxic T cells (CD8+) or B cells (CD20+). TLS were identified in 73% of tumors with again no significant differences between the BRCA groups. Examination of checkpoint molecule expression identified 33% tumors as PD-1 positive and 40% as PD-L1 positive. PD-1 expression was correlated with PD-L1 expression and both with TIL positivity and the level of immune infiltration but not BRCA mutational status.

Overall, our analyses revealed that BRCA wt and BRCA-mutated TNBC are remarkably similar in terms of TIL heterogeneity, a TLS presence and checkpoint molecule expression. These data suggest that BRCA gene mutations are not immunogenic nor do they directly drive immune infiltration in TNBC.

**Title:** Immunomodulation effects of metronomic oral Vinorelbine (mVRL), with or without capecitabine (CAPE), on Treg levels in advanced breast cancer (ABC) patients (pts). Preliminary results of the VICTOR-5 study

Cazzaniga ME E, Baroni S, Riva F, Vigorè L, Malandrin S, Cicchiello F, Pelizzoni D, Lissoni P, Manfrida I, Brando B and Bidoli P. ASST Monza; Immunology Unit - ASST Monza and Laboratory Unit - Legnano.

**Body:**

**BACKGROUND**

In cancer patients, the accumulation of Tregs is associated with tumor progression and the suppression of anti-tumor immune response. Metronomic cyclophosphamide (mCTX) induces a profound and selective reduction of circulating Tregs, whereas no data are available regarding a possible effect on immune system. In the present analysis, we report preliminary data of Treg frequencies and function during a period of treatment of 2 months and correlations with anti-tumour T-cell response, in a group of HR+/HER2ve ABC pts.

**PATIENTS AND METHODS**

Following approval by the Ethical Committee, a sample of 3 ml of peripheral blood was drawn from 12 ABC pts for which mVRL 40-50 mg thrice a week (N=10), ± mCAPE 1500 mg/day (N=2), was indicated. Median age was 66.5 years (45-86); 2/12 received the mCHT as 1st-line therapy, 10/12 as 2nd-line or further. Blood samples were collected at baseline (T0) and after 14 (T1), 28 (T2), 42 (T3) and 56 days (T4) of treatment. Total lymphocytes (TL) and lymphocyte subgroups were determined according to NaacK et Al guide lines. The Treg subpopulations have been identified by monoclonal antibodies CD45 V500, CD3 V450, CD4 PerCP-Cy5.5, CD25 PE, CCR4 PE-Cy7, CD 27 Alexa 647, CD45RO APC-H7, CD28 FITC, (BD Biosciences, San Jose, CA) and analyzed with BD FACS Canto™ II (Becton Dickinson, San Jose, CA), technic Lyse/Wash and software FACSDiva™.

**RESULTS**

Data for the purpose of this analysis are available for 10 out of 12 enrolled pts. mVRL ± mCAPE induced a significant reduction of circulating Treg in 6/10 pts (60%) – Group A - at day 14. Median percentages of Treg among CD4+ cells were 9.4% ±1.5% SE at baseline vs 6.8% ± 4.5% SE and 7.6% ± 1.2% SE after 14 and 28 days of treatment in Group A. In patients without Treg depletion – Group B – median percentages of Treg were 8.4% ± 0.9% SE, 9.6% ± 1.3%SE and 8.2% ± 1.5%SE as measured at the same time points. The depletion of Treg is associated with a slight expansion of CD8+ cells in Group A at all times of evaluation. No increase in CD8+ population has been observed in Group B. Median percentages of Treg and CD8+ cells in the two Groups are reported in Tables 1 & 2.

CONCLUSION
Our results suggest that mVRL induces different immunomodulation effects in an unselected population of ABC pts. Treg depletion seems to increase the adaptive immune response. Data obtained from a longer follow up will be presented. These findings are hypothesis-generating for future evaluation of mVRL as a priming agent to increase response to anti PDL-1 agents.
Title: Targeting of the unfolded protein response signaling arms differentially regulates macrophage proliferation, plasticity, and breast cancer cell clearance

Cook KL L, Wilson A, Westwood B and Soto-Pantoja DR R. Wake Forest University, Winston Salem, NC.

Body: The unfolded protein response (UPR) is an endoplasmic reticulum stress pathway controlled by the protein chaperone, glucose-regulated protein 78 (GRP78), to mediate inositol-requiring enzyme 1 (IRE1), PKR-like endoplasmic reticulum kinase (PERK), and activating transcription factor-6 (ATF6) signaling. UPR signaling has been shown to be upregulated in many different types of cancers, including breast cancer and melanoma, and is associated with the development of therapeutic resistance. These data suggest the importance of targeting UPR signaling as a possible cancer therapy. We have previously shown GRP78 to be upregulated in human breast tumor samples and leads to endocrine targeted therapy resistance. We recently showed inhibiting GRP78 in human orthotopic xenografts potentiates tamoxifen therapy effectiveness in sensitive tumors and restores endocrine therapy responsiveness in resistant tumors. In these GRP78-inhibited tumors there was a significant increase of CD68 positive macrophage population, suggesting that targeting UPR signaling has critical effects on the tumor microenvironment. Therefore, consideration of each UPR signaling component and how it effects the different cellular compartments of the tumor microenvironment need to be investigated to optimally induce both an antitumor immune effect and inhibit tumor epithelial cell growth. We now show deletion of GRP78, IRE1, and PERK through RNAi differentially regulates macrophage polarization. Specifically, PERK inhibition enhances macrophage proliferation and macrophage-mediated phagocytosis of 4T1 breast cancer cells, but not GRP78 or IRE1 inhibition. Targeting UPR signaling in the breast cancer cells also differentially affected macrophage cytolytic capacity; Specific breast cancer cell inhibition of IRE1 or GRP78 enhanced macrophage-mediated phagocytosis. Conditioned media from control or GRP78 silenced ZR-75-1 breast cancer cells indicated reciprocal regulation of CD206 and CD80; suggesting regulation of macrophage plasticity by GRP78-controlled secreted factors. GRP78 targeting in mice resulting in a cytokine shift and increased tumoral CD80+/CD68+ cells, suggesting that GRP78 inhibition favors a M1-like macrophage profile. Inhibition of UPR components in both macrophage and breast cancer cells, similar to what would be observed in systemic cancer therapies, indicated that either PERK or GRP78 inhibition enhances macrophage cytolytic clearance of breast cancer cells. Taken together, these data suggest that targeting GRP78 or PERK promotes an anti-tumor immune response by either directly promoting macrophage cytolytic activity (PERK targeting) or indirectly by shifting tumoral cytokine secretion (GRP78 targeting).
Title: Immune profiling of post neoadjuvant high metastatic risk (RCB-II/III) residual disease in patients with early triple negative breast cancers

Body: Background: Poor prognosis in TNBC can be predicted in the significant fraction of patients with large volume residual cancer burden (RCB-II/III) after neoadjuvant chemotherapy (NACT). Whilst residual disease has been characterised to identify “driver” mutations and copy number variations, the contribution of the immune response within its tumour microenvironment remains unclear. Here we aimed to: 1) assess the potential spatial heterogeneity of immune transcript related gene expression between areas of tumour approximately 1cm apart as might still occur with a radiologically guided biopsy through the residual disease; and 2) assess the immune stroma composition of the TNBC high metastatic risk RCB II/III disease.

Method: 12 TNBC post NACT RCB II/III residual cases were identified from the KHP biobank. H&E sections were reviewed and areas of tumor 1cm apart within a residual resection specimen marked as area A and area B. HistoQuest analysis software was used to quantify the proportion of tumor infiltrating lymphocytes (per total cell count) within both areas. RNA was extracted from both areas and immune gene expression profiling performed using a Nanostring nCounter® on all 24 samples. The immune PanCancer panel consisted of 770 genes combining markers for different immune cell populations. Differential genes between paired samples were compared and unsupervised hierarchical clustering using 770 genes and immune cell types performed.

Results: Quantitative comparison of the tumour infiltrating lymphocytes (TILS) between area A and B revealed that 73% (8/11) of the cases had a <2-fold difference in the percentage of TILS within a residual specimen; and 27% (3/11) displayed a >2-fold (range 2.03-3.16) difference in the TILS. When comparing the 770 gene expression profiles between sampling areas in the same tumour, we found little spatial heterogeneity with areas A/B clustering together in 10 out of 12 cases. Interestingly, the two cases that revealed spatial heterogeneity within the paired samples displayed little immune cell heterogeneity histologically (i.e. <1-fold change in the TILS percentage score between area A and B). Comparing patient samples by immune gene expression profiling divided the patients into two groups: i) those with immunologically enriched tumors in whom gene signatures for majority of the immune cell types (DC, Macrophages, CD8+ T-cells, T-helper cells (Th17, Th2, Th1), Tregs, NK, B-cells, Neutrophils, Mast cells) were highly expressed and ii) those with immunologically inert tumors in whom the immune cell signatures were not highly expressed. Within our patient cohort, patients with immunologically enriched gene expression profiles were also seen to display higher TILS score (ranging between 28.17% to 40.66%) as compared to patients with immunologically inert gene expression with scores ranging from 11.82% to 16.80%.

Conclusion: The findings that high metastatic risk residual disease can be further characterized as either “immunologically inert” or “immunologically enriched” at the level of extensive immunological transcript gene expression and by histological assessment of TILS requires further investigation; and is being validated in a larger sample set.
Title: BGB324, a selective small molecule inhibitor of the receptor tyrosine kinase AXL, enhances immune checkpoint inhibitor efficacy in mammary adenocarcinoma

Body: The AXL receptor tyrosine kinase is associated with poor overall survival in breast cancer. Axl signaling is an important regulator of tumor plasticity related to epithelial-to-mesenchymal transition (EMT) and stem cell traits that drive metastasis and drug resistance. Signaling via AXL is also a key suppressor of the anti-tumor innate immune response. AXL is expressed on several cells associated with the tumor immune microenvironment including natural killer cells, dendritic cells and tumor-associated macrophages. AXL is required for tumor immune evasion in mammary adenocarcinoma models and EMT-mediated resistance to cytotoxic T cell and natural killer (NK)-cell mediated cell killing. Hence AXL signaling contributes uniquely to both tumor cell intrinsic and microenvironmental anti-tumor immune suppression mechanisms in breast cancer. We evaluated whether blocking AXL signaling with BGB324, a selective clinical-stage small molecule Axl kinase inhibitor, enhances the effect of immune checkpoint blockade in the aggressive mammary adenocarcinoma (4T1) syngeneic (Balb/C) mouse model that display limited immunogenicity.

Immune therapy with anti-CTLA-4/anti-PD-1 increased AXL and EMT-marker expression in 4T1 tumors, and correlated with lack of response to immune therapy. Combination treatment with BGB324 (50 mg/kg bid) significantly enhanced responsiveness to anti-CTLA-4/anti-PD-1 treatment (10 mg/kg of each, 4 doses) in Balb/C mice bearing established 4T1 tumors. The combination of BGB324 + anti-CTLA-4/anti-PD-1 resulted in durable primary tumor clearance in 23 % of treated mice versus 5.6% obtained with anti-CTLA-4/anti-PD-1 alone (p=0.0157). In a separate study, BGB324 + anti-CTLA-4 treated resulted in 22% long-term primary tumor clearance while no response was observed with anti-CTLA4 treatment alone. The extensive metastasis to the lung, liver and spleen characteristic of this model were concomitantly abrogated in the animals responding to the combination treatment. In addition, BGB324 + anti-CTLA-4/anti-PD-1 treated tumors displayed enhanced infiltration of cytotoxic T lymphocytes (CTLs). Enhanced presence of CTLs was also detected in spleens from animals responding to treatment. BGB324 + anti-CTLA-4/anti-PD-1 treatment increased the number of NK cells, macrophages and polymorphonuclear neutrophils, but decreased the number of mMDSC. Importantly, responding animals rejected orthotopic 4T1 tumor cell re-challenge, demonstrating sustained tumor immunity.

Together with recent results in other tumor types that support a prominent role for AXL in resistance to immune therapy and encouraging results from ongoing clinical trials with BGB324, support combining BGB324 with immune checkpoint inhibitors to improve treatment of breast cancer.

**Title:** The prognostic and predictive effect of tumor infiltrating lymphocytes is not determined by B-cells or PD-L1 expression in inflammatory breast cancer

Van Berckelaer C, Parizel M, Van Dam P, Dirix L, Rypens C, Bertucci F, Schats KA A, Kockx MM M, Van Laere S and Colpaert C. Centre of Oncological Research (CORE), University of Antwerp, Antwerp, Belgium; GZA Sint-Augustinus, Wilrijk, Belgium; Multidisciplinary Oncology Centre Antwerp, Gynaecologic Oncology Unit, Antwerp University Hospital, Edegem; Département d’Oncologie Médicale, CRCM, Institut Paoli-Calmettes, Marseille, France; Immunohistochemistry, HistoGeneX, Antwerp, Belgium; Molecular Pathology, HistoGeneX, Antwerp, Belgium and Antwerp University Hospital, Antwerp, Belgium.

**Body: Background**

The tumor stroma with tumor infiltrating lymphocytes (TILs) plays a crucial role in the aggressive inflammatory breast cancer (IBC) phenotype and a gene signature enriched for immunity-related genes showed that response to neo-adjuvant chemotherapy was associated with immunity related processes in IBC. In both IBC and non-inflammatory breast cancer (nIBC), tumors are infiltrated by B-cells, but their role in regulating anti-tumor immunity is not well understood. In this study we looked at the prognostic and predictive effect of B-cells in the immune infiltrate of 178 IBC and 247 nIBC patients.

**Methods**

TIL scoring was done on standard H&E stained sections of formalin-fixed paraffin-embedded pre-treatment tumor tissue according to international guidelines (Salgado et al., 2015). B-cells in the immune infiltrate were defined as CD79α (clone JCB117) positive cells and scoring was done semi-quantitatively, both intra- and peritumorally. Slides, stained with a validated PD-L1 assay (clone SP142) were scored on immune cells (IC) according to Herbst et al., 2014.

**Results**

Most of our IBC patients presented with a grade 3 (67.7%), ductal (91.1%) carcinoma. A quarter of the patients (25.7%) with initially localized disease (71.6%) achieved complete pathological response (pCR) after neo-adjuvant chemotherapy. The mean TIL score was 18.02% (1.0 – 80.0) and 67 out of 156 patients (42.9%) were PD-L1 positive. Categorical scores of the immune infiltrate are summarized in the table.

<table>
<thead>
<tr>

<td>8.6 % (n= 15)</td>
<td>13.5 % (n= 23)</td>
</tr>
</tbody>
</table>

TILs were significantly higher in oestrogen receptor negative (ER-) groups compared to ER+ groups (21.26% vs. 15.58%, p= 0.017). In IBC, univariate analysis showed that achieving pCR was significantly associated with more TIL infiltration (p< 0.001), PD-L1 IC expression (p= 0.013) and intratumoral CD79α scores (p= 0.036). However, in multivariate analysis the effect of PD-L1 and CD79α positive cells was lost. When corrected for different molecular subtypes the predictive effect of TILs was only present in ER- groups. Survival analysis showed a significant beneficial effect of TILs (p= 0.014) but only in the ER+ groups, while PD-L1, intra- and peritumoral CD79α scores were not significant. Intratumoral CD79α scores correlated with both TIL score (p= 0.024) and PD-L1 expression (p= 0.007) in multivariate analysis.

When comparing IBC to nIBC, TILs were significantly higher in IBC patients (15.58 % vs. 11.29%, p= 0.009) in the ER+ group, while in the ER- group they were significantly lower (21.27% vs. 37.19%, p < 0.001). This was also seen for CD79α peritumoral positivity, but logistic regression revealed that this was a TILs effect.

**Conclusion**

A high TIL score correlates with a better OS and pCR in IBC, depending on the ER status. B-cells and PD-L1 expressing IC
appear not to contribute to this effect, but do correlate independently with each other. Further research is needed to unravel the driving and targetable components of the immune responses in IBC.
**Title:** High-affinity activated natural killer (haNK) cells augment trastuzumab efficacy in a mouse model of HER2-positive human metastatic breast cancer

**Body: Background.** The ability of NK cells to kill cancer cells makes them an attractive choice for clinical immunotherapy. Early phase clinical trials in patients (pts) with advanced cancers have demonstrated the safety of activated NK (aNK [NK-92]) cells, an investigational cell line that was established from the peripheral blood mononuclear cells of a pt with non-Hodgkin lymphoma. NK cells can participate in antibody-dependent cellular cytotoxicity (ADCC) mediated by recognition of the Fc fragment of the target-bound antibody (IgG) via the CD16 Fc receptor. Among pts with HER2-positive breast cancer treated with trastuzumab (IgG) the high-affinity CD16 V/V genotype was significantly correlated with better clinical outcomes (Musolino. *JCO*. 2008;26:1789-96). To enhance the killing activity of aNK cells, we modified aNK cells to stably express high-affinity CD16 and evaluated the resulting haNK cells in combination with trastuzumab in a mouse xenograft model of HER2-positive human breast cancer.

**Methods.** haNK cells were generated by transfection of aNK cells with a bicistronic plasmid coding for CD16 (158V) and an intracellular form of IL-2, which enables haNK cells to grow in the absence of exogenous IL-2. Female, 7 to 8-week-old NOD-scid IL2Rgamma^{null} (NSG) mice were inoculated subcutaneously in the left and right flank area with 0.1mL of 1x10^8/mL MDA-MB-453 human breast cancer cells in 50% Matrigel. When tumors reached ≥100mm^3, mice were randomly assigned to 10 groups of 4 mice per group and dosed (IV) with PBS, 1 or 3mg/kg IgG, 1 or 3mg/kg trastuzumab (determined from a dose range finding study), 1x10^7 non-irradiated haNK cells, or non-irradiated haNK cells in combination with IgG or trastuzumab. The dosing schedules were: PBS/haNK cells twice weekly for 4 weeks; IgG/trastuzumab once weekly for 4 weeks. For the combination treatments, mice received antibodies at least 3h prior to the injection of haNK cells. Tumor growth and animal weights were measured twice weekly.

**Results:** Results obtained after 4 weeks of treatment are shown in the table. haNK alone and both doses of trastuzumab alone significantly inhibited the growth of human MDA-MB-453 breast tumors. The combination of haNK plus 1mg/kg trastuzumab was synergistic with a T/C value of -60.1%.

**Conclusions:** The combination of haNK cells and trastuzumab was synergistic at 1mg/kg trastuzumab resulting in tumor regressions and significantly better efficacy vs each agent alone. Trastuzumab monotherapy at 3mg/kg was very effective and likely masked any synergistic effect of haNK. This study illustrates the potential for combining haNK cells with trastuzumab in a clinical trial of pts with HER2-positive metastatic breast cancer.

Title: Promotion of immunogenicity using epigenetic modulation and immune checkpoint inhibition in mouse models of breast cancer

Roussos Torres ET T, Ma H, Armstrong T, Connolly R, Stearns V and Jaffee EM M. Johns Hopkins Hospital, Baltimore, MD.

Body: Checkpoint inhibition has been a very successful treatment strategy in cancers that are naturally immunogenic by attracting T cells into the tumor microenvironment (TME) and promoting cytotoxic signaling pathways. While this strategy has shown some efficacy in metastatic breast cancer, most breast cancers are not highly immunogenic likely due to an immunosuppressive microenvironment and a lack of tumor antigen expression and recognition. One strategy to transform the breast TME into one that is immune responsive, is to use epigenetic modulation to expose tumor antigens and promote cytokine production, which in turn will attract T cells into the tumor. Additionally, dissection of the specific inhibitory mechanisms including checkpoint pathways that inhibit T cell attraction and function in breast tumors, will inform combination therapies that effectively activate the immune response. This approach could open the door for successful immunotherapy approaches for breast cancer patients. We are using two different mouse models, a syngeneic transplantable model using the triple negative breast cancer cell line 4T1 in BALB/C mice; as well as the Her-2/neu (neu-N) transgenic model. These models will allow us to study the efficacy of different combinations of an epigenetic agent, the histone deacetylase inhibitor Entinostat, and checkpoint inhibitors anti-programmed cell death protein (PD1) and anti-cytotoxic T-lymphocyte-associated protein 4 (CTLA4) antibodies, on tumor growth and metastatic progression, and to help identify co-stimulatory and inhibitory factors regulating T cell responses. Characterization of tumor infiltrating lymphocytes and their functional capabilities are being investigated in both primary tumors and within metastatic foci using fluorescence-activated cell sorting and immunohistochemistry. BALB/c mice were inoculated in the mammary fat pad with the highly metastatic 4T1 cell line. Thus far, there seems to be a trend toward incomplete tumor regression in mice treated with combination anti-PD1, anti-CTLA4 and Entinostat. There is also a trend toward improved survival in the combination treatment group. Additionally, similar results are seen using the transgenic neu-N mouse model whereby, combination therapy leads to a delay in tumor progression and improved survival. Preliminary results also suggest that epigenetic modulation with Entinostat improves the immune response within these tumors as evidenced by detection of different T-cell populations and myeloid derived suppressor cells (MDSCs) within treated tumors. Thus far, in both the 4T1 and neu-N models of breast cancer, treatment with Entinostat seems to prime the TME to be more immunogenic by altering the population of T cells and MDSCs in the tumor. Combination therapy with anti-PD1 and anti-CTLA4 affect tumor growth and further modulate the immune response; however, the specific signaling pathways involved have yet to be elucidated. Given these observations, we hypothesize that triple combination therapy will significantly affect specific immune modulatory pathways and we hope to uncover the specifics of how these pathways are leading to improved overall outcome.
Title: Targeting of phosphatidylserine by monoclonal antibodies enhances the activity of immune checkpoint lag3 targeting antibodies in murine breast tumors

Body: Previous preclinical modeling has demonstrated that antibodies targeting the programmed cell death ligand 1 (PD-1) have activity in murine breast cancers (BC), and this activity is significantly enhanced when combined with phosphatidylserine (PS) targeting antibodies. This suggested that the addition of PS targeting antibodies could be capable of augmenting anti-tumorigenic properties of other checkpoint inhibitors and alternative immune activating therapies in BC. The ability of PS targeting antibodies to enhance the activity of anti-PD-1 therapy occurs in part through increasing tumor infiltrating lymphocytes (TILs), boosting the Th1 immuno-profile, and the suppression of tumor promoting cytokines induced by anti-PD-1 therapy. PS normally resides in the inner leaflet of the plasma membrane in many types of cells. Conditions that incite cellular stress in the tumor microenvironment, such as ROS, hypoxia, and irradiation, promote PS externalization and exposure on tumor associated endothelial cells and tumor cells, where it is recognized by specific receptors, including members of TIM and TAM family. This PS recognition promotes an innate system driven immunosuppressive condition in part by promoting the recruitment of myeloid derived suppressor cells (MDSCs), M2-like macrophages, and suppressing dendritic cells maturation, while inducing anti-inflammatory cytokines. To identify additional immuno-therapeutic targets that may have activity when used in combination with PS targeting antibodies, we employed bioinformatics analysis on tumors from murine triple negative breast cancer (TNBC) treated with PS and PD-1 targeting antibodies, alone or in combination. Interestingly, expression of the lymphocyte activation gene 3 (LAG3) increased in each treatment arm, suggesting it may be a potential target for combinational therapy in breast cancers. To test this hypothesis, immune competent mice harboring the murine TNBC line E0771 were treated with a PS targeting antibody or a LAG3 targeting antibody as single agent or in combination. Our data demonstrate that while PS-blocking and anti-LAG3 therapies each have efficacy in E0771 as single agents, combinational treatment significantly improved growth inhibition and was capable of increasing TILs, including CD8 + and CD3 + T-cells, while reducing the population of MDSCs. Overall, our data suggest that LAG3 targeting may also represent a viable option for the treatment of breast cancer and that the addition of PS targeting antibodies to LAG3 therapy can effectively increase the anti-tumor and immune-activating effects mediated by additional T-cell checkpoint therapies.
Body: Background
Immune checkpoint therapy only benefits a fraction of patients, thus huge efforts have been made to develop predictive biomarkers to identify those patients. Immune biomarkers like PD-L1 expression are extremely dynamic and the timing of evaluation, on primary or metastatic disease, may be critical. We have already shown that tumour-infiltrating lymphocytes (TILs) decrease during metastatic progression in triple-negative (TN) and human epidermal growth factor-2 positive (HER2+) breast cancers (Ogiya R, ASCO 2015), suggesting that mechanisms of immune escape contribute and favour the metastatic progression. In this work we aimed to characterize the modulation and changes of specific immune markers during the metastatic spread comparing paired samples from primary and recurrent breast cancers.

Methods
We retrospectively identified 25 patients with HER2+ (n = 14) and TN (n = 11) early breast cancer diagnosed between 1990 and 2009 at Tokai University Hospital, and who subsequently experienced a first regional or distant recurrence confirmed by tumour biopsy/resection. Haematoxylin and eosin-stained slides of these paired samples were evaluated for stromal TILs. Immunohistochemical staining was performed using primary antibodies against CD4, CD8, Foxp3, PD-L1, PD-L2, and HLA-class I.

Results
The sites of first recurrence was the skin (n = 7), brain (n = 6), lymph node (n = 4), lung (n = 3), bone (n = 2), and one of each of bone marrow, liver and muscle. Immunohistochemical evaluations could not be performed in 5 primary tumours and 2 recurrent tumours because of the small quantity of the specimens. The percentage of CD8+ T cells staining in the primary tumours was significantly higher (median 16%) than that in recurrent tumours (median 10%) (paired t-test, p = 0.008). Similarly, the percentage of CD4+ T cells staining in the primary tumours was significantly higher (median 40%) than that in recurrent tumours (median 25%) (p = 0.026). The percentage of Foxp3+ T cells was low (<10%) and similar in both primary and recurrent tumours (p = 0.16). PD-L1, PD-L2, and HLA class I antibody expression was not statistically different between primary and recurrent tumours, but conversions from positive to negative and vice versa were observed. PD-L1+ staining (≥1%) was 90% and 85% in primary and metastatic tumours, respectively.

Conclusions
Tumours at first metastatic recurrence in HER2+ and TN breast cancers have a lower percentage of both CD8+ and CD4+ T cells compared to primary tumours, confirming a potential role of immune escape in tumour progression. Other immune markers, including PD-L1, were not found to change significantly, but negative/positive conversions were observed. This suggest that an evaluation of disease at the time of immunotherapy administration might be more informative. These findings warrant larger confirmation studies.
Title: T cell profile associated with regional lymph node progression in breast cancer

Adhikary S, Guo Y, Sieling PA A and Lee DJ J. John Wayne Cancer Institute, Santa Monica, CA.

Body: In 2015, the FDA has approved use of seven immune therapies for cancer, an unprecedented level of approval. Most of these immune therapies involve elicitation of a T cell response against the tumor. In order to advance these therapies into additional tumor types, we must gain a better understanding of the role T cells play in antitumor immunity and immune surveillance. There is still a dearth of information on the role of T cells in human breast and breast cancer to allow immune therapies to have the success in breast cancer as in other tumors. One of the limiting factors in studying breast T cells is the availability of sufficient biopsy tissue from the excision of primary tumors. In this study using a 3-D tissue explant approach, previously described for skin T cells, we expanded tumor infiltrating T cells from fresh breast cancer tissue and examined phenotypic and functional qualities of breast T cells using multiparameter flow-cytometry and multiplex Luminex assay. Examination of the expanded breast tumor infiltrating T cells showed presence of both CD4 and CD8 T cells with CD4 T cells at slightly higher frequency (means CD4 54% vs. CD8 35%, p=0.07). Analysis of memory populations utilizing expression of the memory markers CD45RO and CD62L revealed the dominant phenotype to be the effector memory (EM) subtype (CD45RO+, CD62L-) in both CD4 and CD8 compartments (means CD4 69% and CD8 65%). When samples were grouped by clinical information, we found that the T cell profile from breast tissue of breast cancer patients showed a distinct T cell profile associated with regional lymph node progression (LN+) vs. disease localized to the primary site (LN-). We found that the frequency of effector type CD8 T cells (EFF) (CD45RO-CD62L- subtype) was higher in breast tumor tissue of patients without lymph node metastasis (LN-) than those with metastasis (LN+) (means 32% vs 12%, p= 0.01). Similar pattern was observed in CD4 compartment, although the overall frequency of CD4 EFF cells was much lower than CD8 (means 5% vs 1%, p= 0.04). Analyses of culture supernatant of the expanded T cells via multiplex Luminex assay showed robust production of cytolytic granule proteins at basal state. Levels of granzymes A and B were significantly higher in culture supernatants of breast tumor infiltrating lymphocytes of LN- patients compared to LN+ patients (3815 vs 1645 pg/mL, p=0.005, 500 vs 268 pg/mL, p=0.04, respectively) while there was no difference in the levels of perforin. More importantly the frequencies of total CD4 or CD8 T cells were not significantly different in breast tumor tissue of LN- vs LN+ patients (means CD4 57% vs. 51%, p=0.6, CD8 30% vs. 40%, p=0.3). Lymph node status is the single most important indicator of disease-free survival and overall survival in breast cancer. Our observation of a distinct T cell profile associated with lymph node metastasis strongly suggests that our 3-D explant method of T cell expansion could serve as an important profiling / prognostic tool. Furthermore, our finding of higher levels of granzymes associated with LN- disease status begs consideration of including these molecules during selection of T cells for adoptive T cell therapy in breast cancer.
Title: Abstract Withdrawn
Body: Background: The presence of tumor-infiltrating lymphocytes (TILs) is a prognostic factor in triple-negative breast cancer (TNBC). In particular, cytotoxic CD8+ cells are associated with favorable outcome in TNBC. Recently, the integrin CD103 have been suggested as a potential prognostic marker in a small cohort of triple-negative/basal-like breast cancer (Wang et al, *Clin Cancer Res* 2016). In this study, we aimed to evaluate the functional status and clinical relevance of CD8+ and CD103+ TILs in TNBC.

Methods: A large collection of formalin-fixed, paraffin-embedded tissues was retrospectively collected from 210 patients with primary invasive ductal TNBC. The presence of CD8, CD103 and the checkpoint receptor PD-1 was assessed by immunohistochemistry. Whole tumor slides were independently assessed by two pathologists blinded for patient characteristics and outcome. Cases where $\geq 5\%$ of TILs expressed CD103 or PD-1 were considered positive. Statistical analyses were performed using Spearman's correlation, Kaplan-Meier and Cox regression analyses.

Results: We found that CD103+ cells mostly co-expressed the CD8 marker, and were preferentially distributed within tumor epithelium. No consistent correlation was found between the presence of CD103+ lymphocytes and the expression of its ligand E-cadherin by TNBC cells ($r_s=0.365$). CD8+ lymphocytes were consistently associated with better relapse-free survival (RFS) and overall survival (OS) in both univariate (HR=0.61; $P=1.06\times 10^{-2}$ for RFS; HR=0.59; $P=1.93\times 10^{-2}$ for OS) and multivariate analysis (HR=0.65; $P=2.45\times 10^{-2}$ for RFS; HR=0.63; $P=3.96\times 10^{-2}$ for OS). The presence of CD103+ lymphocytes significantly correlated with prolonged RFS and OS in univariate analysis only (HR=0.82; $P=4.12\times 10^{-2}$ for RFS; HR=0.85; $P=4.93\times 10^{-2}$ for OS), and a trend for longer RFS was also observed in univariate analysis for PD-1 (HR=0.71; $P=5.22\times 10^{-2}$). Interestingly, a subset of TNBC showed co-expression of CD103+/PD-1+ in lymphocytes localized to the intraepithelial areas of the tumor.

Conclusions: The expression of CD103 on CD8+ T cells in direct contact with cancer cells may identify a subpopulation of cells with potent cytolytic activity. The interaction between CD103+ cytotoxic lymphocytes and cancer cells is mediated by mechanisms other than the binding to E-cadherin. Even though CD103 has a role in mediating an effective anti-tumor immune response, its presence alone may not be sufficient to impact the outcome of TNBC patients. Immunomodulatory therapies may be useful to boost the anti-tumor activity of potentially quiescent CD103+/PD-1+ cells in a subgroup of TNBC.
Title: Directing NK cells to Trop-2-expressing breast and other cancers, with chimeric antigen receptors

Body: Adoptive immunotherapy with chimeric antigen receptor (CAR)-engineered T or NK cells is in active clinical and preclinical development, with recent interest increasingly focused on advancing the availability of off-the-shelf allogeneic clonal NK cell lines capable of targeting tumors with appropriately designed CARs. Among the human NK cell lines established, the IL-2-dependent NK-92 is the most studied and has been transduced with human IL-2 to generate NK-92MI, which exhibits cytotoxicity similar to NK-92, and is independent of IL-2 for its cytotoxicity, viability and proliferation. We report the assembly of E1.BB.3z-92MI, a novel CAR-NK for potential therapy of diverse Trop-2-expressing breast, lung, bladder, ovarian, and other cancers. The Trop-2-specific CAR, referred to as hRS7-CAR, consists of the CD8α signal peptide, the V\textsubscript{K} and V\textsubscript{H} of hRS7 (a humanized anti-human Trop-2 mAb used in the antibody-drug conjugate, IMMU-132), the hinge region and transmembrane domain of CD8α, the intracellular domains (ICD) of 4-1BB, and the ICD of CD3ξ. The construct of hRS7-CAR is introduced into NK-92MI either by electroporation of the mRNA synthesized in vitro, or by inoculation with the lentiviral particles harvested from the 48-h supernatants of Lenti-X 293T cells transduced with pLVX-puro-hRS7-CAR.

The presence of hRS7-CAR in E1.BB.3z-92MI was probed by Western blot using an HRP conjugate of a rat anti-id antibody against hRS7, which detected a distinct band of about 50 kDa from the cell lysates of NK-92MI transfected with hRS7-CAR mRNA, but not from the mock-transfected NK-92MI. As the calculated molecular weight of hRS7-CAR is about 51 kDa, these results support that hRS7-CAR is produced in NK-92MI cells transfected with hRS7-CAR mRNA. Additional evidence by flow cytometry shows about 41% of NK-92MI cells transfected with hRS7-CAR mRNA are alive at the time of analysis and 25% of this subpopulation expresses hRS7. The cytotoxicity of E1.BB.3z-92MI was evaluated against the Trop-2-expressing, human breast cancer cell line, HCC1806, in 96-well plates (4,500 cells/well) at 3 different effector-to-target (E/T) ratios (1:1, 2:1, or 4:1). As shown in the Table, the results of the MTS assay indicate that NK-92MI cells transfected with hRS7-CAR mRNA significantly killed more HCC1806 cells at the E/T ratio of 2:1 or 4:1, in comparison to mock-transfected NK-92MI. Another study performed by flow cytometry using dye-labeled HCC1806 at the E/T ratio of 3:1 indicates that the specific lysis of HCC1806 cells by NK-92MI cells transfected with hRS7-CAR mRNA was about 2-fold higher than that observed for mock-transfected NK-92MI. Finally, the initial results obtained for NK-92MI cells transduced with the lentiviral pLVX-puro-hRS7-CAR show about 70% viability and greater than 30-fold higher MFI in the live population than the control transduced with pLVX-puro or not transduced. Together, these results demonstrate the feasibility of developing E1.BB.3z-92MI as a novel CAR-NK for targeting Trop-2-expressing cancers, including breast cancer.

**Title:** JAK2 and PD-L1 amplification enhance the dynamic expression of PD-L1 in triple negative breast cancer

Chen M, Pockaj B, Andreozzi M, Barrett MT, Ocal IT Tolgay, McCullough AE E, Krishna S and Anderson KS S. Center for Personalized Diagnostics, Biodesign Institute, Arizona State University, Tempe, AZ; Public Laboratory, Tianjin Medical University Cancer Institute and Hospital; Tianjin Medical University, Tianjin, China; School of Biological and Health Systems Engineering, Arizona State University, Tempe, AZ; Mayo Clinic, Phoenix, AZ; Mayo Clinic, Phoenix, AZ and Mayo Clinic, Phoenix, AZ.

**Body: Background:** Triple negative breast cancer (TNBC) is a heterogeneous disease. Amplification of chromosome 9p24.1 encoding JAK2 and PD-L1 has been reported in up to 25% of TNBC and is associated with poor clinical outcome. In lymphoma, JAK2 is a transcriptional activator of both PD-1 ligands, and chromosome 9p copy number gain has been associated with therapeutic activity of nivolumab. We evaluated the interaction of JAK2 and PD-L1 expression in TNBC.

**Methods:** 9p24.1 amplification in 4 TNBC cell lines (MDA-MB-231, MDA-MB-436, HCC1937, and HCC70) was measured using array comparative genomic hybridization (aCGH). Amplification was defined as aCGH log_2 ratio \(>2.0\). Cell surface expression of PD-L1 was detected by flow cytometry and compared with the median fluorescence intensity (MFI) of isotype control Ig. To selectively inhibit JAK2, lentiviral vectors encoding two different shRNA were generated. JAK2, pSTAT1 and pSTAT3 expression were measured by immunoblot. The effects of the anti-JAK1/2 inhibitor ruxolitinib and interferon-gamma (IFN-\(\gamma\)) induction of PD-L1 was measured.

**Results:** 9p24.1 copy number loss was measured in MDA-MB-231 (log_2 ratio \(=-1\)), neutral in HCC1937 (log_2 ratio \(=0\)), gained in MDA-MB-436 (log_2 ratio \(=+1\)) and amplified in HCC70 (log_2 ratio \(=+2\)). No correlation was observed between PD-L1 expression and the 9p24.1 amplification, with the MFI ratio range from 5 to 16.5, mean 8.3 by flow cytometry. TNBC cell lines had higher baseline expression of PD-L1 compared to the ER+ cell lines T47D and MCF-7 (ratio, 0 p=0.1). Low dose IFN-\(\gamma\) (1.0-10.0 ng/ml) rapidly induced expression of PD-L1 in MDA-MB-231 (1.5 fold increase) and HCC70 (3.3 fold increase) with significant activation of the JAK2/STAT1 pathway. The induction of pSTAT1 and PD-L1 expression by IFN-\(\gamma\) was blocked with low dose (1mM) JAK1/2 inhibitor ruxolitinib. Knockdown of JAK2 with shRNA (\(>80\%\)) did not impact PD-L1 baseline expression in MDA-MB-231 and HCC70 but abrogated IFN-\(\gamma\)–mediated induction of PD-L1 and the phosphorylation of STAT1.

**Conclusion:** These data suggest that TNBC cell lines have baseline PD-L1 expression, but the cells with 9p24.1 amplification are highly sensitive to PD-L1 induction with IFN-\(\gamma\) which can be abrogated with inhibition with a JAK1/2 inhibitor or shRNA. Synergistic inhibition of PD1/PD-L1 and JAK2 may have therapeutic efficacy in the subset of TNBC with 9p24.1 amplification, and the dynamic effects of tumor PD-L1 expression in response to local inflammation should be considered in the evaluation of PD-1/PD-L1 checkpoint blockade.
Title: Elucidating the tumor immune microenvironment phenotype in early stage untreated BRCA mutated breast cancer patients

Body: Background: Increased stromal tumor infiltrating lymphocytes (TILs) are predictive and prognostic for improved outcomes from neoadjuvant or adjuvant chemotherapy in triple negative breast cancer. Increased tumor mutational burden may promote neoantigens causing immune system upregulation. Microsatellite instability in gastrointestinal cancer predicts for response to checkpoint inhibition and is associated with inherited cancer predisposition. The immune system response in BRCA mutated breast cancer has not been described. The purpose of this study is to assess tumor infiltrating immune cells in early stage breast cancer patients with and without BRCA gene mutations.

Methods: We retrospectively investigated 124 early stage breast cancer patients with BRCA mutations (n=62, BRCA+) and without BRCA mutations (n=62, BRCA WT). The %TILs was measured manually by H&E. Our control group consisted of age, stage, and receptor status matched early stage untreated breast cancer patients who were deemed BRCA WT by extended gene panel testing or were negative for BRCA 1/2 and had a posttest probability of harboring an autosomal dominant mutated gene of ≤ 1% using the Bayes-Mendel algorithm. We used a two-sample binomial arcsin approximation to detect a 20% difference in TILs between cohorts to attain 80% power with a one-side alpha of 0.05. Wilcoxon Rank-Sums test was used to compare differences in the central tendencies for continuous variables. We used the Nanostring PanCancer immune profiling panel to immunophenotype a portion of the BRCA+ and BRCA WT cohorts and used nSolver for quality control, normalization, and bioinformatics analyses.

Results: Here we report TILs from the first 21 patients of our study. Thirteen patients harbored BRCA mutations and eight patients did not. All patients were HER2 negative. Eight (61%) and four (50%) patients were hormone receptor positive (HR+) in the BRCA+ and BRCA WT cohorts, respectively. Median %TILs were not significantly different between the BRCA+ (15, range 0-70) and BRCA WT (17.5, range 5-60; p=0.7) groups. Median %TILs in the HR+/BRCA+ (12.5, range 0-50) and HR-/BRCA+ (15, range 5-70) cohorts were not statistically different when compared to HR+/BRCA WT (10, range 5-15; p=0.4) and HR-/BRCA WT (30, range 20-60; p=0.2) cohorts, respectively. There were 2 patients with lymphocyte predominant breast cancer (n=1, HR-/BRCA+; n=1, HR-/BRCA WT).

Conclusions: This is the first study to characterize TILs and a tumor immune microenvironment phenotype in early stage breast cancer patients with BRCA mutations. These results suggest harboring a BRCA mutation is not associated with increased TILs in early stage untreated breast cancer patients. This conclusion stayed true regardless of hormone receptor status. However, a trend of decreased TILs was seen in HR-/BRCA+ patients when compared to those with HR+/BRCA WT disease. Moreover, the median and range of TILs were higher in the HR+/BRCA+ group compared to the HR+/BRCA WT group. This suggests increased TILs may exist in some HR+ patients with a BRCA mutation. Further investigation of TILs and immune profiling of early stage untreated breast cancer patients with and without BRCA mutations is warranted.
**Title:** PD-L1 expression in triple negative breast cancer (TNBC) is associated with improved outcomes

Mardones MA A, Grosser D, Levin MK K, Daoud Y, Palucka K, O'Shaughnessy J and Osborne C. Baylor University Hospital, Dallas, TX; Texas Oncology, Dallas, TX; The Jackson Laboratory, Farmington, CT and Center for Clinical Effectiveness Baylor Scott and White Health, Dallas, TX.

**Body:**

**Background:**
Breast cancer (BC) evolution is influenced by tumor microenvironment. Presence of CD8+ cytotoxic T lymphocytes (TILs) has been proposed as surrogate marker of adaptive immune response, and programmed death ligand-1 (PD-L1) is a negative regulator of the tumor immune microenvironment. However, whether PD-L1 expression adversely affects breast cancer outcome is unknown (Oncotarget 2014; 6:5449). Tumor-associated macrophages (TAMs) in the tumor microenvironment may contribute to BC progression and metastagenicity. We assessed the potential correlations between PD-L1 expression, the presence of TAMs and TILs, and BC outcomes.

**Methods:**
59 primary BCs (16 HR+, 16 HER2+, and 27 TNBC) with known clinical and pathological features and patient (pt) follow-up for a median of 3.9 years were evaluated by immunohistochemistry for expression of CD8, CD68, and PD-L1 within tumor and stroma. The average number of CD8+ cells within 10 high power fields was determined separately for invasive tumor cell nests and for stroma within each sample, and the median number of CD8+ cells within tumor vs stroma was calculated (Breast Cancer Res Treat 2011 128:703–711). Non-lymphocyte mononuclear cells in tumor and stroma were used in counting CD68+ TAMs. BCs were positive for CD8+ TILs (Cell Marque clone #C8144B) or CD68+ TAMs (Cell Marque clone #KP1) if the number of cells positive in the sample was greater than the median. PD-L1 (Dako 28-8 pharmDx) was positive if at least 1% of tumor cells expressed PD-L1. The log-rank was used to compare the survival and progression free survival between groups and Spearman's rank-order correlation tests were conducted to determine associations between CD8, CD68, and PD-L1.

**Results:**
57% of TN, 26% of HER2+ and 13% of HR+ BCs expressed PD-L1 in tumor. TNBC pts received anthracycline/ taxane chemotherapy (62%) or taxane therapy alone (22%). HR+ and HER2+ pts received standard endocrine therapy and trastuzumab-based therapy. Stromal CD8+ TILs were associated with improved OS in the overall population (log rank p=0.026). In TNBC, PD-L1 expression was positively correlated with the presence of TILs (p=0.0002) and TAMs (p=0.0005) as well as with improved 3 year PFS and OS (log rank p=0.04 and p=0.03, respectively). Furthermore, stromal CD8+ TILs and stromal CD68+ TAMs correlated positively with each other in the TNBC group (p=0.0094).

**Conclusions:**
PD-L1 expression correlated with TILs and TAMs in TNBC and was associated with a favorable outcome. PD-L1+ TNBCs with high levels of TILs and TAMs may be primed for exceptional response to immunogenic chemotherapy alone. Whether some pts with PD-L1+ TNBCs with high TILs/TAMs will benefit additionally from an anti-PD-L1/PD-1 agent is being investigated currently.
Abstract Withdrawn
Cancer genome sequencing and new technologies to identify immunogenic tumor mutations have offered an unprecedented opportunity to target tumor-specific neoantigens for effective cancer treatment with the vaccination strategy. However, lack of potent adjuvants to effectively stimulate antigen-presenting cells and promote sustained antigen processing and presentation in the immunosuppressive microenvironment has severely limited therapeutic cancer vaccine development. Our recent study has shown that porous silicon microparticle (PSM) is an ideal adjuvant for therapeutic cancer vaccines (Xia et al: Cell Reports 2015, 11:957-966). PSM can 1) stimulate expression of type I interferons in dendritic cells through TRIF/MAVS-dependent signal transduction pathways leading to dendritic cell maturation, 2) synergize with soluble adjuvants to promote dendritic cell maturation, 3) facilitate intracellular antigen transport and mediate antigen processing in lysosomes and proteosomes, 4) enhance dendritic cell accumulation in secondary lymphoid tissues of tumor-bearing mice, and 5) serve as a reservoir for sustained release of tumor antigen and soluble adjuvants. Treatment of murine models of HER2 positive breast cancer with a PSM-based therapeutic cancer vaccine activates and expands antigen-specific CD8+ T cells and promotes a Th2-to-Th1 transition in the tumor microenvironment, leading to potent inhibition of tumor growth and metastasis. In summary, PSM-based cancer vaccine is a promising immunotherapeutic agent for effective treatment of human cancers including cancer types that are traditionally considered as weakly immunogenic.
Title: A monoclonal antibody against hypo-glycosylated bone sialoprotein II has application for diagnostic purposes in samples of breast cancer patients and for treatment of skeletal metastasis caused by MDA-MB-231 breast cancer cells in rats

Body: The SIBLING protein bone sialoprotein II (BSP) has been implicated in lytic skeletal metastasis as it is expressed in a subset of primary breast cancers and can be detected at elevated levels in the serum of patients with increased risk to develop skeletal metastasis. The aim of this study was to investigate the potential application of a rat monoclonal antibody against hypo-glycosylated BSP (IDK1) for diagnostic and therapeutic purposes.

The diagnostic part of this study was based on breast cancer specimens from the biobank / repository of the Institute of Pathology of the Municipal Hospital Kassel, Germany. Immune-histochemical analyses were performed with IDK1 for comparing BSP expression between ten human primary breast tumor sections and their corresponding bone metastatic tissue samples. The therapeutic part of this study was based on a model in nude rats, in which the rats were implanted with human MDA-MB-231 breast cancer cells for selective and orthotopic appearance of osteolytic skeletal lesions. Tumor bearing rats were treated with IDK1 starting at two or four weeks after tumor cell inoculation into the femoral artery of one hind leg. Tumor growth was monitored by light emission, caused by luciferase mediated metabolism of luciferin. Photon emission was recorded at regular intervals by a Xenogen IVIS 100 imaging system. After sacrifice, samples of lesions and apparently healthy tissues were investigated by H&E staining as well as by immune-histological staining for BSP.

BSP staining was found within the cytoplasm of tumor cells. Increased expression of BSP was also detected in healthy bone cells, e.g. osteoblasts, as soon as breast tumor cells invaded bone tissue. An elevation of BSP expression near necrotic centers was also found. Expression of BSP in primary breast tumors was positively correlated with BSP expression in bone metastases. Furthermore, bone metastases showed higher and more intensive expression of BSP than their respective primary breast tumors (p<0.0039).

In the experimental treatment part, all but one untreated tumor bearing rats showed rapid tumor growth accompanied with lytic destruction of femur and tibia of the respective hind leg (18/19; tumor take rate 95%). In contrast, rats treated with the anti-BSP antibody did not show a significant increase in light emission nor a clinical deterioration. In fact, 8 of 10 rats receiving the antibody at a dose of 10 mg/kg/week starting at two weeks after tumor implantation did not show any light emission after 4 to 6 weeks (p = 0.01 versus control) as well as 6 of 10 rats receiving the antibody at the same dose starting at four weeks after tumor implantation (p < 0.05). Radiological and histological examination confirmed that animals without light emission were free of tumor growth, corresponding to a complete remission.

In conclusion, the rat monoclonal antibody directed against BSP is a powerful tool with potential for diagnostic and therapeutic applications in breast cancer skeletal metastasis and warrants further development.

Title: Changes of tumor-infiltrating lymphocytes and programmed death-ligand1 positivity after neoadjuvant chemotherapy in patients with locally advanced breast cancer

Choi YJ, Lee JH, Moon SY, Choi JY, Jung SP, Bae JW and Park KH. Korea University Anam Hospital, Seoul, Republic of Korea.

Body: Background
Recently, the balance in immune system between immune surveillance and tolerance is known to be associated with the prognosis of breast cancer patients. The aim of this study was to investigate changes of tumor-infiltrating lymphocytes (TILs) and programmed death-ligand1 (PD-L1) status after neoadjuvant chemotherapy (NAC) and their impact on recurrence in patients with locally advanced breast cancer.

Methods
Paired samples (before and after NAC) of triple negative or HER2+ breast cancer tissue were obtained from clinical stage II or III patients (n=39) undergoing NAC and subsequent breast resection. The assessment of immunohistochemical (IHC) staining for PD-L1 were performed. Immunostaining of forkhead box P3 (Foxp3) and CD4/CD8 were performed for subtyping of TILs in triple negative breast cancer (TNBC) only. Clinicopathologic data including baseline characteristics, tumor response and recurrence were reviewed.

Results
Proportion of PD-L1 (+) tumor cells in pre-chemotherapy tissue was 20% (5/25) in HER2+ and 28.6% (4/14) in TNBC. It could not predict pathologic complete response. Most post-chemotherapy tissue (21/24) showed same PD-L1 positivity with pre-chemotherapy tissue. The rest showed the decreased PD-L1 positivity after NAC.

In cases of TNBC, the increased number of CD8+ T cells was significantly associated with PD-L1 positivity in pre-chemotherapy tissue. (p=0.001) Foxp3+ T cell proportions decreased significantly (p=0.046) and CD8+/Foxp3+ T-cell ratio increased significantly (p=0.023) after NAC. The patients with increased number of CD8+ T cells after NAC had a tendency to live longer without recurrence compared to patients with decreased CD8+ T cells (62.3 vs 38.1 months, p=0.158).

Conclusion
Our data provides the clinical evidence that PD-L1 positivity are associated with CD8+ T cell proportion and increased CD8+ T cells after NAC might be good prognostic marker. The role of immunologic balance as a prognostic marker for recurrence must be evaluated in future study.

Title: Breast cancer patients after kidney and liver transplantation: A Report from Asan medical center

Jung I and Kim HJ. Asan Medical Center, College of Medicine, University of Ulsan, Seoul, Song Pa, Republic of Korea.

Body: Background: Improvements in immunosuppressant and operation have resulted in long life expectancy of transplantation. Immune mechanism becomes important issue while cancer development and progression. This study was to evaluate the nature of post transplant breast cancer(PTBC) compared with breast cancer in general population, and to evaluate the relationship between immunosuppression and breast cancer development.

Methods: Using information from three asan medical center databases between 1989 and 2014, including asan medical center breast cancer (AMCBC) database, Kidney transplantation database and liver transplantation database, two cohort composed of PTBC cohort and normal breast cancer control cohort. Survival were compared the patients who received breast cancer operation before 2008.

Results: After median 58.3 month after liver transplantation, 10 patients were diagnosed as breast cancer and 23 patients after median 108.3 month kidney transplantation (p<0.001) Mean age of breast cancer were 53.2±8.5 years old in liver transplantation patients and 44.2 (±4.8) years old in kidney transplantation patients. The age in kidney transplantation patients was significantly younger than general breast cancer population (44.2±4.8 years old, 47.52±10.0 years old respectively, p=0.006). Asymptomatic screening were the detection method of 33.4% of PTBC cohort but 21.0% of control cohort (p<0.001) On PTBC cohort, 21.3%(10 patients) were stage 0 breast cancer compared with 9.4%(1002 patients) in control cohort(p<0.001), 90% (28) patients were lymph node negative tumor compared with 62.9% (6669 patients) in control group (p<0.001). Estrogen receptor, Progesteron receptor, Her2 positivity were not difference between cohorts. On multivariate analysis, immunosuppressant is not a poor prognostic factor for breast cancer patients (HR 1.319 95%CI 0.329-5.287).

Conclusion
The age of breast cancer diagnosis was younger in the patients who received kidney transplantation. PTBC patients have early breast cancer due to early detection and prognosis was comparable compared with general breast cancer patients. Immunosuppressnats does not adversely affect breast cancer prognosis.
Title: Identifying patient-specific neoepitopes for cell-based and vaccine immunotherapy across breast cancer classifications reveals rarely shared recurrent neoepitopes

Nguyen A, Sanborn JZ, Vaske CJ J, Rabizadeh S, Niazi K, Soon-Shiong P and Benz SC C. NantOmics LLC, Santa Cruz, CA; NantOmics LLC, Culver City, CA and Chan Soon-Shiong Institute of Molecular Medicine, Culver City, CA.

Body: Introduction: Targeted therapies for breast cancers such as trastuzumab and everolimus have durable clinical benefits for patients that express the relevant biomarkers (HER2 and mTOR respectively). Triple negative breast cancer patients lack these biomarkers and are left with few options. Recent advances in immunotherapy agents against PD-1/CTLA4 for patients with melanoma have yielded amazing clinical benefits for a subset of patients and may have similar results in breast cancer patients, but again the vast majority of patients still undergo disease progression. We analyzed whole genome sequencing (WGS) and RNA sequencing data from The Cancer Genome Atlas (TCGA) to identify neoepitopes among breast cancer patients that could be used to develop next-generation, patient-specific cancer immunotherapies. Neoepitopes are tumor specific markers that arise from mutations acquired from cancer and may represent a path to targeted therapies even in triple negative breast cancers.

Results: We analyzed 99 breast cancer patients from TCGA, containing a mixture of PR+/HER2+/ER+ and TNBC classifications. These breast cancer patient samples were selected by the availability of whole genome sequencing (WGS) data, RNA-sequencing data as well as clinical outcome data. We identified an average of 680 potential neoepitopes per patient based solely on WGS data. To further refine and select high quality neoepitopes we restricted these neoepitopes based on gene expression yielding an average of 304 expressed neoepitopes per patient. We predicted each patient's HLA typing using only omics data, which we then used to predict HLA-expressed neoepitope binding analysis resulting in an average of 11 high-quality tumor specific neoepitopes per patient. We identified few recurrent neoepitopes that were bound and expressed, indicating the need for a personalized medicine approach.

Conclusions: Within the TCGA dataset, the majority of neoepitopes among patients with breast cancer were unique to each patient. Rarely within subsets of breast cancers such as HER2+, we identify neoepitopes that are shared between patients. For breast cancer patients who do not respond to targeted therapies, high-throughput identification of neoepitopes could serve as the basis for the development of next-generation, patient-specific immunotherapies.
Title: CTLA-4 and PD-1 checkpoint inhibitors enhance individually tailored adaptive anti-tumor immune responses to overcome tumor immunosuppression and effectively treat triple-negative breast cancer

Body: Despite a lack of unifying drivers in Triple-Negative Breast Cancer (TNBC), our lab and others have uncovered that these cancers have elevated expression of inflammatory genes and immunosuppressive molecules (i.e. PD-L1), as well as elevated numbers of infiltrating immune cells (including CD8+ T-cells and Foxp3+ T-regulatory cells) which suggests the therapeutic potential for single and combinations of checkpoint blockade antibodies. While early trials with PD-1 inhibitors have been encouraging for TNBC, only a fraction of treated patients respond to this therapy. To test and define the mechanisms that govern responses, we explored the utility and mechanistic basis of both PD-1 and CTLA-4 inhibition in generating tumor-specific immunity in an established murine model of TNBC.

Consistent with patient samples, we found TNBC tumors from our model exhibited elevated PD-1+ expressing CD8+ T-cell infiltrates, Foxp3+ T-regulatory cell infiltrates (~66% of CD4+ TILs), as well as highly elevated tumor cell expression of PD-L1. We also found that while TNBC cells were easily killed by T-cell in vitro, TNBC tumors were highly immuno-suppressive and resistant to antigen-specific T-cell attack in vivo, even after adoptive transfer of up to 5x10E6 tumor-specific T-cells. However, we found that both CTLA-4 and PD-1 antibodies could curtail this immunosuppression to different degrees and through alternate mechanisms. Specifically, we found that CTLA-4 antibody mediated anti-tumor immunity through the elimination and blockade of Foxp3+ T-regulatory cells in the tumor microenvironment, which allow for potent T-cell expansion. Conversely, PD-1 antibodies elicited anti-tumor immunity through blockade of PDL1/PD1 signaling between tumor cells and T-cells in the TNBC tumor microenvironment that allowed for a more modest expansion of individually tailored T-cell specific clones in vivo.

Strikingly, the combination of these antibodies and their alternate mechanisms of action resulted in greatly enhanced anti-tumor responses and led to regression of ~80% of tumors. This was accompanied by an augmented infiltration of T-cells into the tumor microenvironment and significantly enhanced systemic tumor-specific T-cell responses, which appear to be emergent properties of dual CTLA-4/PD-1 antibody treatment.

However, we found that these treatments did not expand a common tumor-specific T-cell clone, despite adoptive transfer of identical tumor-specific immunodominant T-cells into mice after tumor implantation. Thus, despite our use of a highly homogeneous model utilizing genetically identical mice implanted with an identical tumor line bearing a unique tumor antigen under identical conditions, the tumor-specific T-cell responses were highly unique for each individual tumor. Collectively, our study suggest that dual blockade could be an effective therapeutic clinical strategy against TNBC and further suggest the utility of monitoring systemic immune response and TCR expansion of TILs as the most useful correlates in clinical studies utilizing CTLA-4 and PD-1 antibodies.
**Title:** Clinico-pathological relationships with Ki67 in POETIC (CRUK/07/015) – Critical lessons for assessing Ki67 for prognosis and as a pharmacodynamic marker

Bliss JM M, Morden J, Evans A, Holcombe C, Horgan K, Mallon E, Raghavan V, Skene A, Dodson A, Hills M, Detre S, Zabaglo L, Graf M, Banerji J, Gillman A, Robertson J, Dowsett M, Smith I and On Behalf of the POETIC Trialists. Institute of Cancer Research, London, United Kingdom; Poole Hospital, Poole, United Kingdom; Royal Liverpool University Hospital, Liverpool, United Kingdom; Leeds General Infirmary, Leeds, United Kingdom; Western Infirmary, Glasgow, United Kingdom; Royal Wolverhampton Hospitals, Wolverhampton, United Kingdom; Royal Bournemouth Hospital, Bournemouth, United Kingdom; Royal Marsden Hospital, London, United Kingdom; Nottingham University Hospitals, Nottingham, United Kingdom and POETIC Trialists, United Kingdom.

**Body: Background** Higher levels of the proliferation marker Ki67 at breast cancer (BC) diagnosis are increasingly recognised to indicate poorer prognosis. Change in $\Delta$Ki67 in response to endocrine treatment reflects response. The precise relationship between Ki67 and other clinico-path factors and how associations are affected by short exposure to aromatase inhibitor (AI) has been unclear.

**Methods** POETIC was a UK-wide, phase III, randomised trial which tested perioperative use of AI (anastrozole (A), letrozole (L)) in postmenopausal women with early BC (Dowsett JNCI Monogr 2011). Ki67 was measured in a single central lab at diagnosis (B=baseline) and 2 weeks later at surgery (S) allowing in vivo assessment of AI sensitivity. POETIC recruited 4483 women from 130 UK centres. Paired biopsies were available for 96%. Relationship between Ki67 and clinico-path factors is described by summary statistics (median) and independent associations explored in multivariable linear regression models (MVM). Analyses of Ki67 at S and $\Delta$Ki67 (reduction) were adjusted for B Ki67 and surgical sample type.

**Results**

Absolute Ki67 (B) was associated with each classic prognostic factor. Factors affecting ΔKi67 in control pts were Ki67 (B), grade (B) and surgical sample type (core cut 4.1%; excision 17.7% p<0.001). After 2 weeks of AI, variation in extent of ΔKi67 was dominated by PgR, HER2 and grade (B). Centres using L more often supplied excision samples (p<0.001). In spite of this both surgical sample type and choice of AI (both p<0.001) independently influenced ΔKi67 (core cut: A 65.1% L 73.8% excision A 75.2% L 81.3%). Pattern of change in grade between B and S differed for AI and control.

**Summary** POETIC provides the largest multi-centre series of women in whom centrally assessed Ki67 has been correlated with classic clinico-path factors and impact of short term AI exposure explored. Choice of AI and surgical sample type are both dictated by participating site and their inter-relationship requires further review. Whether the greater suppression of Ki67 following L, a drug associated with better E2 suppression and aromatisation than A has clinical consequences is beyond the scope of this work. Relationships found (e.g. sample type, grade) are critical for interpretation of studies using Ki67 for prognosis and ΔKi67 as a pharmacodynamic response marker.
Title: Active surveillance with a combination of tumor marker CA27.29 and detection of circulating tumor cells two year after primary diagnosis strongly predicts subsequent prognosis

Janni W, Rack B, Häberle L, Friedl TWP WP, Tesch H, Lorenz R, Jäger B, Fehm T, Müller V, Schneeweiß A, Lichtenegger W, Blohmer J, Beckmann MW W, Scholz C, Pantel K, Trapp E and Fasching PA A. University of Ulm, Ulm, Germany; University of Munich, Munich, Germany; University of Erlangen, Erlangen, Germany; Onkologische Praxisklinik, Frankfurt, Germany; Onkologische Praxisklinik, Braunschweig, Germany; Heinrich-Heine-University, Duesseldorf, Germany; Universitätsklinikum Eppendorf, Hamburg, Germany; University of Heidelberg, Heidelberg, Germany and Charite University Hospital, Berlin, Germany.

Body: Introduction

The prognosis of patients with early breast cancer is commonly estimated by prognostic factors obtained at the time of the initial diagnosis. However, patients and physicians alike are seeking for factors evaluating the prognosis years thereafter during follow-up. The identification of a patient group with an unfavourable prognosis could lead to secondary treatment intervention, potentially improving outcome. Aim of the study was to assess the added prognostic value of circulating tumor cells (CTCs) and CA27.29 beyond established predictors.

Materials and Methods

Patients of the phase III SUCCESS-A study were included into this analysis (n=1005). SUCCESS-A is a chemotherapy study for high risk patients with a comprehensive translational research program, which included the determination of CTCs and CA27.29 two years after the initial diagnosis. A Cox regression model with disease-free survival (DFS) as outcome and well-established predictors (age, BMI, pT, pN, histology, grading, ER, PR, Her2neu) was compared with an extended Cox model with the well-established predictors and additionally CTC (>0 versus 0) two years after randomization, and CA27.29 (in U/mL) measured after chemotherapy and again two years after randomization using a likelihood ratio test. In case of significance, the extended model was applied to predict for each patient the risk of disease recurrence within the next 12 months (0 to 100%). Cross-validated AUC, sensitivity and specificity values were determined to assess clinical usefulness of risk prediction.

Results

The markers CA27.29 and CTC were both significantly associated with subsequent prognosis (p < 0.000001). The detection of CTCs increased the risk of subsequent DFS events (HR=2.14, 95%CI: 1.31-3.48), while CA27.29 after two years increased the risk for DFS events with a HR of 1.12 per U/mL increase (95%CI: 1.09-1.15). The combination of the two markers significantly empowered the prognostic relevance, with a HR of 6.64 for patients with CTCs and an elevated CA27.29 by 10 U/mL compared to patients without CTCs and without CA27.29 elevation. The mean risk of disease recurrence in the third year after randomization was 2.38%. Discrimination of patients with and without disease recurrence based on risk prediction from the extended Cox model (AUC: 0.80) was better than discrimination based on the clinical model without the markers CTC and CA27.29 (AUC: 0.64). Sensitivity with regard to decision thresholds 1%, 2%, 3%, and 4% predicted risk was 0.89, 0.77, 0.65, and 0.55, respectively. The corresponding specificity was 0.42, 0.69, 0.81, and 0.88.

Discussion

Both CTCs and CA29.27 values determined 2 years after primary diagnosis are clinically relevant predictors of subsequent prognosis for those patients. This study extends evidence for active surveillance of breast cancer survivors. Identifying a group of women with a high recurrence risk after two years could be the basis for the development of secondary adjuvant treatment.
Title: Intra-tumor heterogeneity of the estrogen receptor predicts less benefit from tamoxifen therapy and poor long-term breast cancer patient survival – Retrospective analyses of the STO-3 randomized trial

Lindström LS S, Yau C, Czene K, Thompson CK K, van't Veer LJ J, Nordenskjöld B, Stål O, Fornander T, Benz CC C, Borowsky AD D and Esserman LJ J. Karolinska Institutet and University Hospital, Stockholm, Sweden; University of California at San Francisco, UCSF, San Francisco, CA; Buck Institute for Research on Aging, Novato, CA; Linköping University, Linköping, Sweden and University of California at Davis, Davis, CA.

Body: Background
We and others have shown that the clinically used breast cancer markers alter their expression throughout tumor progression, influencing patient survival (Lindström et al, JCO 2012). What are the likely explanations to our findings? Here, we aimed to determine whether breast cancer intra-tumor heterogeneity of the estrogen receptor (ER) is a marker of tumor aggressiveness and benefit of tamoxifen therapy in a large randomized trial.

Material and methods
The Stockholm Tamoxifen (STO-3) trial enrolled postmenopausal lymph node negative breast cancer patients with a tumor size of less than 30 mm, between 1976 and 1990, to be randomized to receive adjuvant tamoxifen versus not. From the original randomized trial cohort approximately half of the patients (778 patients) had primary tumor formalin-fixed paraffin-embedded blocks available and were included in our study. No significant differences in age and period of diagnosis, type of surgery received, receptor status, tumor grade and size were observed between the treatment arms.

All tumor slides were immunostained in a central laboratory using the SP1 antibody. ER slides were scored by two independent breast cancer pathologists assessing the fraction of cancer cells for each ER intensity level (0, +1, +2 or +3) compared to established standards. The resulting distribution of ER stained tumor cells defines intra-tumor heterogeneity of ER (Rao's quadratic entropy (QE), Potts et al, Lab Invest 2012). Intra-tumor heterogeneity was categorized using the third tertile as cut-off for high heterogeneity (726 patients).

Analyses of long-term breast cancer specific survival (25 years) by intra-tumor heterogeneity of ER were performed using univariate Kaplan-Meier and multivariate Cox proportional hazard modeling adjusting for treatment arm, age and period of diagnoses, type of surgery received, receptor status, tumor grade and size were observed between the treatment arms.

All tumor slides were immunostained in a central laboratory using the SP1 antibody. ER slides were scored by two independent breast cancer pathologists assessing the fraction of cancer cells for each ER intensity level (0, +1, +2 or +3) compared to established standards. The resulting distribution of ER stained tumor cells defines intra-tumor heterogeneity of ER (Rao's quadratic entropy (QE), Potts et al, Lab Invest 2012). Intra-tumor heterogeneity was categorized using the third tertile as cut-off for high heterogeneity (726 patients).

Analyses of long-term breast cancer specific survival (25 years) by intra-tumor heterogeneity of ER were performed using univariate Kaplan-Meier and multivariate Cox proportional hazard modeling adjusting for treatment arm, age and period of diagnoses, ER, progesterone receptor (PR), HER2, Ki-67, tumor grade, and tumor size. Further, a test of correlation was performed to investigate whether intra-tumor heterogeneity of ER was correlated to the percentage of ER positive cells, the H-Score or the Luminal A and B subtype (PAM50).

Results
In the univariate Kaplan-Meier analyses, a statistically significant difference in long-term survival by intra-tumor heterogeneity of ER was seen for all patients (log rank, $P=0.018$), tamoxifen treated arm (log rank, $P=0.0033$), but not untreated arm (log rank, $P=0.19$). However in the multivariate analysis, patients with high intra-tumor heterogeneity of ER in the treated arm as well as in the untreated arm had an almost two-fold increased long-term risk of fatal breast cancer disease as compared to patients with low or intermediate heterogeneity (Treated arm: HR, 2.06; 95% CI, 1.04-4.07 and Untreated arm: HR, 1.71; 95% CI, 1.01-2.87). No significant correlation of intra-tumor heterogeneity to the tested variables was seen.

Conclusions
Patients with high intra-tumor heterogeneity of ER had less benefit from tamoxifen therapy and an increased long-term risk of fatal breast cancer disease. Our findings should be clinically relevant since therapy benefit was evaluated in a randomized trial with long-term follow-up.

Title: Evaluation of intra-tumor heterogeneity, test reproducibility and their impact in breast cancer samples assessed by Prosigna™: Results from a decision impact prospective study and a matched case-control study

Body: Background: Recent molecular biology technologies reveals insight into tumor heterogeneity but quantification and impact on reproducibility of tests is not well known. The objective of this study was to assess the extent to which tumor heterogeneity may affect the prognosis of patients assessed by Prosigna™ (PAM50) gene signature assay compared to test reproducibility.

Methods: Reproducibility was measured by testing replicate tissue sections from 186 FFPE breast tumor blocks across 2 sites (Institut Curie, Centre Jean Perrin) following independent pathology review at each site. Consecutive slides came from blocks of patients included in the Decision Impact prospective study which examined whether the Prosigna™ test influences adjuvant treatment decision (Clinical trial information: NCT02395575). To evaluate heterogeneity and its impact in terms of outcome, we selected among T1N0 patients treated in Institut Curie between 2003 and 2008, 32 patients who did recur and 28 matched control group who did not (2 ‘controls’ recurred during the study). Analyses were performed on two parts of each tumor. NanoString’s Prosigna™ outputs (risk of recurrence (ROR) score, 10 year probability of distant recurrence, risk category, and intrinsic subtype (Luminal A/B, HER2-enriched, Basal-like)) were measured and compared to evaluate heterogeneity (defined as difference in terms of subtype and/or risk category between the two parts) and reproducibility. Correlation between heterogeneity and outcome was performed. Impact was assessed by tumor board analysis.

Results: Pearson correlation coefficients for ROR score and probability of distant recurrence predicted were .95 and .97, respectively in the reproducibility study and .82 and .86, in the tumor heterogeneity study. The measured standard deviation (SD) was 5.4 and 8.1 ROR units corresponding to 1.6% and 2.8% in terms of risk of distant metastasis free survival within the reproducibility study and the tumor heterogeneity study, respectively. Kappa coefficients for intrinsic subtype and risk category agreement were 0.88 and 0.87 in the reproducibility study, and 0.67 and 0.58 in the tumor heterogeneity study. Tumor board analysis of discordant cases showed that the impact, in terms of decision of chemotherapy administration, concerns 3% of patients because of reproducibility and 8% because of tumor heterogeneity, comparing favorably with the discordance between Prosigna™ and immunohistochemistry (27%). Probability of distant recurrence was higher in the cases (15%) compared to control (9%) (p=.001) in the tumor heterogeneity study confirming the performance of the Prosigna™ test.

Conclusion: We validated in the prospective Decision Impact study the analytical performance of NanoString’s Prosigna™ assay across multiple clinical testing laboratories. We showed in these two studies that tumor heterogeneity has more impact than reproducibility performance. The clinical impact on the decision making based on tumor heterogeneity is however limited, since it does not correlate to outcomes, whereas the Prosigna™ ROR score has been shown to correlate very well to outcomes.
Body: **Background:** The tumor immune environment not only modulates the effects of immunotherapy, but also the effects of other anticancer drugs and treatment outcomes. Thus, the importance of inhibiting and improving the tumor immune microenvironment is now recognized. These immune responses can be evaluated with tumor-infiltrating lymphocytes (TILs), which has frequently been verified clinically. On the other hand, residual cancer burden (RCB) evaluation has been shown to be a useful predictor of survival after neoadjuvant chemotherapy (NAC). In this study, RCB and TILs evaluations were combined to produce an indicator that we have termed “RCB-TILs”, and its clinical application to NAC for breast cancer was verified by subtype-stratified analysis.

**Materials and Methods:** A total of 177 patients with resectable early-stage breast cancer were treated with NAC. The correlation between TILs evaluated according to the standard method, and prognosis, including the efficacy of NAC, was investigated retrospectively. The RCB was calculated using the Residual Cancer Burden Calculator on the website of the MD Anderson Cancer Center. The RCB and TILs evaluations were combined to create the “RCB-TILs”. Patients who were RCB-positive and had high TILs were considered RCB-TILs-positive, and all other combinations were RCB-TILs-negative.

**Results:** Univariable analysis of patients with high TILs found that this contributed significantly to prolonging DFS in all patients \( p = 0.022 \), TNBC patients \( p = 0.004 \), hazard ratio = 0.177), and HER2BC patients \( p = 0.026 \), hazard ratio = 0.123). For HRBC patients, however, high TILs did not contribute to survival \( p = 0.990 \), hazard ratio = 0.992). Being RCB-TILs-positive, however, contributed significantly to prolonging DFS in all patients \( p < 0.001 \), hazard ratio = 0.181), TNBC patients \( p < 0.001 \), hazard ratio = 0.099), HER2BC patients \( p = 0.026 \), hazard ratio = 0.123), and HRBC patients \( p = 0.039 \), hazard ratio = 0.258). On multivariable analysis, being RCB-TILs-positive was an independent factor for recurrence after NAC in all patients \( p < 0.001 \), hazard ratio = 0.048), TNBC patients \( p = 0.018 \), hazard ratio = 0.041), HER2BC patients \( p = 0.036 \), hazard ratio = 0.134), and HRBC patients \( p = 0.002 \), hazard ratio = 0.081).

**Conclusion:** The results of the present study suggest that RCB-TILs is a significant predictor for breast cancer recurrence after NAC and may be a more sensitive indicator than TILs alone.
Body: Background: MetaSite Breast™ is a validated assay to predict risk of distant breast cancer metastasis in patients with HR+/HER2- ESBC. The assay measures the number of MetaSites defined as tumor microanatomic structures composed of MENA protein expressing tumor cells in contact with CD31+ endothelial cells and CD68+ macrophages. Previous studies have demonstrated that an increased number of these microanatomic structures is associated with distant metastasis (DM) in HR+/HER2- ESBC independent of clinicopathologic features. Analytical validation of MetaSite Breast™ demonstrated precision of 97-99% (repeat image analysis of the same slide) and performance of 91-96% (staining and image analysis of serial tumor sections). We sought to further understand the importance of the MetaSite in predicting distant breast cancer metastasis utilizing a fully automated prognostic assay in an independent large patient cohort.

Methods: We conducted a nested case-control study within a cohort of 3,760 patients diagnosed between 1980 and 2000 with invasive breast cancer from the Kaiser Permanente Northwest health care system. Cases (n=259) were women who developed a subsequent distant metastasis; controls, selected using incidence density sampling, were matched closely to cases (1:1) on age at and calendar year of primary diagnosis. Of the 481 patient tumor samples evaluated in this study, 57% were HR+/HER2-, 19% were triple negative (TN), and 15% were HER2+ disease. Multivariate models were adjusted for clinical factors including: lymph node status, tumor size, tumor grade, and HRT; as well as matching variables: age and year of diagnosis. Odds ratios (ORs) and 95% confidence intervals (CIs) were estimated using logistic regression.

Results: In the HR+/HER2- group, MetaSite Score (MS) ranged from 0-357 and the mean was 44.6. MS was a significant predictor of DM (P=0.039) in patients with HR+/HER2- disease. Cut-points based on tertiles of MS in all 259 controls defined intermediate (13-41) and high (>41) risk groups that were significantly associated with risk of DM versus the low risk group (OR=2.24; 95%CI=1.23-4.13, P=0.009) and (OR=2.94; 95%CI=1.62-5.41, P=0.0005), respectively. Univariate estimates of absolute risk of DM with cutoffs based on 90% sensitivity and specificity were 9.4% for the low risk group (MS<7), 14.1% for the intermediate (MS=7-91), and 23.4% for the high (MS>91). When adjusted for clinical factors, estimates of absolute risk of DM were 6.6%, 14.1%, and 33.0% for the low, intermediate, and high risk groups, respectively. A binary cut-point for the high risk group was determined (MS>14) and was significant with a 2-fold higher risk of DM versus the low risk group and adjusted for clinical covariates (P=0.036). MS was not positively associated with DM in TN or HER2+ disease.

Conclusions: MetaSite Breast™ significantly predicted the risk of distant breast cancer metastasis in ESBC patients with HR+/HER2-disease, independent of classical clinicopathologic features.

Title: Comparison of the Xpert breast cancer stratifier mRNA assay with central ER, PR, HER2, and Ki67 immunohistochemistry (IHC) for rapid biomarker analysis in developing countries

Body: Breast cancer care in the developing world is limited by access to quality ER and HER2 IHC diagnostic assays needed to justify hormone and HER2 therapeutics. Shipping pathology specimens to a central testing site often out of country delays therapy and is costly. The Xpert Breast Cancer Stratifier assay makes quantitative measurements of ESR1, PGR, ERBB2, and MKi67 mRNAs from FFPE specimens in <2 hours on an easy-to-use automated diagnostic platform, the GeneXpert (GX). 10,000 GX machines are currently in use in 182 countries offering the possibility of a point-of-care solution. We compared concordance in tumor samples between IHC and mRNA intending to challenge the limits of the GX mRNA assay.

83 breast tumor samples were chosen including those with low cellularity, small volume disease, unusual subtypes, ER- tumors with surrounding benign epithelium, and low level HER2+ tumors. mRNA, IHC and FISH assays were performed. Slides were tested following macrodissection of invasive carcinoma and as non-macrodissected whole sections. GX measurements for Ki67 were compared with mitotic rate as an alternative to Ki67 IHC.

Overall percent agreement following macrodissection was 95% for ER, 89% for HER2, 76% for PR, and 80% for Ki67 (>20% positive cut), and using whole section, 99% for ER, 80% for PR, 92% for HER2, and 73% for Ki67. Concordance was 92% for both macrodissection and whole section using mitotic rate to assess proliferation. Ignoring HER2 2+ calls which represented low level amplified tumors by FISH, the concordance rates were 95% for macrodissection and 99% for whole section. Discordance when testing long-term stored 4µm sections was resolved in a number of cases by using a fresh cut from the FFPE block. Half the ER discrepancies were in very small volume tumors ≤25mm² and 75% were classified as ER-ve by IHC, and positive by Stratifier. 80% of ER IHC- cases were appropriately identified as ER- by the Stratifier in the presence of benign breast epithelium. HER2+ DCIS adjacent to HER2- invasive tumor resulted in a discrepant HER2 mRNA result even with macrodissection. No ER or HER2 discrepancies occurred in low cellularity tumors (≤30% cellularity) nor in lobular and mucinous subtypes.

In a study intended to challenge an mRNA breast biomarker assay, concordance between mRNA results and IHC was high for ER and HER2, the two most important prognostic markers needed for therapeutic decision making. Use of whole sections rather than tumor macrodissection did not decrease concordance. Discrepant ER cases were more prevalent when analyzing low volumes of tumor and in this setting were seen in ER IHC- tumors surrounded by ER+ normal epithelium, or with weak IHC expression, highlighting predictable limitations of the assay. Concordance was better between Ki67 mRNA and mitotic rate than with IHC. Re-test data suggested that a fresh cut of the FFPE block yields the best results by GX, perhaps due to mRNA degradation in stored 4µm sections. The Xpert Breast Cancer Stratifier may provide a rapid, cost-effective solution to the problem of obtaining accurate diagnostic results at the point-of-care in low resource settings, and deserves further evaluation in developing countries.
Title: Impact of treatment history on prognostic ability of breast cancer index (BCI): Subset analysis from a validation study of patients with hormone receptor-positive (HR+) breast cancer with 1-3 positive nodes

Background: A new BCI model integrating tumor size and grade (BCIN+) was specifically developed and validated for prediction of risk of overall (0-15y) and late (5-15y) distant recurrence (DR) in HR+ women with 1-3 positive nodes (N1). The objective of this study was to evaluate the impact of treatment history on the prognostic performance of BCIN+ in a large clinical validation cohort of pre- and post-menopausal HR+, N1 patients.

Methods: The validation cohort was comprised of 402 HR+, N1 patients diagnosed at Massachusetts General Hospital between 1993-2007 with at least 5y of follow-up. BCIN+ risk scores were determined and patients stratified into low or high risk categories using a pre-specified cut-point blinded to clinical outcome. Kaplan-Meier estimates of overall (0-15y) and late (5-15y) DR were estimated and the difference was evaluated by log-rank test. Treatment-specific subsets were analyzed based on adjuvant endocrine (tamoxifen [TAM] only vs any history of aromatase inhibitors [AI]), and adjuvant chemotherapy treatment history.

Results: Mean age of patients was 53y. 99% were ER+, 91% PR+, and 13% HER2+. The majority of tumors were T1 (62%) or T2 (35%). Adjuvant endocrine treatment included TAM only for 191 (48%) patients and either AI only or a sequence of TAM and an AI in 211 (52%) patients. Most patients received chemotherapy (n=324; 81%). BCIN+ classified 20% and 80% as low and high risk, respectively.

In patients treated with TAM only, BCIN+ low and high risk had significantly different 15y rates of DR (95% CI) of 4.0% (0.0-11.4%) vs 41.7% (33.0-49.3%), respectively (p=0.0005). For patients disease-free at year 5, rates of late DR (5-15y) were 4.0% (0.0-11.5%) vs 20.0% (11.4-27.8%), respectively (p=0.04). In patients treated with an AI, BCIN+ low and high risk had significantly different 15y rates of DR of 0% (0.0-0.0%) vs 15.0% (8.1-21.5%), respectively (p=0.006). For patients disease-free at year 5, rates of late DR were 0.0% (0.0-0.0%) vs 12.2% (5.6-18.3%), respectively (p=0.02). There was no statistically significant difference in the prognostic performance of BCIN+ between patients treated with TAM only versus those with treatment including any history of AI (interaction p=0.99).

In the subset of patients treated with chemotherapy, BCIN+ classified 19% and 81% of patients as low and high risk with significantly different 15y rates of DR of 1.7% (0.0-4.9%) vs 30.9% (24.4-36.8%), respectively (p<0.0001). For patients disease-free at year 5, rates of late DR were 1.7% (0.0-4.9%) and 16.3% (10.2-21.9%), respectively (p=0.006).

Conclusions: In this subset analysis from a validation study of N1 patients, BCIN+ identified a significant proportion with a significantly low risk of late DR. This study confirms the ability of BCIN+ to identify a subset of patients with significantly low risk of recurrence across adjuvant endocrine and chemotherapy treatment backgrounds. BCIN+ may provide additional prognostic information to facilitate selection of N+ patients for extended endocrine treatment, wherein patients identified as BCIN+ low may be considered adequately treated with adjuvant therapy alone.
Title: Programmed death 1 (PD-1) and PD-1 ligand (PD-L1) distribution in triple negative breast cancer (TNBC)

Baker TM M, Gatalica Z, Goldstein LJ J and Obeid E. Caris Life Sciences, Phoenix, AZ and Fox Chase Cancer Center, Philadelphia, PA.

Body: Background: Recent data indicate a promising response to immune checkpoint inhibition in patients with metastatic TNBC. Ample research showed that PD-L1, a PD-1 ligand, is expressed in multiple tumor types, including TNBC, and may be a predictor of response to PD-1/PD-L1 blockade. Quantification of the stromal composition, particularly PD-1 and PD-L1 expression, continues to be controversial in its relationship to immune checkpoint inhibition in several cancer types, and it remains unclear whether PD-L1 expression is necessary to predict response. Here, we aimed to determine the distribution of PD-1 and PD-L1 in a large set of centrally ascertained specimens of TNBC.

Methods: The study cohort consisted of 993 tumor samples (both primary and metastatic TNBC) analyzed for either PD-1 or PD-L1 expression in one laboratory (Caris Life Sciences; Phoenix, AZ). Estrogen receptor and progesterone receptor status was assessed by immunohistochemistry (IHC). HER2/Neu expression or amplification was assessed by either IHC or in-situ hybridization. PD-1 and PD-L1 expression were confirmed using IHC with validated antibodies. For PD-L1, clone SP142 (Roche Diagnostics) was utilized and a sample was considered positive if there was > 5% membranous staining of tumor cells. For PD-1, clone EH21.1 (BD Biosciences) was used. Tumor infiltrating lymphocytes (TILs) expressing PD-1 were counted and a sample was considered positive if there was at least one PD-1 positive TIL per 40x microscopic field.

Results: The median age in this cohort was 56 years (range: 22 – 88). A total of 363 TNBC specimens were tested for PD-1 via IHC. One hundred fifty eight (158; 43.5%) were negative for PD-1 expression. Two hundred five (205; 56.5%) were positive for PD-1. Of those that were PD-1 positive, 116 (56.6%), were in samples from a primary site (breast) and 89 (43.4%) in samples from a metastatic site. A total of 630 TNBC specimens were tested for PD-L1 via IHC. Five hundred seventy four (574; 91.1%) were negative for PD-L1. Fifty-six (56; 8.9%) were positive for PD-L1. Of those that were PD-L1 positive, were equally distributed between primary site and metastatic sites (28/324, and 28/306, respectively).

Conclusion: In this retrospective analysis, we describe, to the best of our knowledge, the distribution of PD-1 and PD-L1 expression in one of the largest datasets reported in TNBC. Unlike prior reports showing a high PD-L1 expression in excess of 50% in TNBC, this analysis show a low distribution of PD-L1 positivity. Our cohort represents a biased sample as those were unselected patients with recurrent breast cancer. Additionally, other factors can be implicated, including a change in the antibody used. These findings call for future standardization of the PD-L1 assay, particularly if further exploration showed PD-L1 to be a predictive or prognostic biomarker in mTNBC, particularly in relationship to therapy with immune checkpoint blockade.
**Title:** UCBG 2-14: A prospective multicenter non-randomized trial evaluating the effect of EndoPredict® (EPclin®) clinico-genomic test on treatment decision making among patients with intermediate clinical risk

Penault-Llorca F, Kwiatkovski F, Grenier J, Levy C, Leheurteur M, Uwer L, Derbel O, Le Rol A, Jacquin J-P, Jouanaud C, Quenel-Tueux N, Girre V, Foa C, Guardiola E, Lortholary A, Catala S, Lemonnier J and Delaloge S. Centre Jean Perrin, Clermont Ferrand, France; Institut Sainte Catherine, Avignon, France; Centre Francois Baclesse, Caen, France; Centre Henri Becquerel, Rouen, France; Institut de Cancérologie de Lorraine, Vandoeuvre les Nancy, France; Hôpital Privé Jean Mermoz, Lyon, France; Centre Hospitalier Intercommunal, Quimper, France; Institut de Cancérologie Lucien Newirth, Saint Priest en Jarez, France; Institut Jean Godinot, Reims, France; Institut Bergonié, Bordeaux, France; Centre Hospitalier Départemental de Vendée, La Roche sur Yon, France; Hôpital Saint Joseph, Marseille, France; Centre Hospitalier de la Dracénie, Draguignan, France; Centre Catherine de Sienne, Nantes, France; Centre Catalan d’Oncologie, Perpignan, France; R&D Unicancer, Paris, France and Gustave Roussy, Villejuif, France.

**Body:**

**Background:** Genomic tests can identify ER-positive Her2-negative localized breast cancer (BC) patients (pts) who may not derive any benefit from adjuvant chemotherapy (CT). Several genomic tests have reached a high level of analytical and clinical validity, as well as clinical utility in such situation. Recent results suggest that the safe de-escalation of adjuvant chemotherapy may be most beneficial in pts with clinical high or indeterminate risk, as assessed by classical variables or online tools, through the use of a genomic test. The clinical risk though remains quite uncertain with variable definition and grey zones. The present study aimed at determining if EPclin clinico-genomic test had a significant impact on treatment decision making among pts with predefined intermediate/borderline clinical risk.

**Patients and methods:** Women were eligible for the present study if they had complete surgical removal of a localized ER+ Her2- pN0 or pN1mi BC, and were considered by the multidisciplinary team meeting (MTM) of the center as being in a “grey zone” of uncertain CT benefit based on classical clinic-pathological assessment. The MTM1 proposed a decision (chemo/no chemo). After informed consent, an EPclin signature classified the tumor as low risk (EPclin Score < 3.3, no chemo advised) or high risk (≥ 3.3, a theoretical indication for adjuvant chemo). Primary end point was the proportion of change between initial adjuvant CT decision at MTM1 and final administration of CT (yes/no). A 5 steps Fleming design was planned, considering that a change rate of 15% or less was not acceptable (low clinical utility). A one-step design was used (unilateral $\alpha = 2.5\%$ and $\beta = 1\%$).

**Results:** 203 pts were included, of whom 198 are evaluable for the main end point. 74% of the tumors were grade 2, 72% T1, 25% T2, 3% T3; 16% were pN1mi and 84% pN0. Median age was 57. EpClin® was low risk in 67% and high risk in 33% of the cases. The global rate of decision change between MTM1 and final administration of CT was 70/198 (35.4% IC-95% = [28.7-42.1]), with 55 (27.7%) decreases and 15 (7.6%) increases in CT indication. 27% instead of 47% of all pts finally received CT (43% decrease in CT prescription). In the multivariate analysis, the factors associated to decrease for less CT were EPclin score (OR 0.11 [0.03-0.35]), proliferation (OR 1.08 [1.03-1.13]) and higher grades (OR 5.22 [1.04-26.08]); while EPclin score was positively (OR 76.6 [7.11-824.8]), but higher grades inversely (OR 0.06 [0-0.86]) associated to an increase in CT administration. Of note, the change in final decision occurred after the MTM2 and after report of the results and discussion with the patient in 9 of the 70 cases (12% of changes; 4.5% of the whole population) (8 decreases and 1 increase in CT administration).

**Conclusion:** Adendom met its primary objective, with 35% of intermediate clinico-pathological risk pts getting significant therapeutic changes upon the receipt of an EPclin gene expression profile. 43% of these “intermediate risk” pts planned for CT avoided it. 12% of the changes were discrepant with the test’s results and occurred after discussion with the patient.
Title: miR363-3p mediates maintenance and resistance of breast cancer stem cells (BCSC)

Renaud S, Fiche M, Stravodimou A, Scabia V, Dormoy VM, Galmiche R, Rindisbacher M, Brisken C, Mermod N and Zaman K. Laboratory of Molecular Biotechnology, University of Lausanne, Lausanne, Switzerland; University Hospital CHUV, Lausanne, Switzerland; Breast Center, University Hospital CHUV, Lausanne, Switzerland; Ecole Polytechnique Fédérale (EPFL), Switzerland and CHU Maison Blanche, University of Reims Champagne-Ardenne (URCA), France.

Body: Background
BCSC are considered to be involved in the recurrence of breast cancer and its resistance to the systemic therapies. Their detection and targeting remain challenging.

Patients and methods:
The study was conducted in vitro, in xenografted immunecompromised mice and samples of 38 patients with early stage BC having biopsies and blood samples before and after anthracycline + taxane-based neoadjuvant chemotherapy (NAC). All patients gave written informed consent before inclusion. 1) MCF7 cells grown as mammospheres (MS) for BCSC enrichment were treated with 5FU or paclitaxel (Pac) to select chemo-resistant BCSC. miRNA microarray was performed to identify specific miRNAs for chemo-resistant BCSC. The results were compared to miRNAs found in immortalized non-tumorigenic MCF10A cells to exclude miRNAs related to normal stem cells. 2) The correlation between the most highly expressed miRNA and the BCSC was confirmed by RT-qPCR in ALDH+ and ALDH- cells sorted from MCF7 and MDA-MB-231 cells by flow cytometry. 3) The impact of the miRNA on MS and colony development was assessed by up- and down-regulating its expression. MCF7 cells transfected with ectopic expression of miRNA, anti-miRNA or miRNA control were grown in MS before being injected in mice using a mouse INtraDuctal xenograft Model (MIND). In vivo tumor growth was assessed by luciferase imaging, then measured and quantified with human GAPDH ex vivo at 6 weeks. 4) The miRNA was quantified by RT-qPCR in tumor samples and sera of the patients before and after treatment, and its levels were correlated with pathological complete response and patients' outcomes.

Results:
379 miRNAs out of 2006 were altered in chemo-resistant versus untreated MCF7 MS. Thirteen were specific for 5FU and 5 for Pac. Three were common for both drugs. Of these, miR-363-3p was overexpressed specifically in chemo-resistant BCSC-enriched MCF7 cells and all the other tested BC cell lines, but not in non-tumorigenic MCF10A cells. Compared to adherent MCF7 cells, miR-363-3p was 12-, 60-, and 10-folds more expressed in BCSC-enriched MS treated with 5FU, Pac, or without treatment, respectively. miR-363-3p was 20- and 100-folds higher in ALDH+ compared to ALDH- in MCF7 and MDA-MB-231 cells. Anti-miR-363-3p reduced MS size and decreased their number 50%. A significant decrease of the number of colonies was also observed in soft agar. Consistently, miR-363-3p downregulation decreased tumor growth and metastasis by MCF7 cells transplanted in mice. In patients' sera with lower baseline level (n=15), miR-363-3p appeared decreased upon NAC. Patients with high miR-363-3p serum levels (n=22) had more risk to maintain higher level after chemotherapy. Triple-negative and HER2+ BC were more frequent in this second group. No significant difference was observed in term of pCR between the 2 groups. However 3 patients relapsed with distant metastases and all were in the second group with high baseline level and no decrease after NAC.

Conclusions:
miR363-3p appeared to be a mediator of chemo-resistant BCSC. Its measurement in the serum of BC patients may predict resistance to neo-/adjuvant chemotherapy and higher risk of distant recurrence. Further investigations are warranted to confirm its role as biomarker and potential therapeutic target against BCSC.
Title: The ASCO-recommended prognostic factors uPA/PAI-1 in a multicenter cohort study (PiA)

Vetter M, Hartung C, Hanf V, Lantzsche T, Uleer C, Peschel S, John J, Buchmann J, Bürig K-F, Weigert E, Thomssen C and Kantelhardt EJ Johanna. Martin-Luther-University, Halle (Saale), Germany; Klinikum Fürth, Fürth, Germany; St. Elisabeth St. Barbara, Halle (Saale), Germany; Praxis Uleer, Hildesheim, Germany; Klinikum St. Bernward, Hildesheim, Germany; Klinikum Hildesheim, Hildesheim, Germany; Institut of Pathology, Krankenhaus Martha-Maria, Halle (Saale), Germany; Institut of Pathology Hildesheim, Hildesheim, Germany and Institut of Pathology, Klinikum Fürth, Fürth, Germany.

Body: Introduction
The PiA-study (Prognostic assessment in routine Application, NCT 01592825) was designed as a representative cohort of breast cancer patients to estimate the proportions of traditional and modern prognostic factors. The ASCO-recommended biomarkers uPA (urokinase-type plasminogen activator) and its inhibitor PAI-1 were used for biological risk assessment particularly for intermediate risk breast cancer patients and disease-free survival of the patients after 5 yrs of follow-up (F/U) was calculated.

Material & Methods
Between 2009 and 2011, 1,074 non-metastasized, primarily operated breast cancer patients from six centers in Germany were included. From 815 patients, fresh frozen tissue was obtained and processed for central testing uPA/PAI-1 by ELISA (FEMTELLE®, Sekisui Diagnostics GmbH). Low uPA/PAI-1 status is defined by uPA and PAI-1 concentrations below the published cut-offs, high status means one or both were higher than the corresponding cut-offs. Tumor characteristics were based on local pathology. The centers had to follow the national guidelines. In low-risk patients, adjuvant chemotherapy was spared. The median F/U is 56 months (range 0-78).

Results
In the total cohort of 1,074 patients, 166 had G1- and 237 had G3-tumors. Of the 671 patients with a G2-tumor, the following were allocated to the high-risk group: node-positive (n=371), younger than 35 yrs (n=17), and triple-negative (TN) or HER2-positive (n=118). For 253 tumors of the remaining 355 patients with an intermediate risk of recurrence (pN0, G2, HR positive, HER2-negative, ≥35 yrs), uPA/PAI-1 status was available. 126 (49.8%) were allocated to the low-risk group, one patient had a recurrence. At 5 yrs, in the total cohort 90.6% (95% CI, 89.5-91.7) of the patients were free of invasive disease. Of 114 HER2-positive tumors, 94 (82.4 %) had a high uPA/PAI-1 status, only one of the 38 HR negative/HER2 positive tumors had a low uPA/PAI-1 status. In the TN group, the majority of tumors had a high uPA/PAI-1 status (66 of 81; 81.5 %). In 30 patients lymph nodes were involved, 18.5% (n=15) had a low uPA/PAI-1 status, one event was detected. In N pos. patients with an high uPA/PAI-1 6 events were observed.

Conclusion
Testing for uPA/PAI-1 in the daily routine is feasible, fresh frozen tissue has been prepared from 76% of the tumors of the recruited patients, 37% of them had a low risk status. Using uPA/PAI-1, about half of the node-negative patients with an intermediate risk of recurrence were allocated to a group with an extremely low risk of recurrence and thus chemotherapy could be spared. Also in node-positive disease, uPA/PAI-1 has a prognostic impact.

Title: Negative progesterone receptor is associate early breast cancer relapse, even among good prognosis tumors

Winner M, Rosman M, Mylander C, Jackson RS S, Pozo ME E, Wolff AC C, Tafra L and Umbricht CB B. Johns Hopkins University School of Medicine, Baltimore, MD and The Breast Center, Anne Arundel Medical Center, Annapolis, MD.

Body: Background/objective: A minority of estrogen-receptor (ER) positive breast cancers lack progesterone receptor (PR) expression, but little is known of the clinical meaning of PR negativity (PR-). In the present study we sought to clarify the association between PR- and outcomes of ER+, human-epidermal growth factor (HER2)-negative breast cancers using a large, single institution database.

Methods: We retrospectively analyzed consecutive, non-metastatic, unilateral HER2- invasive breast cancers diagnosed between 2000 and 2011. Records were reviewed for age at diagnosis, disease stage, tumor features, and histologically confirmed recurrence. ER+ and PR+ status was defined as ≥1% immunoreactive cells. We used Kaplan-Meier curves to determine the association between PR- and early (≤5 years) and late (>5 years) disease recurrence, defined as locoregional or distant breast cancer relapse >6 months after diagnosis.

Results: We identified 1,933 patients with TN (n=337) or ER+/HER2- (n=1,596) breast cancer. Patients with ER+/PR- (n=107) vs. ER+/PR+ (n=1,489) tumors did not differ in age or disease stage at diagnosis; however, PR- tumors were more frequently high grade (37.9% vs. 17.8%, p<0.001), with higher median Ki67 indices (20.0% vs. 10.0%, p<0.001). Median ER expression was also lower in PR- as compared to PR+ tumors (80.0% vs. 90.0%, p<0.001).

Over a median follow-up of 84 months, there were 119 early and 54 late locoregional or distant breast cancer relapses. Negative PR was strongly associated with early relapse, with PR- tumors demonstrating a 2.1-fold higher hazard of relapse in the first 5 years as compared to PR+ tumors (95% CI 1.0-4.2).

Hazards of early (<5 years) breast cancer relapse by hormone status. Shown are univariable Cox proportional hazard ratios and 95% confidence intervals among all tumors, and in subsets defined by %ER, node status, Ki67, and grade.

*Significant at p<0.05; **too few subjects/events for analysis

Negative PR remained significantly associated with a higher hazard of early relapse even in node-negative (HR 2.7, 95%CI 1.0-7.0) and low-proliferating tumors (Ki67<14%, HR 4.1, 95%CI 1.2-14.1). There was no significant association between PR-
and late breast cancer relapse (HR 0.7, 95%CI 0.2-2.9).
Conclusions: Compared to ER+/PR+ breast cancers, ER+/PR- breast cancers have a significantly greater risk of early recurrence, similar to triple-negative cancers. These results suggest that negative PR expression is importantly and independently associated with early breast cancer prognosis, and may be an indicator of unique tumor biology.
Title: Prognostic impact of genomic risk stratification with breast cancer index in patients with clinically low risk, hormone receptor-positive, node-negative, T1 breast cancer

Body: **Background:** Tumor size and nodal status are prognostic for risk of both early and late disease recurrence in patients with early stage, HR+ breast cancer, and are incorporated into both adjuvant chemotherapy and extended endocrine therapy treatment decisions. In a recent EBCTCG meta-analysis of over 46,000 patients [Pan H, et al. J Clin Oncol 34, 2016 (suppl; abstr 505)], risk of late distant recurrence was assessed in patient subsets based on nodal status and tumor size. Patients with T1N0 disease who were treated with 5 years endocrine therapy had a good overall prognosis, with 4%, 9%, and 14% risk of distant recurrence from years 5-10, 5-15, and 5-20, respectively. Breast Cancer Index (BCI) has been validated as prognostic biomarker for risk of both early and late distant recurrence in multiple randomized trial cohorts. The aim of this analysis was to assess distant recurrence (DR) risk stratification with BCI in patients with clinically low-risk T1N0 tumors.

**Methods:** Primary tumor samples from the subset of patients with T1N0 disease from 2 independent validation cohorts of HR+ breast cancer patients were examined [Stockholm randomized controlled trial (N=259) and a retrospective multi-institutional cohort (N=237)]. Patients in the Stockholm RCT cohort were treated with adjuvant tamoxifen only; patients in the multi-institutional cohort were treated with adjuvant tamoxifen +/- chemotherapy (20.3%). No patients received extended endocrine therapy. Kaplan-Meier analysis was used to assess the risk of DR within distinct BCI risk groups. Time dependent analysis was performed by combining BCI Low and Intermediate risk groups for risk of early recurrence (0-5y), and BCI Intermediate and High risk groups for risk of late recurrence (>5y).

**Results:** In the Stockholm cohort, BCI identified 13% of T1N0 patients as high risk for relapse within the first 5y, and these patients had a significantly reduced distant recurrence-free survival (DRFS, 85.3%) compared to BCI Low Risk patients (97.7%; P=0.0004). In patients disease-free at year 5, BCI identified 32% of patients as high risk for late recurrence; these patients had significantly lower DRFS (86.7%) between years 5-15 compared to BCI low risk patients (95.4%; P=0.0263). In the multi-institutional cohort, 22% of T1N0 patients were identified by BCI as high risk for relapse within the first 5y, and these patients had a significantly reduced DRFS (77.3%) compared to BCI low risk patients (96.2%; P<0.0001). In patients disease-free at year 5, 36% of patients were identified by BCI as high risk for late recurrence, with significantly lower DRFS (89.6%) between years 5-10 compared to BCI Low Risk patients (98.4%; P=0.008).

**Conclusions:** HR+ Patients with favorable clinical features (T1N0) have a good overall prognosis. However, results of this study demonstrated that adding molecular resolution on tumor biology with BCI identified a significant subset of women with higher risk of both early and late distant recurrence; findings support consideration of genomic classification in T1N0 patients to identify additional candidates for adjuvant chemotherapy and/or extended endocrine therapy, respectively.
Title: The lymph node ratio as an independent prognostic factor for node-positive triple-negative breast cancer

Body:

Purpose: To evaluate the prognostic value of the lymph node ratio (LNR) in patients with axillary lymph node-positive triple-negative breast cancer (TNBC).

Patients and methods: Based on X-tile plots, we classified women into low-, medium-, and high-risk LNR groups. Univariate and multivariate Cox proportional hazards regression analyses for overall survival (OS), breast cancer-specific survival (BCSS) and disease-free survival (DFS) were performed. The prognostic efficacy of the LNR was investigated in the first cohort from the Surveillance, Epidemiology, and End Results (SEER) database (n=4114) and was further validated in an independent cohort from Fudan University Shanghai Cancer Center (n=417).

Results: The patients were classified into low- (≤0.30), medium- (0.30 to 0.70) and high-risk (>0.70) LNR groups. Multivariate analysis revealed that the LNR was an independent predictor of OS (hazard ratio (HR) for high-risk LNR: 3.24; 95% confidence interval (CI): 2.56 to 4.09) and BCSS (HR for high-risk LNR: 3.57; 95% CI: 2.76 to 4.62) in the SEER population and also for DFS (HR for high-risk LNR: 4.29; 95% CI: 2.24-8.21) in the validation population. Subgroup analysis revealed that patient classification according to the LNR could discriminate among groups of patients with different survival rates based on pN staging.

Conclusion: The LNR shows potential for use as an additional prognostic factor for TNBC patients with positive lymph node involvement. Considering the heterogeneity of TNBC, use of the LNR might allow for optimization of the pN staging system, and this ratio should be considered when making treatment decisions.
Title: Establishment of molecular profiling for individual treatment decisions in early breast cancer – Clinical impact of PAM50 and PAM50 risk of recurrence score after more than 16 years follow up

Body: Background
Molecular profiling has recently been included in recommendations for decisions on adjuvant treatment in breast cancer (BrCa). However, the use of molecular profiling has not yet been widely established in all countries. Additional studies may give important information about the clinical relevance of the tests.

Aims
The study aims to discover the long term prognostic impact of PAM50 and PAM50 ROR score on survival for early BrCa pts according to treatment, with comparison to the routine clinical and histopathological parameters.

Patients and methods
Unselected early BrCa pts (n=651) from the Oslo Micromet project (n=920) having available FFPE primary tumor tissue were included in the current study. The pts were enrolled from 1995-1998. Follow up status is available for distant disease (median FU 7 years) and BrCa death (16.0-19.7 years after study inclusion). Clinical and histopathological parameters have been collected from the hospital records. FFPE tissue sections were macrodissected, RNA isolated from the dissected tumor tissue, followed by analysis of the PAM50 gene list on the Nanostring Platform. The samples were run in research mode and the raw data was sent to Nanostring (Seattle) for determination of the PAM50 subtype and ROR score.

Results
Of the 651 included pts, 323 did not receive any adjuvant systemic treatment (pT1pN0 patients), 161 tamoxifen only, the rest chemotherapy+/-tamoxifen. Twelve preoperatively treated pts were excluded from the analyses. Of the 639 remaining pts, PAM50 molecular profiling defined 52.3% as LumA, 26.8% LumB, 10.6% HER2enriched and 10.3% Basal. Multivariate analysis showed that the PAM50 intrinsic subtypes yielded prognostic information in addition to the established clinicopathological variables (pT, Grade, pN, age HR/HER2 subgroups, systemic treatment)(BCSS: HazardR vs LumA: 2.7 (95% CI 1.7-4.1) for LumB, 3.5 (1.8-6.8) for HER2enriched, 1.8 (0.8-4.2) for Basal). For the HR+HER2- pts, the risk classification by ROR score was an independent prognostic factor (BCSS: HazardR vs low risk: 3.1 (1.2-8.1) for intermediate, 6.6 (2.5-17.1) for high risk). In univariate analysis, the PAM50 intrinsic subtype classification separated clinical outcome both for all pts, for no adjuvant treated pts (both p<0.001, log rank), for the HR+HER2- (p<0.001), HR+HER2+ (p=0.061) and HR-HER2- (p=0.015) subgroups. Among the pT1-2pN0 HR+HER2- pts with no adjuvant treatment (n=222), risk classification by ROR score categorized 52.7% of the pts as low risk with excellent prognosis (BrCa death 4.2%), 29.7% as intermediate risk (BrCa death 16.7%) and 17.6% as high risk (BrCa death 35.9%)(p<001, log rank). For the pT1-2pN0-1 HR+HER2- pts who received adjuvant tamoxifen only (n=102), a low and similar risk of BrCa death was observed among the low and intermediate ROR risk groups. The high risk group had poor prognosis (BrCa death 32.7%)(p<0.001). Similar results were obtained for patients classified as LumA.

Conclusions
PAM50 subtype classification and ROR score improves classification of BrCa pts into prognostic groups, allowing more precise identification of future recurrence risk and improved basis for adjuvant treatment decisions.
Title: Development of a recurrence risk stratification schema to inform treatment decisions in breast cancer patients undergoing mastectomy with 1-3 positive nodes

Scanlan JM M, Ellis ED D, Kaplan HG G, Kieper DA A, Morris AD D and Atwood M. Swedish Center for Research and Innovation, Seattle, WA; Providence Health and Services, Seattle, WA and Swedish Cancer Institute, Seattle, WA.

Body: Introduction

Controversies exist regarding the appropriateness of radiation therapy (XRT) in mastectomy patients who have 1 – 3 positive nodes (LN+). We sought to create a straightforward recurrence and survival prediction model derived from clinical and pathologic parameters common in the community cancer center setting at the time of surgery (SX) that may help determine the patients most likely to benefit from XRT.

Subjects

In this retrospective observational study, we examined our institution's breast cancer patient registry to identify mastectomy patients with one to three LN+ at the time of diagnosis and tumor pathology results including Her-2 receptor status. Consistent with current treatment standards, Her-2 positive tumors that were not treated with Herceptin were excluded.

Methods

Breast cancer registry data elements including clinical, pathology, treatment and outcomes data were extracted. Logistic multiple regressions were used to predict loco-regional recurrence (LRR), distant recurrence (DR) and total recurrence (TR) as well as breast cancer mortality (BCa mortality) and all-cause mortality (ACM) based on clinical and pathologic parameters available at SX. The parameters included in the regression model were: tumor receptor status - estrogen (ER), progesterone (PR) and HER-2, the number of nodes examined, presence or absence of lymphovascular invasion (LVI), extension of LVI, number of LN+, node positivity ratio (positive/examined), surgical margins or “tumor on ink”, (SxM); and patient age.

Results

The application of these filters to our breast cancer registry yielded 935 patients with a mean follow up time of 7 years. Our sample was “modern”: 95% of our patients were diagnosed after 1999, 80% after 2004. Across multiple analyses, the four most consistent risk indicators were PR(-), LVI (+), LN+>1 and SxM (+). In our model, patients with none of the four factors were designated low-risk, those with only one factor were medium-risk, those with 2+ were high-risk (see Table 1).

Discussion We believe this risk group concept is straightforward, feasible and clinically useful in all clinical settings. Our future work seeks to validate this concept in another independent cancer registry. In our analyses we noted that while both PR- and ER- were predictive of patient outcomes in simple correlations, PR- was more predictive in all multivariate equations.
Title: Correlation of breast cancer index (BCI) risk classification with tumor grade and Ki-67 in a large series of patients with early-stage, ER+ breast cancer

Soliman H, Schroeder BE, Zhang Y, Magliocco AM and Schnabel CA. Moffitt Cancer Center, Tampa, FL and Biotheranostics, Inc., San Diego, CA.

Body: Background: Breast Cancer Index (BCI) is a gene expression-based test that integrates biomarker panels of both proliferation (molecular grade index, MGI), and endocrine response (HoxB13/IL17BR). BCI has been validated as a significant and independent prognostic factor both for risk of overall (0-10y) and late (>5y) distant recurrence, and is predictive of extended endocrine benefit in patients with early-stage, ER+ breast cancer. In this study, correlative analyses of risk stratification by BCI and MGI versus tumor grade or Ki67 were assessed to characterize their relationship to other markers of proliferation.

Methods: Retrospective analysis of consecutive cases (N=1359) from node negative early-stage breast cancer patients submitted for clinical testing with BCI were analyzed. Median age at diagnosis was 58 years, 57% and 6% were HER2 negative and positive, respectively, with 37% unknown status. Tumor grade and Ki67 information was abstracted from pathology reports, and was available for 1335 and 372 cases, respectively. 29%, 52% and 17% of patients had grade 1, 2 and 3 tumors, respectively, with 2% having unknown grade. Tumor sizes were 26% (≤1 cm), 48% (>1-≤2 cm), 23% (>2-≤5 cm), 2% (≥5 cm) and 1% were unknown. Ki67 categories were based on 10% and 20% IHC expression levels into low, intermediate and high groups. Statistical methods included Pearson correlation between BCI/MGI versus Ki67 as continuous variables & coefficient of determination derived from the analysis of variance (ANOVA) model between continuous BCI/MGI versus tumor grade. Chi-square test assessed the significance of concordance between BCI, MGI risk groups to tumor grade and Ki67 groups.

Results: As continuous variables, BCI and MGI correlated weakly with tumor grade (coefficient of determination= 0.26 and 0.22, respectively) and Ki67 (r² = 0.35 and 0.33, respectively). Although statistically significant concordance was demonstrated between BCI/tumor grade, MGI/tumor grade, BCI/Ki67, MGI/Ki67 categories (p<0.0001 for all, Tables 1 & 2), discordance between BCI versus tumor grade or Ki67 was 51% and 45%, respectively. In particular, BCI classified 4% of well differentiated tumors as high-risk and 18% of poorly differentiated tumors as low-risk. Similarly, BCI classified 4% of low Ki67 patients as high risk and 28% of high Ki67 patients as low risk.

Conclusions: Data from this large retrospective analysis show that correlation of BCI and its mitogenic panel, MGI, to tumor grade and Ki67 are moderate to weak. These findings indicate that BCI and MGI are capturing distinct information related to tumor proliferative status compared with tumor grade and Ki67.
Body: Background: Next-generation sequencing (NGS) has improved our understanding of breast cancer (BC) biology. Somatic TP53 mutations (TP53m) are present in 30% of BC, and are particularly common in triple negative (TN) tumors. Although multiple studies have indicated poor prognosis in BC patients (pts) with TP53m, there is still uncertainty regarding its correlation with clinical outcomes, which may be influenced by other molecular, histological and clinical factors. Our aim was to investigate the functional effect of TP53m in advanced BC pts and evaluate associations with clinical outcomes in different BC subtypes.

Methods: Advanced BC pts enrolled in an institutional molecular screening program (NCT01505400) were evaluated. TP53m were assessed on archived FFPE tumor samples using NGS Illumina MiSeq TruSeq Amplicon Cancer Panel (500x depth of coverage; 10-15% variant detection threshold). Functional effect of TP53m was classified as gain of function (GOF), loss of function (LOF) and variants of unknown significance (VUS), as adapted from IARC TP53 database. Patients' medical records were reviewed for clinical data. TP53m functional effect class was correlated with BC subtypes using Fisher's exact test. TP53m were correlated with time from surgery with curative intent to distant relapse (TTR) and overall survival from diagnosis to death (OS) using Log-rank test. Impact of TP53m functional type on TTR and OS was determined by Cox proportional hazard model.

Results: The study enrolled 220 pts from Oct 2012 - Nov 2015. Median age at diagnosis was 46 years (range 21-80). The cohort included 141 ER+/HER2- (64%), 25 HER2+ (11%) and 54 triple negative (TN) (25%) BC pts. Stage at diagnosis was: I (14%), II (33%), III (24%), IV (21%) and not documented in 8%. Median follow-up was 15 months (m) (range 1-41). Somatic TP53 variants were identified in 80 patients [36%; 23 ER+/HER2- (16%), 18 HER2+ (72%), 39 TN (72%)]. By TP53 functional class, there were 19 GOF (24%), 35 LOF (44%) and 26 VUS (32%). Histologic subtypes were not correlated with TP53m function (p = 0.09). TTR for 174 pts, who underwent surgery with curative intent to distant relapse (TTR) and OS (94 death events, 43%) are reported in Table 1. TTR and OS were shorter in TP53m compared to TP53 wild type (wt) in the overall cohort and the ER+/HER2- subgroup, but not the HER2+ and TN subtypes.

In the ER+ subgroup TP53m was significant prognostic factor associated with poor outcome in univariate analysis and remained significant after adjusting for age, stage and grade at diagnosis, neoadjuvant chemotherapy and germline BRCA1/2 status, with HR for TTR 3.4 (95% CI: 1.9-6.0, p<0.001) and OS 10.2 (95% CI: 4.5-23.4, p<0.001). Within the TP53m group, the functional class of TP53m (GOF, LOF, VUS) was not associated with TTR (23 m, 28 m, 17m, p =0.94) or OS (75 m, 58 m, 49 m, p =0.47).

Conclusions: In advanced breast cancer, somatic TP53m status is prognostic for outcome in ER+/HER2- but not TNBC or HER2+ subtypes. TP53m functional class was not associated with any difference in survival outcomes.
Title: Tumor infiltrating lymphocytes in recurrent HER2+ and triple negative breast cancer: Prognostic value according to tumor phenotype

Body: Background: Tumor infiltrating lymphocytes (TILs) have emerged as a prognostic and potential predictive factor in early triple negative (TN) and HER2+ breast cancer (BC). The prognostic role of TILs in advanced disease is largely unknown.

Methods: 109 HER2+ and TNBC patients with available tumor tissue from regional/distant BC recurrence (collected between 2001 and 2015) were identified from a prospectively maintained database at the Istituto Oncologico Veneto of Padova (Italy). Ipsilateral in-breast relapse/second primaries and contralateral BC were excluded from the definition of recurrence. StrTILs were assessed according to consensus guidelines (Salgado, 2014) on hematoxylin and eosin stained slides from BC recurrence samples and, when available, matched primaries. Post-progression survival was calculated as the time from first BC recurrence to last follow up or death.

Results: StrTILs were evaluable on recurrent BC for 72 cases (HER2+ n=43, TN n=29), after exclusion of lymphnode metastases. Median time to recurrence from initial BC diagnosis was longer for HER2+ than TN cases: 37 months (95%CI 23-51) and 18 months (95%CI 13-23), respectively. Accordingly, median time to biopsy of recurrence from initial BC diagnosis was 43 months (95%CI 35-51) for HER2+ patients and 20 months (95%CI 9-31) for TN patients. Site of biopsy was visceral metastasis in 54% and soft tissue metastasis in 46% of cases (similar for HER2+ and TN).

Median StrTILs level on recurrence was 5% (Q1 2.5%, Q3 10%), without differences according to TN or HER2+ phenotype (Student’s t-test p=0.5).

In the whole cohort, post-progression survival did not differ for patients with high (>10%) vs low (≤10%) StrTILs on recurrence (HR 0.83 95% CI 0.38-1.80, p=0.64).

In the TN subgroup, high StrTILs on recurrence were associated to a better post-progression survival (median not reached vs 12.7 months for StrTILs >10% and ≤10%, respectively, HR 0.03 95%CI 0.00-3.64, log-rank p=0.019). To the opposite, in the HER2+ subgroup, high StrTILs were associated to worse post-progression survival compared to low StrTILs (median 27.7 vs 41.1 months for high vs low StrTILs, HR 2.93 95%CI 1.17-7.31, log-rank p=0.016). Test for interaction between tumor phenotype and StrTILs was p=0.15. Similar results were obtained when including only those patients maintaining a concordant TN or HER2+ phenotype on both primary tumor and recurrence (n=59).

StrTILs were assessed on matched primary tumors for 43 patients. Overall, no significant StrTILs variation between primary tumor and recurrence was observed (mean change -4.5%, Wilcoxon p=0.5). Mean change was -2.5% and -7% in HER2+ and TN cases (Wilcoxon p=0.63 and p=0.15, respectively). For TN patients with StrTILs ≤10% on recurrence, a significant reduction from the primary tumor was observed (mean StrTILs 16% and 4% on primary and recurrent BC, respectively, Wilcoxon p 0.008).

Conclusions: Levels of StrTILs on recurrent BC seem to have an opposite effect on prognosis of metastatic BC patients according to tumor phenotype. Immunohistochemical characterization of TILs is ongoing, data will be available for the meeting.
Title: Predictive value of quantitative HER2 and HER3 levels combined with downstream signaling markers in HER2-positive advanced breast cancer patients treated with lapatinib

Duchnowska R, Sperinde J, Czartoryska-Arlukowicz B, Mysliwiec P, Winslow J, Radecka B, Petropoulos C, Demlova R, Orlikowska M, Kowalczyk A, Lang I, Ziółkowska B, Debska-Szmich S, Merdalska M, Grela-Wojewoda A, Zawrocki A, Biernat W, Huang W and Jassem J. Military Institute of Medicine, Warsaw, Poland; Monogram Biosciences, Inc. Laboratory Corporation of America® Holdings, South San Francisco, CA; Białystok Oncology Center, Białystok, Poland; Oncology Center, Zielona Góra, Poland; Opole Oncology Center, Opole, Poland; Masaryk Memorial Cancer Institute, Brno, Czech Republic; Warmia and Masuria Oncology Center, Olsztyn, Poland; Medical University of Gdańsk, Gdańsk, Poland; National Institute of Oncology, Budapest, Hungary; Regional Hospital, Wroclaw, Poland; Medical University of Łódź, Łódź, Poland; Oncology Center, Kielce, Poland and Oncology Institute, Kraków, Poland.

Body: Background: Clinical correlates of lapatinib resistance have not been well defined. Previous studies implicated genes regulated by the estrogen receptor (ER) and activation or mutation of proteins downstream from HER family receptors. In the current study, HER2 and HER3 expression levels were quantitatively measured using a VeraTag® fluorescence-based assay, in addition to seven downstream signaling proteins determined by IHC. All biomarkers were correlated with overall survival (OS) in patients treated with lapatinib.

Methods: Formalin-fixed, paraffin-embedded samples were obtained from the primary tumor of 191 patients treated with lapatinib plus capecitabine following progression on trastuzumab. The HERmark® Breast Cancer Assay (Monogram Biosciences, South San Francisco) was used to quantify HER2 protein expression levels. HER3 protein expression was quantified using the VeraTag® technology (Monogram Biosciences). Expression of ER, PTEN, Cyclin E, HIF-2alpha, p-p70S6K, p-AMPK and p-MAPK were determined by IHC (Duchnowska et al., Oncotarget 2016; 7:550). OS analyses of HER2 and HER3 were stratified by key clinical variables, including stage and presence of a brain metastasis prior to lapatinib-based therapy.

Results: Among the downstream signaling molecules, HIF-2alpha (r = -0.23; p = 0.047) and ER (r = -0.27; p = 0.005) were negatively correlated with HER2 expression after adjustment for multiple testing. PTEN appeared to correlate with HER3, but was not significant after adjustment for multiple testing. OS was significantly shorter for those below the cut-off level of positivity by the HERmark assay (HR = 1.8; p = 0.029), and those with above median HER2 levels (HR = 1.7; p = 0.009), as compared to cases with in between levels. The relationship between HER2 and OS is also captured by a U-shaped, parabolic function in HER2 (p = 0.005). Elevated HER3 showed a trend toward a correlation with longer OS (HR = 0.66/log; p = 0.16), somewhat stronger in the ER-negative subset (HR = 0.55/log; p = 0.085) and in the subset with above-median HER2 (0.48/log; p = 0.10), where inhibiting HER2 activation of HER3 may be more important. In multivariate Cox models, HER2 (parabola, intermediate HER2 best, p = 0.001), presence of brain metastases (HR = 2; p < 0.001), ER (HR = 0.60; p = 0.009) and either p-p70S6K (HR = 0.66; p = 0.018) or p-AMPK (HR = 0.67; p = 0.022) were significantly associated with OS (p-p70S6K and p-AMPK were mutually correlated).

Conclusions: Patients with moderately increased HER2 levels may have best outcomes while receiving lapatinib following progression on trastuzumab. This supports recent findings of a less benefit from lapatinib in patients with high HER2 expression (Nunciforo et al., SABCS 2015, P3-07-08). HER3 levels do not seem to substantially impact the prognosis. Further studies are warranted to explore the predictive utility of quantitative HER2 and HER3 in guiding HER2-directed therapies.
Title: Prognostic significance of nuclear factor kappa B in node-negative breast cancer is most pronounced in luminal B breast cancer

Schmidt M, Madjar K, Heimes A-S, Battista M, Lebrecht A, Almsetdt K, Hasenburg A, Rahnenführer J and Hengstler JG G. University Medical Center, Mainz, Germany; Technical University, Dortmund, Germany and Leibniz Research Centre for Working Environment and Human Factors (IfADo), Technical University, Dortmund, Germany.

Body: Background: The importance of the cellular as well as the humoral immune system is increasingly recognized in breast cancer. The transcription factor nuclear factor kappa B (NFKB1) plays an important role in immune cell development. We examined the prognostic significance of NFKB1 in node-negative breast cancer.

Methods: Microarray based gene-expression data for NFKB1 (209239_at) were analysed in four previously published cohorts (Mainz, Rotterdam, Transbig, Yu) of node-negative breast cancer patients not treated with adjuvant therapy (n=824). A meta-analysis of previously published cohorts was performed using a random effects model. Intrinsic subtypes were determined using gene-expression data. Prognostic significance of NFKB1 for metastasis-free survival (MFS) was examined in the whole cohort, in estrogen receptor (ER) positive as well as ER negative patients, and in different intrinsic subtypes: luminal A, liminal B, basal-like, HER2-enriched (HER2-E), and normal-like. Independent prognostic relevance was analysed using multivariate Cox regression.

Results: Higher RNA expression of NFKB1 was related to better MFS in a meta-analysis of the whole cohort (HR 0.48, 95% CI 0.34–0.67, P<0.0001). NFKB1 was significantly associated with MFS only in ER positive (HR 0.41, 95% CI 0.24–0.69, P=0.0008) but not in ER negative (HR 0.76, 95% CI 0.39–1.48, P=0.4245) patients. Regarding intrinsic subtypes, the prognostic significance of NFKB1 was most pronounced in luminal B breast cancer (HR 0.40, 95% CI 0.17–0.93, P=0.0338) as compared to luminal A (HR 0.67, 95% CI 0.16–2.73, P=0.5738), basal-like (HR 0.67, 95% CI 0.29–1.56, P=0.3484), HER2-E (HR 0.70, 95% CI 0.25–2.00, P=0.5083), and normal-like (HR 0.49, 95% CI 0.18–1.32, P=0.1579) breast cancer. However, NFKB1 failed to show independent prognostic significance (HR 0.72, 95% CI 0.42–1.24, P=0.235) in multivariate analysis. Only histological grade of differentiation (HR 2.06, 95% CI 1.27–3.35, P=0.003) and tumor size (HR 1.58, 95% CI 1.01–2.48, P=0.045), but neither age nor HER2 status nor hormone receptor status maintained an independent prognostic association with MFS.

Conclusions: The transcription factor NFKB1 shows prognostic significance in node-negative breast cancer. Higher expression of NFKB1 is associated with improved outcome. The prognostic impact of NFKB1 differs between intrinsic subtypes and is most pronounced in luminal B breast cancer.
Title: EP3-receptor expression is a prognostic marker for overall survival and progression-free survival in sporadic breast cancer

Body: Aim: Prostaglandins are tissue hormones with a variety of biological effects and are mainly associated with infection and inflammation. However, elevated prostaglandin synthesis, especially of prostaglandin E2 (PGE$_2$) caused by overexpression of cyclooxygenase-2 (COX-2), has also been associated with the development and progression of different kinds of cancer. Clinical trials have shown the potential of non-steroidal anti-inflammatory drugs or specific COX-2 inhibitors (coxibs) in prevention and treatment of malignant disease, as they reduce prostaglandin levels via inhibition of COX-2. Unfortunately, the clinical use of these drugs is limited due to their various side effects. PGE$_2$ exerts its effects by signaling through four specific membrane-bound receptors, the EP-receptors 1-4. In recent research, the relevance of EP-receptors in carcinogenesis is investigated in the attempt to find a more specific target for the reduction of prostaglandin-effects without inducing side effects. This study evaluates the expression of EP3-receptor on breast cancer tissue and its correlation to progression and survival

Material and methods: A total of 277 sporadic breast cancer samples without primary distant metastases were immunohistochemically analyzed for EP3-receptor expression. Tissue samples were stained with primary anti-EP3 antibodies (monoclonal rabbit IgG). EP3-receptor-expression was quantified by the semi-quantitative immunoreactivity score (IRS); samples with an IRS $\geq$ 2 were scored as EP3 positive. Statistical analyses were performed with SPSS software using chi-squared test as well as Kaplan-Meier-estimates and Cox regression for survival analyses.

Results: EP3-receptor was expressed in 71.1 % of all cases. EP3-receptor expression did not correlate with clinicopathological parameters such as tumor size or lymph node status at primary diagnosis or with the expression of other immunohistochemical markers (estrogen and progesterone receptor, Her2). Distant metastasis occurred in 49.1 % of EP3 negative cases but only in 32.8 % of EP3 positive cases in an observation period of up to ten years ($p = 0.03$). EP3 receptor positive cases also showed significantly improved progression-free survival rates (overall [$p = 0.01$], ten years [$p = 0.002$] and five years [$p = 0.04$]). Furthermore, EP3-receptor positivity was associated with an improved overall survival rate ($p = 0.002$) and ten years survival rate ($p = 0.001$), whereas short-time survival rate (five years) did not differ between both EP3-groups ($p = 0.10$). In a multivariate analysis comparing all factors with significant influence in univariate testing, EP3-receptor could be confirmed as an independent factor.

Discussion: Our results show that EP3-receptor positivity is a relevant prognostic factor in sporadic breast cancer. Its correlation with a favorable course of disease is especially interesting as EP3 is known to regulate uPA, a well-known parameter which is – on the contrary - associated with unfavorable survival in breast cancer. Therefore, ongoing studies by our group aim to examine the correlation of EP3-receptor to the uPA/PAI1-pathway and to evaluate the possibility to target EP3-receptor in future anti-tumor therapy in breast cancer.
Title: Prognostic value of circulating PIK3CA mutations revealed with digital PCR in patients with HER2-positive advanced breast cancer: Results of West Japan Oncology Group study 6110BTR

Tsurutani J, Sakai K, Takao T, Kimura H, Kawabata H, Tanaka K, Takahashi M, Ito Y, Takao S, Aogi K, Sato K, Tsuji Y, Yamanaka T, Nakanishi Y, Saeki T and Nishio K. Kindai University Faculty of Medicine, Osakasayama, Osaka, Japan; Toranomon Hospital, Minato, Tokyo, Japan; Respiratory Medicine, Kanazawa University Hospital, Kanazawa, Ishikawa, Japan; NHO Hokkaido Cancer Center, Sapporo, Hokkaido, Japan; Cancer Institute Hospital, Japanese Foundation for Cancer Research, Koto, Tokyo, Japan; Hyogo Cancer Center, Akashi, Hyogo, Japan; National Shikoku Cancer Center Hospital, Matsuyama, Ehime, Japan; Tokyo-West Tokushukai Hospital, Akishima, Tokyo, Japan; Tonan Hospital, Sapporo, Hokkaido, Japan; Yokohama City University, Yokohama, Kanagawa, Japan; Kyushu University, Fukuoka, Japan and Saitama Medical University International Medical Center, Hidaka, Saitama, Japan.

Body: Background: Evolution and heterogeneity are the hallmarks of cancer that confer a survival advantage under various stresses, including chemotherapy. However, determining the molecular profile of individual tumors requires biopsies of each site upon recurrence, which is often impractical. Use of a liquid biopsy of circulating DNA in the peripheral blood of cancer patients shows potential for obtaining gene profiles rapidly. In this study, we evaluated the gene status of the primary tumor site and circulating cell-free DNA after recurrence from the serum of patients with HER2-positive breast cancer. This cancer is generally resistant to HER2-targeted therapy due to PIK3CA mutations and loss of HER2 amplification.

Methods: Fifty patients with HER2-positive advanced breast cancer previously treated with trastuzumab and taxane were enrolled and treated with either trastuzumab or lapatinib in combination with capecitabine in West Japan Oncology Group (WJOG) study 6110BTR. PIK3CA mutation status and HER2 copy number was assessed and compared among 41 tissue specimens of the primary tumor and 35 serum samples after recurrence using digital PCR.

Results: HER2 copy number gain and a PIK3CA mutation were present in 61% (25/38) and 33% (13/39) of the primary tumor tissue samples, and in 23% (8/35) and 23% (8/35) of the serum samples after recurrence, respectively. Among the 26 matched tumor and serum samples, concordance of HER2 copy number and PIK3CA mutation status was 50% and 85%, respectively. Median follow-up was 44 months. Median OS and PFS was 15.5 (95%CI: 4.67 – undefined) and 5.1 months (95%CI: 2.53-8.35) for pts with the PIK3CA mutations and undefined and 6.5 months (95%CI: 4.41 – 9.90) for non-mutated pts, respectively. The mutated pts had shorter overall survival (p value = 0.0709) and progression free survival (HR=0.43 [0.16 – 1.16], p value = 0.0962).

Conclusions: The high concordance rate of PIK3CA gene mutation status between primary tumor and serum samples after recurrence was observed and the genetic analysis of circulating cell-free DNA using digital PCR was demonstrated to be a feasible and reliable method for predicting prognosis in the current population. A trend for worse OS and PFS was observed in mutated pts treated with HER2-targeted therapy in combination with capecitabine.
Title: Predictive value of ultra-high ESR1 mRNA expression in early breast cancer

Wirtz RM M, Scheffen I, Marme F, Laible M, Sclombs K, Schumacher C, Schneeweiss A, Eidt S and Sinn H-P. STRATIFYER Molecular Pathology GmbH, Cologne, Germany; St. Elisabeth-Hospital Köln-Hohenlind, Cologne, Germany; National Center for Tumor Diseases, University-Hospital Heidelberg, Heidelberg, Germany; BioNTEch Diagnostics GmbH, Mainz, Germany; Institute of Pathology at the St. Elisabeth-Hospital Köln-Hohenlind, Cologne, Germany and University Clinic Heidelberg, Heidelberg, Germany.

Body: Background
Quantitative determination of estrogen receptor mRNA expression in luminal breast tumors is predictive for benefit from adjuvant tamoxifen compared to placebo treatment as has been shown in the large randomized NSABP B-14 trial, while protein determination by IHC or LBA is not (Kim et al JCO 2011). Interestingly, the ultrahigh expression of ESR1 mRNA (above ER score 10 by Oncotype test) has been indicative for tamoxifen benefit. This predictive cut-off value of mRNA expression is significantly higher than the diagnostic cut-off (at ER score 6.5). Here we tested whether the ultrahigh expression of ESR1 mRNA determined by commercial MammaTyper® testing is predictive for survival after neoadjuvant chemotherapy treatment of advanced breast cancer.

Materials and Methods
Pretreatment core cut biopsies from n=54 patients with PBC treated within a randomized phase II trial (2) of anthracyline/taxane based NAC with available clinical follow-up information were examined. RNA was extracted from the FFPE sections and ESR1 mRNA from each section was measured by commercial assays. For technical comparison of ESR1 mRNA values by Oncotype DX versus MammaTyper® from n=113 surgical samples were analyzed by both commercial assays in a blinded fashion. Statistical analysis was performed using the SAS JMP® 9.0.0 software.

Results
Quantification of ESR1 mRNA expression after RNA extraction from separate slices of 113 primary breast tumors and determination by different commercial RT-qPCR assays resulted in high correlation of continuous expression results (Spearman r=0.85; p<0.0001). The rate of ESR1 mRNA negative cases by both methods by predefined diagnostic cut-offs was low in this cohort (1/113 and 6/113, respectively) resulting in high concordance for positive ER status by both methods. The median expression of ER score and ESR1 40-DDCq was high (10.2 and 39.8, respectively) and almost exactly at the predictive ER score cut-off. Hence, the Tamoxifen benefit cut-off of ER score 10 by Oncotype is comparable with a 40-DDCq value of 39.6 for ESR1 mRNA determination by MammaTyper®, which resembles an ESR1 mRNA expression 3-fold above the diagnostic cut-off. In the independent chemotherapy cohort the optimal discrimination for overall survival could be achieved by an elevated ESR1 mRNA expression exactly at 39.6 resulting in 100% overall survival for ultra-high expressors and 75% overall survival for lower ESR1 mRNA expression after 5 years (p=0.006).

Conclusion
Previous data suggest that ultrahigh expression of ESR1 mRNA is predictive for improved overall survival and tamoxifen benefit (1). Here we show that ultrahigh expression of ESR1 mRNA is also prognostic in more advanced breast tumors after neoadjuvant chemotherapy. These findings validate the importance of quantitative determination of estrogen receptor expression and substantiate the understanding of receptor expression being a continuous determinant with indication specific cut-off values. Ultrahigh expression of ESR1 seems to identify a distinct subset of luminal breast tumors with superior prognosis and benefit from tamoxifen treatment. These findings warrant further investigation, which are currently being done in independent large breast cancer cohorts.
Title: uPA/PAI-1 and adjuvant chemotherapy decision-making in early breast cancer

Deluche E, Venat-Bouvet L, Leobon S, Fermeaux V, Aubard Y, Saïdi N, Jammet I and Tubiana-Mathieu N. University Hospital, Limoges, France and Mother and Child Hospital, Limoges, France.

Body: Background: Adjuvant chemotherapy decisions are relatively simple using clinicopathological parameters (Goldhirsch et al. 2007), some cases require the addition of biomarkers as in patients with node negative or micrometastatic (N0), grade II (GII) breast cancer. The objective of this study was to evaluate the impact of uPA/PAI-1 compared to classical criteria +/- Ki67 in adjuvant treatment decision-making in this population.

Methods: This retrospective study included patients, treated from March 2008 to May 2016 in the Department of Medical Oncology at Limoges University Hospital (France). Ki67 and uPA/PAI-1 were analyzed on the initial specimen tumor. Optimal cut-off of Ki67 was defined at 20% (Coates et al. 2015). The positivity thresholds of uPA and PAI-1 were 3 ng/mg and 14 ng/mg respectively (Look et al. 2002). A positive uPA/PAI-1 level was defined as the elevation of at least one of these markers above the positivity threshold. All clinicopathological parameters were recorded prospectively.

Results: 2364 patients with breast cancer were screened. Among these patients, 256 N0, GII breast cancer patients were included with a median age of 62 years (32-87). Discordance between the two markers uPA/PAI-1 and Ki67 was observed in 58% of tumors. Adding Ki67 to the other classical clinicopathological parameters, 143 cases were defined as high risk versus 111 cases without Ki67; low risk were defined in 113 cases versus 145 cases without Ki67. Considering Ki67 status, the indication to perform adjuvant chemotherapy was increased by 29% compared to clinicopathological parameters. uPA/PAI-1 level was positive in these 143 high risk tumors in 93 cases and negative in 50 cases; in the 113 low risk tumors uPA/PAI-1 was positive in 72 cases and negative in 41 cases. uPA/PAI-1 increased indication to perform adjuvant chemotherapy by 15% compared to St Gallen criteria (including Ki67) and by 49% compared to St Gallen criteria (excluding Ki67). Using these two markers the final decision of chemotherapy by the multidisciplinary board was increased by 3% compared to St Gallen criteria (including Ki67).

Conclusions: This study highlighted that uPA/PAI-1 and Ki67 assessment provides additional information for adjuvant chemotherapy decision-making. This study confirms the difficulty to assess the level of importance (weighting) of these biomarkers in adjuvant chemotherapy decision-making. The use of uPA/PAI-1 was feasible, cost-effective in N0, GII breast cancer's patients.
Title: Baseline serum CA15-3 levels are associated with prognosis for breast cancer patients with non-complete pathological response to neoadjuvant chemotherapy

Body: Background: It has been well demonstrated that patients who achieved pathological complete response (pCR) after neoadjuvant chemotherapy (NAC) had a favorable prognosis compared with patients who did not (non-pCR). Even though pCR was not attained, reduction in tumor volume after chemotherapy may be associated with improved prognosis for a certain number of patients. However, the association between residual tumor volume and prognosis is not necessarily consistent. In order to identify substitute markers for breast cancer patients with non-pCR after NAC, we investigated the impact of serum levels of carcinoembryonic antigen (CEA) and carbohydrate antigen (CA15-3) at baseline as well as post-NAC.

Patients and Methods: Ninety-six breast cancer patients treated with NAC and operated on at the Hyogo College of Medicine were recruited for this study. Serum CEA and CA15-3 were measured prior to chemotherapy as well as at completion of pre-operative treatment. The optimal cutoff points for CEA (1.55ng/m, normal range: <5.0ng/ml) and CA15-3 (13.25U/ml, normal range: <28.0U/ml) for relapse-free survival (RFS) were determined by analyzing the area under receiver operating characteristic curves in another study involving 613 breast cancer patients. Expression levels of Ki67 in samples obtained at pre- and post-NAC were also determined by means of immunohistochemical staining. Pathological complete response was classified as the absence of residual invasive cancer in the breast and lymph nodes. During a 2.13 years median follow-up period, 15 patients suffered relapse.

Results: pCR and non-pCR was attained by 21 and 75 patients, respectively. For the non-pCR patients, serum CEA levels at baseline were classified into high (n=35) and low (n=38) and serum CA15-3 levels at baseline into high (n=31) and low (n=43). RFS of non-pCR patients with high serum CA15-3 levels was significantly worse than of those with low levels (3-year RFS: 0.47 vs 0.93; p=0.0009). RFS for patients with high and low serum levels of CA15-3 after NAC was also significantly different (p=0.037). As for CEA, no significant association with RFS was observed either at baseline or post-NAC. Univariate analysis demonstrated that tumor size and baseline CA15-3 were significant prognostic factors for RFS. Multivariate analysis showed that both tumor size (hazard ratio (HR): 3.88, 95% confidence interval (CI): 1.21-12.35, p=0.023) and baseline CA15-3 (HR: 13.51, 95% CI: 1.74-105.08, p=0.013) were significant and independent risk factors for relapse. As for lymph node metastasis, tumor grade, residual tumor size and pre- and post-NAC Ki67 expression levels of patients with non-pCR showed no significant association with RFS.

Conclusion and discussion: High levels of serum CA15-3 at baseline constituted a significantly worse prognosis for breast cancer patients with non-pCR. Tumor size at baseline but not residual size and baseline CA15-3 seems to suitable as a substitute for prediction of outcome for patients with non-pCR. Our findings suggest that these markers may be useful for identifying patients with poor prognosis who may be candidates for additional adjuvant treatment.
Title: BCL2 is a prognostic marker for subtype specific breast cancer

Kim HS, Eom YH, Song BJ and Chae BJ. Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Korea.

Body: Background
B-Cell lymphoma/leukemia 2 (BCL2) is an anti-apoptosis protein and an important clinical breast cancer prognostic marker. As the role of BCL2 is dependent on estrogen receptor (ER) status, this effect might differ in molecular subtypes. Patients with BCL2 positive expression in breast cancer have a better prognosis based on overall survival (OS) and relapse free survival (RFS). The frequency of BCL2 expression differs among molecular subtypes of breast cancer and it has a favorable prognostic effect. The aim of this study was to evaluate the relationship between prognostic outcome and BCL2 among the molecular subtypes.

Methods
We retrieved data of 1,356 patients in the breast cancer center of Seoul St. Mary's Hospital between 2006 and 2011. Expression of estrogen receptor (ER), progesterone receptor (PR), human epidermal growth factor receptor 2 (HER2), Ki-67, and BCL2 expression was examined by immunohistochemistry. We classified breast cancer into five molecular subtypes based on the 13th St. Gallen immunohistochemical classification, including luminal A, luminal B (HER2 negative), luminal B (HER2 positive), HER2 overexpression, and triple negative. We analyzed the clinicopathological features and assessed the correlation between BCL2 and clinical outcomes, such as relapse free survival (RFS) and disease specific survival (DSS) according to the five molecular subtypes.

Results
Of the 1,124 patients, 519 (46.2%) were BCL2 negative and 605 (53.8%) were BCL2 positive. BCL2-positive expression was associated with young age (<50 years old) \((p=0.036)\), lower histological grade \((p<0.001)\), low Ki-67 level (<14%) \((p<0.001)\), hormone receptor positive \((p<0.001)\), HER2 negative \((p<0.001)\), luminal breast cancer \((p<0.001)\), and low rate of recurrence \((p=0.016)\). BCL2-positive expression was also associated with favorable 5-year RFS and DSS \((p=0.008, 91.4\%; p=0.036, 95.6\%)\) in among all patients. BCL2-positive expression in the luminal A breast cancer showed significantly favorable 5-year RFS and DSS \((p=0.023; p=0.041, \text{ respectively})\). However, BCL2 expression was not associated with the prognosis in the other subtypes. The multivariate analysis revealed that tumor size, lymph node metastasis, and BCL2 expression were independent prognostic factors for RFS (BCL2: HR, 0.53; 95% CI, 0.29–0.97; \(p=0.015\)) and DSS (BCL2: HR, 0.59; 95% CI, 0.08–0.73; \(p=0.021\)) in luminal A breast cancer.

Conclusion
BCL2 expressed different frequency and played different prognostic roles according to breast cancer molecular subtype. BCL2 is an independent favorable prognostic marker for only luminal A breast cancer.
Title: Spectral CT based radiomics signature: A potential biomarker for preoperative prediction of lymph node metastasis in breast cancer

Dong D, Zhang X, Fang M, Shen J and Tian J. Institute of Automation, Chinese Academy of Sciences, Beijing, China and Sun Yet-Sun Memorial Hospital, Sun Yet-Sun University, Guangzhou, China.

Body: Purpose:
To investigate the usefulness of radiomics signature based on computed tomographic (CT) spectral imaging, during the late arterial phase (AP) and portal venous phase (PVP), in preoperative predicting the lymph node (LN) metastasis in breast cancer (BC).

Patients and methods:
This retrospective study was institutional review board approved, and written informed consent was obtained from all patients. We examined 60 female patients (LN metastasis positivity was 50%) with CT spectral imaging during the AP and the PVP and data was gathered from 2014 to 2016. Excised lymph nodes were located and labeled during surgery according to location on preoperative CT images and were evaluated histopathologically. For each patient, two 3D Hounsfield Unit (HU) gradient maps which revealed the HU change of each voxel were built by quadratic fitting the spectral HU curves during the two phases respectively. Then the radiomics features were then extracted from the regions of BC and a suspicious LN judged manually in these maps. The potential association of the four groups of radiomics features with LN status was assessed by using a Mann-Whitney U test. The area under curves (AUC) of the receiver operating characteristic curves (ROC) were compared with data obtained from the conventional CT image.

Results:
The 3D HU gradient map showed a great power of distinguishing among different components and was considered as a more effective tool for revealing the intratumour heterogeneity than the conventional CT image since the slope of spectral HU curves were significantly higher in malignant tumor. More than 500 radiomics features extracted from the regions of LN during the AP and the PVP exhibited significant differences (P <0.05). Moreover, the numbers of this kind of features extracted from the regions of BC were more than 200. The highest AUC of single feature was 0.70, which was higher than those from the conventional CT image.

Conclusion:
Quantitative radiomics features based on 3D HU gradient maps have the potential to be exploited as an effective biomarker for preoperative prediction of lymph node metastasis in breast cancer.
The molecular subtype has greater influence on prognosis of breast cancer than age at diagnosis

Kim HS, Eom YH, Song BJ and Chae BJ. Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Korea.

Introduction
Young age breast cancers have been considered more aggressive and associated with a poor prognostic factors. But, it remains controversial about the prognostic value of age at diagnosis in breast cancer. While some studies have found that young patients have worse clinical outcomes, others report young patients have a more favorable prognosis, or that there is no relationship between prognosis and age. The purpose of this study was to assess clinical, pathological variables, and different prognosis across three different age cohorts. and we also aimed to identify whether the distribution of molecular subtypes brings a different prognosis at different age cohorts.

Methods
Our study retrieved data from 1,410 patients with primary breast cancer who underwent surgery and the adjuvant treatment in the Department of Surgery, The Catholic University of Korea College of Medicine, Seoul St. Mary's Hospital between January 2007 and December 2011 were retrospectively analyzed. Our study classify each molecular subtype in three age cohort including ages <40, 40-50, >50 years. The association of age and molecular subtypes with recurrence free survival(RFS) and disease specific survival(DSS) were analyzed.

Result
Of 1,138 patients, 152(13.4%) were younger than 40 years, 461(40.5%) were between 40 and 50 years, and 525(46.1%) were older than 50 years. The group of younger patients(age <40 years) had association with poor prognostic factors, such as higher cancer stage, higher rate of lymph node metastasis, lower ER and PR expression, and higher ki-67(≥14%) than older patients(age 40-50 and age >50 group). Patients aged <40 years had higher proportion of triple negative breast cancer(p<0.001), and had significantly shorter RFS than patients aged 40-50 years and >50 years(p=0.047). There was no statistically difference in DSS(p=0.412). In subgroup analysis according to molecular subtypes, inferior RFS was observed for patients aged <40 years with only luminal A breast cancer(p=0.017). No difference according to molecular subtypes was observed in DSS. Aged <40 years is poor prognostic factor only in luminal A breast cancer, so it has limited prognostic value. It is thought to be due to longer exposure to the high level of estrogen in luminal A breast cancer patients aged <40 years.

Conclusion
Our findings suggest that the molecular subtype is the more main determinant of outcome than age at diagnosis in breast cancer. young age at diagnosis is not poor prognostic factor for all breast cancer patients, and it is restrictive prognostic factor of recurrence in luminal A breast cancer. It is necessary to consider the aggressive and extended hormonal treatment to improve outcomes for young patients.
2016 San Antonio Breast Cancer Symposium

Publication Number: P2-05-30

Title: OncotypeDX® for breast cancer: A multigene assay that makes a difference?

Martel S, Prady C, Simon R and Matte C. CISSS Montérégie-Centre/Hôpital Charles-LeMoyne, Greenfield Park, QC, Canada; CISSS Montérégie-Centre/Hôpital Charles-LeMoyne, Greenfield Park, QC, Canada; CISSS Montérégie-Centre/Hôpital Charles-LeMoyne, Greenfield Park, QC, Canada and CISSS Montérégie-Centre/Hôpital Charles-LeMoyne, Greenfield Park, QC, Canada.

Body: Objective: OncotypeDX® (ODX) is a multigene diagnostic assay that can estimate the 10 year-risk of distant recurrence in women with hormone receptor positive (HR+) and node negative (N–) early breast cancer. The test reports a Recurrence Score® (RS) and three risk group categories have been described: low-risk (<18), intermediate-risk (18-30) and high-risk (≥31). It helps the oncologist in the adjuvant chemotherapy decision process and globally leads to a reduction in the recommendation for chemotherapy use. This test is expensive and represents an economic burden in a publicly funded province. Nonetheless, its use has been approved over other gene expression profiling like Mammaprint® based on the evidence of its prognostic and predictive ability. We evaluated the adequacy of the requests for the ODX in an academic setting after the introduction in May 2012 of a reference framework for its use in Québec, Canada and the impact on chemotherapy recommendation. The costs generated by the test were also determined. Methods: We included all patients with an ODX request from two University Centers, CICM and CHUS, and estimated the concordance with the current provincial guideline for which an ODX may be ordered (invasive breast cancer HR+/Her2−/N− that is T1b with unfavorable characteristics or T1c or T2). For the intermediate-risk group, the factors influencing the final decision to use systemic chemotherapy were analysed. The projected cost-effectiveness of the ODX was derived from the proportion of patients (pts) for which the chemotherapy was not recommended. Results: Between May 2012 and December 2014, a total of 201 pts, 123 pts from CICM and 78 from CHUS, had an ODX done. In 93,0% (95%CI, 89,5-96,6) of pts, ODX was ordered correctly with respect to the guideline. There was no statistical differences between both sites (CICM: 92,7% [95%CI, 97,3-88,1]; CHUS 93,6% [95%CI, 88,2-99,0]). A total of 9 pts had high-risk RS (4,5%), 78 pts had intermediate-risk RS (38,8%) and 112 pts had low-risk RS (55,7%). Chemotherapy was recommended for 31 pts (18,2%) instead of an estimated 58,0% prior to the use of ODX according to previous reports published. In the intermediate-risk group, the majority of pts (74,4%) did not receive chemotherapy. The patient's preference and the absence of a proven benefit were the main reasons for withholding chemotherapy in this group. The additional cost associated with the use of the ODX was compensated with the reduction of the adjuvant systemic chemotherapy prescribed and its derived expenses (chemotherapy cost, nursing time and hospitalisations) and savings of 100 K were observed. Conclusions: In early breast cancer HR+ and N−, the use of ODX in two University Hospitals is concordant with published recommendations. ODX use is cost effective. This benefice does not take into account the psychological burden that comes with the decision to use adjuvant chemotherapy; neither does it evaluate potential long term complications. The widespread use of ODX must be looked at critically in face of other emerging gene signature tests like Endopredict® and PAM50®. As for the predictive ability of the ODX for adjuvant chemotherapy, one can question the strength of the actual evidence and argue if it confers this test an advantage over other multigene assays.

Title: High-risk breast cancer is less likely to occur in the ductal hyperplasia lesions or low-grade DCIS – Consideration of long-term follow-up observation after surgical biopsy

Takebe K and Arai T. Takebe Breast Care Clinic, Takamatsu, Kagawa, Japan.

Body: <Introduction>
Even if many ductal hyperplasia lesions and low grade DCIS are detected by breast cancer screening using high-resolution imaging modalities, we have often experienced high-grade breast cancer as an interval cancer. We might consider whether the detection of ductal hyperplasia lesions and low grade DCIS in breast cancer screening really leads to a decrease in breast cancer death. Therefore, we examined the follow-up periods after the removal of lesions. And we would like to refer to the problem of over-diagnosis and over-treatment of LGDCIS.

<Subjects and Methods>
At our facility from 1997 to 2012, we examined 354 cases of ductal hyperplasia lesions which were treated with surgical biopsy and followed up with observations spanning at least three years. The ductal hyperplasia lesions shown here are the usual ductal hyperplasia, flat epithelial atypia, atypical ductal hyperplasia, and intraductal papilloma. The median of the follow-up observation period was 73 months. In addition, we had 153 cases of low-grade DCIS patients who underwent follow-up of more than three years without postoperative irradiation. The median of the follow-up period was 63 months.

<Result>
(1) In ductal hyperplasia lesions, 25 cancers occurred in both breasts. There were 13 cases of DCIS in the histopathological examination (52%) and 12 cases of invasive cancer (46%). In DCIS, low-grade DCIS of Van Nuys1 accounted for 86%. Luminal A was 75% in invasive cancer. Lymph node metastasis was observed in only two cases, with one case having one metastatic lymph node and the other having two. Her2 type and triple-negative type accounted for one case each. Her2 type was microinvasive carcinoma, and Ki67 was 22% in triple negative type. The potential for malignancy in both was not so high.

In low-grade DCIS (non-irradiated), 11 cancers occurred in both breasts. There were 8 cases of DCIS (73%) and three cases of invasive cancer (27%). All of the DCIS cases were VanNuys1. All of the invasive cancer cases were luminal A.

(2) We compared the cancer occurrence in benign lesions and low-grade DCIS (surgery side). The occurrence rate was 2.2% for benign lesions and 3.2% for low-grade DCIS over a five-year period. There was no significant difference found between the two groups.

<Conclusion> High-risk breast cancer is less likely to occur in ductal hyperplasia lesions or low-grade DCIS. In other words, terminal duct lobular unit (TDLU) in both breast who had been affected with ductal hyperplasia or low grade DCIS lost a risk of the occurrence of high grade malignant cancer. Therefore, women with ductal hyperplasia and LGDCIS should be placed in the low-risk group of future breast cancer deaths. Small low grade DCIS might be regarded to be nearly as innocent as benign hyperplastic lesions.
Title: Tissue kallikrein-related peptidase 4, a novel biomarker in triple-negative breast cancer

Dorn J, Yang F, Aubele M, Kiechle M and Schmitt M. Klinikum rechts der Isar, Munich, Germany and Institute of Pathology, Helmholtz Center Munich, Neuherberg, Germany.

Body: Triple-negative breast cancer (TNBC), lacking the steroid hormone receptors estrogen receptor and progesterone receptor and not overexpressing the oncoprotein HER2, is characterized by its aggressive pattern and insensitivity to endocrine and HER2-directed therapy. Human kallikrein-related peptidases KLK1-15 provide a rich source of serine protease-type biomarkers associated with tumor growth and cancer progression for a variety of malignant diseases. In this study, recombinant KLK4 protein was generated and affinity-purified KLK4-directed polyclonal antibody pAb587 established to allow localization of KLK4 protein expression in tumor cell lines and archived formalin-fixed, paraffin-embedded triple-negative breast cancer (TNBC) tumor tissue specimens. For this, KLK4 protein expression was assessed by immunohistochemistry in primary tumor tissue sections (tissue microarrays) of 188 TNBC patients, mainly treated with anthracycline- or CMF-based polychemotherapy. KLK4 protein is localized in the cytoplasm of tumor cells and that of accessory stroma cells. In this patient cohort, elevated stroma KLK4 expression, but not tumor cell expression, is predictive for poor disease-free survival by univariate analysis (hazard ratio: 2.26, p=0.001) and multivariable analysis (hazard ratio: 2.12, p<0.01). Likewise, univariate analysis revealed a trend for statistical significance of elevated KLK4 stroma cell expression for overall survival of TNBC patients as well.
**Title:** Refining the prognostic value of Ki67 biomarker by ataxia telangiectasia mutated (ATM) status in a retrospective study of early stage hormone receptor positive breast cancer

Feng X, Li H, Kornarga E, Dean M, Lees-Miller S, Riabowol K, Magliocco A, Morris D, Watson P, Enwere E, Bebb G and Paterson A. Vancouver Island Cancer Center-British Columbia Cancer Agency, Victoria, BC, Canada; Faculty of Medicine, University of British Columbia, Victoria, BC, Canada; Tom Baker Cancer Center, University of Calgary, Calgary, AB, Canada; University of Calgary, Calgary, AB, Canada; Functional Tissue Imaging Unit, Translational Research Laboratory, Tom Baker Cancer Centre, Calgary, AB, Canada; Health Science Building, University of Calgary, Calgary, AB, Canada and H. Lee Moffitt Cancer Center, Tampa, FL.

**Body:**

**Purpose:** The current study was designed to investigate the combined influence of ataxia telangiectasia mutated (ATM) and Ki67 on clinical outcome in early stage hormone receptor positive breast cancer (ES-HPBC), particularly in patients with smaller tumors (< 4 cm) and fewer than four positive lymph nodes.

**Methods:** Formalin-fixed paraffin-embedded specimens of resected primary breast tumors from 532 patients diagnosed with early stage breast cancer were used to construct a tissue microarray. Samples from 297 patients were suitable for final statistical analysis. We detected ATM and Ki67 proteins using immunohistochemistry and quantified their expression with digital image analysis. Data on expression levels were subsequently correlated with clinical outcome. Data on expression levels were subsequently correlated with clinical outcome.

**Results:** Remarkably, ATM expression was useful to stratify the low Ki67 group into subgroups with better or poorer prognosis. Specifically, in the low Ki67 subgroup defined as having smaller tumors and no positive nodes, patients with high ATM expression showed better outcome than those with low ATM, with estimated survival rates of 96% and 89% respectively at 15 years follow up (p = 0.04). Similarly, low-Ki67 patients with smaller tumors, 1-3 positive nodes and high ATM also had significantly better outcomes than their low ATM counterparts, with estimated survival rates of 88% and 46% respectively (p=0.03) at 15 years follow up. Multivariable analysis indicated that the combination of high ATM and low Ki67 is prognostic of improved survival, independent of tumor size, grade, and lymph node status (p = 0.02).

**Conclusions:** These data suggest that the prognostic value of Ki67 can be improved by analyzing ATM expression in ES-HPBC.
Title: Risk stratification with EndoPredict signature for luminal subtype breast cancers: Re-analyzing microarray experiments with Han Chinese origin

Huang C-C, Tsai M-L, Tu S-H and Huang C-S. Cathay General Hospital, Taipei City, Taiwan; Fu-Jen Catholic University, New Taipei City, Taiwan and Taipei Medical University, Taipei City, Taiwan.

Body: Introduction: Breast cancer is a heterogeneous disease in terms of molecular aberrations. Luminal breast cancers, most of which are estrogen receptor (ER) positive without human epidermal growth factor receptor 2 (HER2) over expression clinically, constitute the majority of human breast cancers with better prognosis compared with basal-like or HER2-enriched subtype. The aim of the study is to evaluate the prognostication of EndoPredict signature, for which high- and low-risk group is defined based on a multi-gene assay. EndoPredict signature is supposed to guide adjuvant therapy for ER+/HER2- luminal breast cancers with up to three positive lymph nodes, while the test has not been validated for Han Chinese population yet.

Materials and methods: Our microarray experiments (partially published under GSE48391) and two publicly available microarray studies (GSE5460 and GSE20685) constituted the combined dataset of 565 breast cancers with Han Chinese origin, of which 280 were ER+/HER2- by immunohistochemical analysis. Transformation of Affymetrix microarray gene expression values to RT-qPCR-based expression values were conducted with the mathematical formula provided by the EndoPredict investigators, with gene-specific transformation factor and offset. Each enrolled patient was categorized into either high- or low-risk group based on the result of EndoPredict (EP) algorithm.

Results: Direct adaptation of the EP algorithm for microarray gene expression data resulted in over inflation of EP scores, and most cases were categorized into the high-risk group with the predefined threshold of EP score of 5 and adjustments with rescaling and relocations of microarray-based EP scores were performed. The proportion was 88% for low-risk group and 74% for high-risk group during the 10-year follow up period, with disease-specific survival advantage reported for those with EP-predicted low-risk group patients.

On the other hand, borderline overall survival discrepancy was observed (89% for low-risk and 80% for high-risk group).

<td>80.1%</td>
</tr>
</tbody>
</table>

P=0.05, log-rank test

In addition, patients with high-risk EP scores were associated with larger tumor size, higher nuclear grade, and more involved lymph nodes.

Discussion and conclusion: The study provides a solution to enhance the comparability between the FFPE/RT-qPCR based EP algorithms and fresh frozen microarray gene expression data. The statistical framework presented here provides an “in-silicon” validation for EP algorithm and further studies taking clinical parameters into consideration will augment the clinical applicability of EP scores and EPclin scores to ascertain the prognostic power of multi-gene assay for luminal breast cancers in Taiwan.
Title: Rs1008805 polymorphism in CYP19A1 gene is related to the prognosis of early breast cancer

**Body:**

**Purpose** Aromatase, encoded by CYP19A1 gene, is a rate-limiting enzyme in the conversion of androgens into estrogens. Given the critical role of CYP19A1 gene in estrogen synthesis, the potential impact of genetic polymorphisms at CYP19A1 gene on breast cancer patient survival deserves further study.

**Methods** Rs1008805 polymorphism in CYP19A1 gene were genotyped on 406 Chinese Han women with stage I-II and operable stage III breast cancer. Associations were explored between rs1008805 genotypes and disease-free survival (DFS).

**Results**

Totally, there were 200 (49.3%) patients with AA genotype, 169 (41.6%) with AG variant, and 37 (9.1%) carrying GG variant. No significant differences were found in DFS or 5-year survival rate among the whole population with these three genotypes. However, in postmenopausal women, rs1008805 genotypes were significantly associated with DFS and 5-years DFS rate (AA versus AG versus GG: 63.1 months versus 54.3 months versus 13.7 months; 48.6% versus 46.0% versus 14.3%; \( P = 0.015 \)). In addition, women with GG variant had a poorer DFS, 5-years DFS rate when compared with those carrying AG or AA genotype (GG versus AG or AA: 13.7 months versus 56.3 months; 0% versus 52.1%; HR, 2.462; 95% CI, 1.310-4.628; \( P = 0.004 \)). Being adjusted by patients features in multivariate analyses, GG genotype remained an independent prognostic factor for DFS (HR, 2.706; 95% CI, 1.393-5.257; \( P = 0.003 \)). Whereas premenopausal women with the homozygous minor allele had a marginally improved DFS, 5-years DFS rate when compared with those carrying the common allele (GG versus AG or AA: 87.0 months versus 48.7 months; 60.3% versus 42.7%; HR, 0.544; 95% CI, 0.295-1.003; \( P = 0.051 \)). However, there was no relationship between GG genotype and DFS or 5-year DFS when adjusted by patients features in multivariate analyses.

**Conclusions** The present study indicated that GG genotype of rs1008805 SNP in the first exon of CYP19A1 gene was significantly related to a worse DFS or 5-years DFS rate in postmenopausal women with early breast cancer. This founding is novel, if confirmed, CYP19A1 rs1008805 genotypes may turned to be a prognostic biomarker for early breast cancer.
Title: Clinicopathological predictors for low risk recurrence distinguished by 21-gene recurrence score in estrogen receptor-positive invasive breast cancer patients

Tsuchida Y, Hayashi N, Omata F and Yamauchi H. St. Luke's International Hospital, Tokyo, Chuo-ku, Akashi-cho, Japan and St. Luke's International Hospital Center for Clinical Epidemiology, Tokyo, Chuo-ku, Akashi-cho, Japan.

Background: The 21-gene Recurrence Score (RS) (Oncotype DX®; Genomic Health, Redwood City, CA) is the most valid and reliable multigene assay to predict prognosis or response to treatment in hormone receptor-positive invasive breast cancer patients. However, in Japan, the test is expensive (about 4,000 US dollars) and one of the problems is that about 30% of patients will be categorized as having moderate recurrence risk. If clinicopathologic factors can be used to predict patients with low recurrence, many patients can avoid postoperative chemotherapy without testing the RS. Such predictors shall have a substantial impact on medical economics too. The aim of this study was to determine significant clinicopathological predictors for low recurrence risk by RS in patients with estrogen receptor-positive primary breast cancer.

Methods: Retrospective cross-sectional study was conducted in tertiary referral hospital in Tokyo, Japan. Two hundreds twenty patients with estrogen receptor-positive invasive breast cancer underwent surgery for breast cancer and tested for RS from November 2009 to March 2016. RS £18 was defined as low recurrence risk. The patients were divided into 2 groups, patients with low recurrence risk (n=143) and with a moderate/high recurrence risk (n=77). Age, menopausal status, histologic type (invasive ductal vs. lobular carcinoma), nuclear grade, progesterone receptor (PR) expression, Ki67 index, tumor size, lymph node status, and lymphovascular invasion were considered as candidate predictors. Student’s t test or Wilcoxon-Rank Sum test and Fisher’s exact test was used for continuous variables and proportion, respectively. Simple and multiple logistic regression model were used to determine significant predictors. Classification and regression tree analysis (CART) was also conducted.

Results: Mean age (SD) of low and moderate/high recurrence patients was 53 years-old (9.4) and 55 years (10.2), respectively. Univariate analyses revealed that the invasive lobular carcinoma, the high PR expression, Ki67 < 24, and the absence of lymphovascular invasion were significantly associated with low recurrence risk. According to multiple logistic regression, The odds ratio (OR) [95%CI] of histological type (invasive lobular), high PR expression, Ki67 < 24, and the absence of lymphovascular invasion was 0.43 [0.08-1.8], 10 [5.4-23.6], 0.95 [0.93-0.97], and 0.57 [0.23-1.18], respectively. The area under the receiver operating characteristic curve was 0.83. CART showed that the probability of low recurrence risk was 79% if with high PR expression, and 92% if with high PR expression and Ki67 < 24.

Conclusions: High PR expression and Ki67 < 24 were significant predictors for low recurrence risk by RS in estrogen receptor-positive invasive breast cancer patients. More than 90% of patients with high PR expression and Ki67 < 24 could be classified as low recurrence risk by RS.
Title: In-situ hybridization of microRNA and support vector machines–based prognostic classifiers for breast cancer

Cao Z, Yao L, Hu X, Zhang Z and Shao Z. Key Laboratory of Breast Cancer in Shanghai, Fudan University Shanghai Cancer Center, Shanghai, China and School of Public Health, Fudan University, Shanghai, China.

Body: Purpose: We plan to use a tissue microarray-based microRNA(miRNA) detection by in situ hybridization with LNA probe and support vector machine on base of data mining to construct the Prognostic model for breast cancer and triple negative breast cancer (TNBC).

Methods: Combining the BreastMark miRNA database and papers published, we chose candidate miRNAs. Then a tissue microarray-based miRNA detection in situ hybridization with LNA probe was used to detect miRNA expression in 445 breast cancer tissue. Univariate analysis with Kaplan-Meier identified independent prognostic factors, 445 patients was divided into the training set and validation set (70% VS 30%) by software R(version 3.2.3), then support vector machine on base of data mining was used to construct the Prognostic model for breast cancer and triple negative breast cancer via software R and predict.svm(e1071).

Results: 15 miRNAs were detected from 445 breast cancer tissue and univariate analysis with Kaplan-Meier identified significant prognostic miRNAs: miR-361-5p, miR-301a, miR-223, miR-421, miR-454, miR-493 were the independent prognostic factors for DFS. By using data mining technique, we combined clinical factors(stage, tumor size, lymphnode status, molecular subtype) and miRNAs mentioned above to establish the personalized predictive mathematical models SVM-BC and SVM-TNBC. In the training set and validation set of SVM-BC model, the AUC value of ROC curve for DFS were 0.86,0.83. The total accuracy,sensitivity,specificity of SVM-BC model for DFS were 94%,73%,99% and 84%,57%,92% in the training set and validation set. The SVM-BC model can divide breast cancer patients into high-risk and low-risk groups, and 5-year survival rates for low-risk patients were higher than that for high-risk patients(96.8% VS 39.3%, p<0.001).

In the training set and validation set of SVM-TNBC model, the AUC value of ROC curve for DFS were 0.84,0.86. The total accuracy,sensitivity,specificity of SVM-TNBC model for DFS were 90%,71%,97% and 84%,55%,94% in the training set and validation set. The SVM-TNBC model can divide breast cancer patients into high-risk and low-risk groups, and 5-year survival rates for low-risk patients were higher than that for high-risk patients(93.9 % VS 23.5%, p<0.001).

Conclusion: The Prognostic model basing of tissue microarray-based miRNA detection in situ hybridization with LNA probe and support vector machine for prognosis can effectively predict the prognosis of breast cancer and TNBC.

**Title:** De novo and relapsed metastatic breast cancer: Presentation and survival changes over time 1990-2009

Malmgren JA, Atwood MK and Kaplan HG. HealthStat Consulting Inc, Seattle, WA and Swedish Cancer Institute, Seattle, WA.

**Body:**

Background: De novo stage IV and relapsed stage IV metastatic breast cancer (MBC) may present with different biology and respond differentially to treatment. De novo stage IV patients are treatment naive which may confer a survival advantage. Prior radiation and chemotherapy treatment for relapsed stage IV (rMBC) patients reduces available treatment options and may confer a survival disadvantage. The possible survival differences have not been adequately studied.

Methods: A retrospective cohort study of de novo and relapsed stage IV MBC patients from a dedicated institutional BC registry database, years 1990-2009 [invasive BC N = 7653, MBC N=1077 (de novo = 221, relapsed = 856)]. Relapsed stage IV MBC (rMBC) patients were identified by continuous annual follow up of stage I-III patients for distant metastases (M1). De novo stage IV MBC was identified as such at diagnosis using AJCC 7 diagnostic criteria (Any T, Any N, M1). Chi square tests, Kaplan Meier plots, and Cox regression survival analysis were conducted. Disease specific survival (DSS) interval was time from diagnosis date to breast cancer death for de novo MBC and time from first distant relapse date to breast cancer death for rMBC patients.

Results: De novo MBC incidence was constant at 3% per year over time but rMBC decreased from 17% to 8% (1990-99 to 2000-09, p<.001). Among rMBC cases, percentage of her2-neu (her2) positive cases decreased 16% over time from 1990-99 to 2000-09. With the decrease in her2 positive cases the relative number of hormone receptor-/her2- (triple negative) rMBC cases increased proportionately. MBC average survival was 3.2 years (.01, 19.67) with median de novo survival equal to 3.81 years and median rMBC survival equal to 1.81 years (p<.001). Overall, 5 year DSS among de novo stage IV patients was superior at 43% vs. 21% among rMBC patients (0<.001). Over time de novo stage IV 5 year DSS improved significantly from 31% to 51% (p =.018). rMBC 5 year DSS did not improve over time and appeared to decline but not significantly [1990-99 23%, 2000-09 18%, p = .079]. In Cox regression analysis, factors associated with worse DSS were TN status (RR = 2.20, 95% CI 1.75, 2.75), age 70+ (RR = 2.35, 95% CI 1.73, 3.19), and rMBC vs. de novo MBC (RR = 2.44, 95% CI 1.95, 3.07).

Conclusions: We observed better overall DSS among de novo MBC patients compared to rMBC patients. DSS rates improved over time in de novo MBC but not among the relapsed MBC patients. Overall, better breast cancer specific survival among de novo MBC patients may be related to better response to treatment in therapy naive de novo MBC and use of neoadjuvant therapy methods. It appears the introduction of targeted her2-neu therapy has reduced the number of Her2+ patients with relapsed MBC. Less effective treatment options for de novo and relapsed triple negative BC and BC in the elderly may be responsible for the elevated risk of mortality from MBC observed among TNBC and elderly patients.
The 3’UTR signature defines a highly metastatic subgroup of triple-negative breast cancer

Wang L, Hu X, Wang P and Shao Z-M. Fudan University Shanghai Cancer Center, Fudan University, Shanghai, China; Shanghai Medical College, Fudan University, Shanghai, China; Shanghai Advanced Research Institute, Chinese Academy of Sciences, Shanghai, China; School of Life Science and Technology, ShanghaiTech University, Shanghai, China and Institutes of Biomedical Sciences, Fudan University, Shanghai, China.

Body: Purpose. Triple-negative breast cancer (TNBC) is a highly heterogeneous disease with an aggressive clinical course. TNBC relapse or metastasis is associated with an unfavorable prognosis so predictive models are needed to chart potential patient outcomes. Alternative polyadenylation (APA) has recently gained attention as a major player influencing the kinetics of gene regulation under diverse physiological and pathological status, resulting in the dynamic usage of 3’ untranslated region (3’UTR). We postulate that alternative 3’UTR patterns, if incorporated into a single model, could improve postoperative risk stratification and identify a highly metastatic subgroup of TNBC. In this study, we used alternative 3’UTR patterns to improve postoperative risk stratification.

Experimental Design. We collected 327 publicly available microarrays and randomly stratified samples in a training (n = 164) and validation set (n = 163). Then, 1,933 3’UTRs were generated based on expression ratios of alternative 3’UTR. After initial feature filtering, we built a 17-3’UTR-based classifier using an elastic net model and validated the prognostic accuracy in both training and validation sets.

Results. Time-dependent ROC comparisons and Kaplan–Meier analyses confirmed an outstanding discriminating power of our prognostic model for TNBC patients. In the training cohort, 5-year event-free survival (EFS) was 78.6% (95% CI 71.2–86.0) for the low-risk group, and 16.3% (95% CI 2.3–30.4) for the high-risk group (log-rank p < 0.0001; hazard ratio [HR] 8.29, 95% CI 4.78–14.4). In the validation set, 5-year EFS was 75.6% (95% CI 68.0–83.2) for the low-risk group, and 33.2% (95% CI 17.1–49.3) for the high-risk group (log-rank p < 0.0001; HR 3.17, 95% CI 1.66–5.42). The 17-3’UTR-based classifier could be used to independently predict outcomes and this outperformed prognosis using classical clinicopathological risk factors.

Conclusions. Our 17-3’UTR-based classifier provides a superior prognostic performance for estimating disease recurrence and metastasis in TNBC patients and it may permit personalized management strategies.
Body: Background
After chest radiotherapy (RT) for Hodgkin lymphoma (HL), women experience a dose-dependent increased breast cancer (BC) risk. It is unknown whether endogenous and exogenous gonadal hormones affect the radiation dose-response relationship.

Methods
We conducted a nested case-control study among female 5-year HL survivors treated before 41 years between 1965-2000. Data were collected through medical records and questionnaires for 174 BC cases and 466 matched controls. RT charts, simulation films and mammography reports were used to estimate the radiation dose to the location of the breast tumor.

Results
The median interval between HL and BC diagnosis was 21.9 years. 98% of BC cases had received chest RT, compared to 92% of controls. We observed a linear radiation dose-response curve with an adjusted excess odd ratio (EOR) of 5.4%/Gray (95%CI:1.8%-13.37%). Women with menopause <30 years (caused by high-dose procarbazine or pelvic RT) had a lower BC risk (OR:0.13, 95%CI:0.03-0.54) than women with menopause ≥50 years. BC risk increased with 7.4% for each additional year of intact ovarian function after RT (P<0.001). Among women with an early menopause (<45 years), the use of hormone replacement therapy (HRT) for ≥2 years did not increase BC risk (OR:0.81, 95%CI:0.30-2.21). Endogenous and exogenous hormones did not statistically significantly modify the slope of the radiation dose-response relationship.

Conclusion
HRT use did not appear to increase BC risk in female HL survivors with a therapy-induced early menopause. Moreover, there was no evidence for interaction between RT dose and years with intact ovarian function or HRT use.

Title: Development and validation of a new non-parametric breast cancer risk assessment model on US and European screening populations

Ragusa S, Gauthier E, Dartois L, Tice J, Dancourt V, Arveux P, Brixi Z, Bernoux A, Soper Y, Delattre H, Brechenade S, Catalar N, Kaufmanis A, Hélin VM, Clavel F, Kerlikowske K, Miglioretti D and Delaloge S. Statlife, Villejuif, France; Centre for Research in Epidemiology and Population Health (CESP), U1018, Team 9, Villejuif, France; University of California San Francisco, San Francisco, CA; ADECA21, Dijon, France; Cote d’Or Registry, Centre Georges François Leclerc, Dijon, France; ADOC94, Charenton Le Pont, France; ADMC91, Briis Sous Forges, France; ADN78, Versailles, France, ADK92, Puteaux, France, PSVO95, France; CDC93, France; ADC77, France; University of California Davis, Davis, CA, France and Gustave Roussy, Villejuif, France.

Body: Background: Stratified breast cancer (BC) prevention is a major option for the future but requires clinically meaningful internationally validated risk models. Non parametric models may be alternate methods for modeling in very large cohorts. We have previously shown that a non-parametric similarity-based k-nearest neighbors’ (kNN) model performs better than the BCRAT/Gail model to on 65 000 women of the E3N French national cohort (Dartois et al 2015). We used this method to develop and validate a mammographic density-based model in larger general screening populations (pops).

Methods: A modified version of a data-mining based algorithm, the kNN method, was implemented and adapted as previously described [ref Dartois]. Core concept of kNN algorithm is to gather similar profiles using a distance computation. We developed a BC risk prediction model on 629 229 women (wn) from the US Breast Cancer Research Consortium (BCSC), with 5 times random selection of learning and validation sets (75/25 %) within the cohort. 5 parameters were included: age, family history, previous breast biopsy, mammographic density and race. The model's performances (discrimination using c-stat (AUC) and calibration using E/0 ratio) were evaluated and compared to the parametric model developed on the same pop (param/BCSC)(Tice et al 2008). This kNN/BCSC model was then tested on two French screening pops after adjustment on French BC incidence: an urban area (Paris suburbs, N=316 775) and a rural area (Côte d’Or, N=32 930). Its performances were compared to those of a model directly developed (same methods) on the Paris cohort (kNN/Paris). Levels of individual risks assessed by the models were assigned into 4 risk categories. The sensitivity of the models was defined as the number of wn who had BC whose 5 yrs-risk category was intermediate (median risk at 50-yrs - 1.66%), high (> 1.66%) or very high (> 20% lifetime) divided by the total number of wn who had BC.

Results: The performances of the different models are shown in Table 1. The kNN model developed on BCSC performed well (c-stat 0.653 and E/0 1.001). It had equivalent performances as the parametric model developed previously on the same pop. This kNN/BCSC had a good discrimination on French pops, although slightly lower than that on US pops. This is expected since French screening starts at 50 (vs 40 in BCSC) and French parameters do not include race. The calibration of such model was excellent on Paris, while it overestimated the risk on Côte d’Or, in which BC incidence is lower. It performed as well as the kNN/Paris model directly developed on Paris’ pop. The sensitivity of the kNN/BCSC on US and French pops was good.

Conclusions: A new non parametric kNN breast cancer risk model developed on an American screening cohort (BCSC) was successfully validated on two French screening cohorts. This new international model could allow stratified prevention.

Title: A clinical model for assessment of the individual breast cancer risk

Body: Background. Most mammography screening programs are not individualized. To efficiently screen for breast cancer the individual risk of the disease should be determined. We describe a model that estimate the 2-year risk of breast cancer and could be used at most mammography screening units without adding substantial cost.

Methods. The study was based on the population based prospective Karma cohort including 70,877 participants. Mammograms were collected up to three years following baseline mammogram. A prediction protocol was developed using mammographic features (density, microcalcifications and masses), use of hormone replacement therapy (HRT), family history of breast cancer, menopausal status, age, and body mass index. Relative risks were calculated using conditional logistic regression. Absolute risks were calculated using the iCARE protocol.

Results. Comparing women at highest and lowest mammographic density yielded a 5-fold higher risk of breast cancer for women at highest density. When adding microcalcifications and masses to the model, high-risk women had a nearly 9-fold higher risk of breast cancer compared to those at lowest risk. The difference in microcalcifications and masses between left and right breast was a better predictor of breast cancer than number of microcalcifications and masses in the breasts.

When calculating the absolute 2-year risk of breast cancer we stratified women using the NICE guidelines for 10-year risk divided by 5 (Table 1). The mean absolute 2-year risk of breast cancer in the different risk categories was 0.12%, 0.33%, 0.83% and 1.95% for women at low, moderate, general, and high risk. In most countries with established mammography screening programs approximately 5 women in a 1000 are diagnosed with breast cancer at regular screening. We managed to identify a low risk group of approximately 10% of all women where 1 woman in a 1000 will be diagnosed with breast cancer, contrasting the 2% of all women at highest risk where 20 women out of a 1000 will be diagnosed with breast cancer within 2 years of last negative screen (Table 1).

In the full model, taking HRT use, family history of breast cancer and menopausal status into consideration, area under the curve (AUC) reached 0.71.

Conclusions. Our model includes three mammographic features that could easily be derived from clinically available software. By adding information on some few established risk factors it is possible to improve clinical care by identifying women in need of additional examination procedures. At the same time there is a substantial proportion of women that will have very little benefit from mammography screening due to their low risk of breast cancer.

Title: Risk of metastases after ipsilateral breast tumour recurrence changes overtime according to patient and tumour characteristics: Implications for treatment

Gennaro M, Di Cosimo S, Ardoino I, Veneroni S, Mariani L, de Braud F, Daidone MG, Biganzoli E and Demicheli R. Fondazione IRCCS Istituto Nazionale dei Tumori, Milano, Italy.

Body: To evaluate the risk of systemic disease of early breast cancer (EBC) patients undergoing breast conservative surgery between 1970 - 2000 and experiencing ipsilateral breast tumour recurrence (IBTR). Patients and Methods The study population included EBC patients randomly assigned onto 5 Milan prospective trials (n= 915) or comparably treated outside clinical trials (n= 1060) with quadrantectomy followed by radiotherapy and with known primary tumor characteristics. Multivariable regression analysis was performed via the piecewise exponential. The model accounts other than known prognostic factors, including age, menopausal status, pathologic size, nodal status and time dependent effect for estrogen receptor (ER) for the IBTR occurrence as time dependent covariate (i.e. switching from 0 to 1 at the time of surgery for IBTR). Also the new time scale induced by IBTR occurrence, namely time elapsed since surgery for IBTR to the end-point of interest, was accounted for in the model. Results Median follow-up was 124 months (IQ Range 96.6 – 179). At the time of analysis, 504 patients were died, 470 presented with systemic disease and 150 with IBTR as first breast cancer event. IBTR was associated with a high risk of systemic disease. This risk was dependent on primary tumor characteristics, including T size, T2 versus T1 (HR 1.79 95% CI 1.46 – 2.21), and nodal status, N1 versus N0 (HR 1.61, 95% CI 1.32 – 1.98), and N2 versus N0 (HR 3.91, 95% CI 3.13 – 4.89). Of note, ER-negative cohort had a slightly earlier and higher hazard of events overtime compared with ER-positive cohort, which, instead, presented higher hazard estimates over the long follow-up period. The most important finding concerned the new timescale induced by IBTR occurrence that revealed to have definite prognostic value, and suggest that patients with IBTR as compared with patients with no IBTR have a sudden and at least 5-fold increase of risk of systemic disease within 2 years following second surgery; of note, this risk decreases thereafter, though it never disappears. Conclusion Breast cancer patients experiencing IBTR are at increased risk of systemic disease. This risk changes overtime and is different according to initial patient and primary tumor characteristics, and hormonal receptor status. The definition of different patterns of BC recurrence can improve BC care through surveillance guidelines and can guide the design of tailored clinical studies.
Body: BACKGROUND Black patients diagnosed with invasive breast cancer (IBC) are more likely to die of the disease than their White counterparts. Differences in IBC subtype, socioeconomic status, and access to healthcare may be contributing factors. We performed this study to determine if there is a racial disparity in breast cancer-free interval (BCFI) for patients treated at a military medical center where equal-access healthcare is provided.

METHODS Three datasets were used: 1) TCGA-Breast Cancer cohort with 149 Black and 706 White patients; 2) Clinical Breast Care Project patients from a military medical center (CBCP-WR) with 112 Black and 372 White patients; and 3) CBCP patients from a civilian facility (CBCP-AAMC) without equal-access healthcare (data collection is ongoing and results will be available for the conference). IHC of ER, PR, and HER2 was performed to subtype IBCs as TN (ER-/PR-/HER2-) or Non-TN. Patients with Stage IV IBC at diagnosis were excluded. Kaplan-Meier method was used to generate survival plots. Cox proportional hazards regression model was used for survival analysis between races (Black vs. White). Univariable and multivariable analyses were performed. All analyses were performed using R 3.2.2. A two-tailed p value < 0.05 was considered significant.

RESULTS The clinicopathologic properties of Black and White patients in TCGA and CBCP-WR cohorts were analyzed, and the results are consistent with the literature. The median follow-up times were comparable between the two races (TCGA: Black=29.4 M, White=27.5 M; CBCP-WR: Black=61.1 M, White=60.9 M).

In TCGA, race significantly affects BCFI in multivariable analysis after adjustment for age, AJCC stage, and PAM50 subtype (HR=1.73, 95%CI=1.02-2.94, p=0.042). Stratifying patients into TN (Black=46.7%; White=53.3%) and Non-TN (Black=14.2%; White=85.8%) subtypes, race trended towards significant in BCFI in TN (HR=2.33, 95%CI=0.98-5.56, p=0.052) but not Non-TN subtypes (HR=1.12, 95%CI=0.55-2.27, p=0.752). Further adjustment for age and AJCC stage did not alter the results.

In CBCP-WR, there was no significant racial difference in both univariable (HR=1.52, 95%CI=0.87-2.68, p=0.145) and multivariable analysis of BCFI adjusted for age, subtype and AJCC stage (HR=1.00, 95%CI=0.5-2.01, p=0.989). Stratifying patients into TN (Black=43.5%; White=56.5%) and Non-TN (Black=18.8%; White=91.2%) subtypes, race was not a significant factor in either group (TN: HR=0.920, 95%CI=0.4-2.14, p=0.846; Non-TN: HR=1.17, 95%CI=0.53-2.61, p=0.701). Further adjustment for age and AJCC stage did not alter the results.

CONCLUSIONS Our results show that in the CBCP-WR cohort, there is no racial disparity in BCFI at the whole cohort level nor is there any trend in the TN subtype. These results contradict those obtained from the TCGA cohort suggesting unequal healthcare access may be a major contributor to racial disparity in BCFI. Analysis of the CBCP-AAMC cohort may provide further insight into whether treatment at a single medical center needs to be considered when investigating racial disparities in BCFI.

Title: Prediction of relapse in patients with locally advanced breast cancer after neoadjuvant treatment

Aseyev O, Simmonds L, Gertler M, Dent S and Verma S. The Ottawa Hospital Cancer Center / The University of Ottawa, Ottawa, ON, Canada.

Body: BACKGROUND. Despite advances in cancer treatment, over 25% of patients (pts) with locally advanced breast cancer (LABC) relapse (DR) during first 5 years after treatment (Trmt).

OBJECTIVES. The primary objective was to construct a prediction tool for risk of relapse (RoR) in pts with LABC after neoadjuvant therapy (NAT). Previously published works (Matsuda N. et al, 2014; Keam B. et al, 2011; Katz A. et al. 2008) have also examined this issue.

MATERIAL AND METHODS. This was single center, retrospective study of 546 pts with LABC who received NAT at the Ottawa Hospital Cancer Center between 2005 and 2015. Median follow-up (FU) was 49 months. The following data collected: demographics, tumor size, nodal and receptor status, grade, HER-2, stage of disease, cancer Trmt and clinical outcomes. Primary endpoints were local (L) and/or distant (D) DR rate during first 5 years and time to DR during the first 5 years. A prediction tool was devised based on the Cox regression model.

RESULTS. In 545 pts NAT was prescribed as follows: FEC-D – 91 (17%), AC-Docetaxel – 330 (60%), other regimens (AC, AC-Paclitaxel, TC, TCH) – 124 (23%). Breast conserving surgery was performed in 67 (12%) pts, mastectomy in 440 (81%) pts. Adjuvant radiotherapy was given in 485 (89%). All patients had trastuzumab – 173 pts (34%) for Her2-positive disease and endocrine Trmt (tamoxifen and/or AI) – 356 (44%) pts – for endocrine-sensitive disease. DR rate during first 5 years of FU was 17.3% (L DR – 3.2%, D DR – 13.2%, L+D DR – 0.9%).

Over 60 variables were included in primary analysis. Cox regression proportional hazards model resulted in only 5 factors with significant influence on RoR during first 5 years of FU. Risk factors and their risk prediction value are: 1) residual disease (yes- 4; no-0), (HR = 4.25; p-value=0.000), 2) lymph nodes status (positive-3; negative-0), (HR = 2.27; p-value=0.006), 3) Inflammatory histology (yes-2; no-0), (HR = 1.90; p-value=0.003) 4) estrogen receptors status (positive-2; negative-0), (HR = 2.07; p-value=0.001), 5) Adjuvant radiotherapy (yes-0; no-1), (HR = 1.76; p-value=0.036). When these factors are combined the following Relapse Prediction (RP) Score can be constructed (table 1).

Table 1. Risk prediction score

<table>
<thead>
<tr>
<th>Score</th>
<th>Risk of relapse (5 years)</th>

</tr>
</tbody>
</table>

Internal validation of proposed model was performed. ROC analysis revealed a sensitivity of 75%. According to this simple RP score, pts can be classified into to three groups (RP score – 0-5; 6-7; 8-12). RoR was 7 times higher in patients with RP Score 8-12 vs pts with score 0-5 (p-value<0.0001).

CONCLUSIONS. Pts with LABC represent a heterogeneous group with diverse risk of DR. Our prognostic tool based on 5 risk factors can be used to predict RoR after NAT with a sensitivity of 75%. Pts with high risk may require additional Trmt and/or more active FU strategies and this simple model may be used to design unique studies in LABC based on RP score. We intend to further validate this model on a larger multi center/provincial population.
Title: Chemoprevention uptake among women with atypical hyperplasia, lobular and ductal carcinoma in situ

Coe AM M, Trivedi MS S, Vanegas A, Kukafka R and Crew KD D. Columbia University Medical Center, New York, NY.

Body: Introduction: Chemoprevention with anti-estrogens can reduce breast cancer risk among high-risk women. However, uptake is estimated to be lower than 15% among women offered anti-estrogens. Women with atypical hyperplasia (AH), lobular carcinoma in situ (LCIS), and ductal carcinoma in situ (DCIS) are at an increased risk of developing invasive breast cancer and often derive more benefit from anti-estrogens compared to other high-risk populations. We sought to determine which factors are associated with chemoprevention uptake in a population of women with AH, LCIS, and DCIS.

Methods: We conducted a retrospective cohort study at an urban academic center in New York, NY of women diagnosed with AH/LCIS/DCIS between 2007 and 2015 without a history of invasive breast cancer (n=1719). Demographic and clinical information, including type of anti-estrogen and medical oncology referral, were collected from the electronic health record. Breast disease in each patient was classified according to the most advanced lesion (DCIS>LCIS>AH). A subset of women with AH/LCIS/DCIS scheduled for an initial consultation with a medical oncologist (n=73) completed questionnaires on their breast cancer and chemoprevention knowledge, risk perception, and behavioral intentions. Descriptive statistics were generated and univariate and multivariable log-binomial regression were used to estimate the association between sociodemographic and clinical factors and chemoprevention uptake.

Results: In our sample, mean age was 60 years (SD 12); white/black/Hispanic/Asian/other (%): 45/9/23/6/17; AH/LCIS/DCIS (%): 35/24/41; and 33% were referred to a medical oncologist. A total of 505 (29%) women had initiated an anti-estrogen, including 54% who used tamoxifen, 15% raloxifene, 19% aromatase inhibitors, and 11% who tried multiple anti-estrogens. Older women and Hispanics compared to non-Hispanic whites were more likely to take anti-estrogens. Compared to women with AH, LCIS (RR: 1.43; 95% CI: 1.16-1.76) and DCIS (RR: 1.54; 95% CI: 1.28-1.86) were significantly associated with chemoprevention uptake. Medical oncology referral was the strongest predictor of chemoprevention uptake (RR: 5.79; 95% CI: 4.80-6.98). According to the survey data, many women had heard of anti-estrogens for chemoprevention (75%), but few were knowledgeable about it. The majority of participants were worried about the side effects of chemoprevention (72%) and considered them very serious (57%). Satisfaction was high among those who reported making a decision to take chemoprevention, however, only 50% of survey participants thought the benefits of anti-estrogens were worth the risks.

Conclusions: At our center, women with AH, LCIS, and DCIS have higher rates of chemoprevention uptake compared to the reported literature. Despite the potential for younger women to see a greater lifelong benefit from chemoprevention, our results indicate this population may be less likely to use anti-estrogens. Misperceptions about personal breast cancer risk and chemoprevention adverse effects may be barriers to uptake. Improving patient-provider communication about breast cancer risk and the risks and benefits of chemoprevention may facilitate informed-decision making about anti-estrogen therapy.
Title: Concordance with National comprehensive cancer network (NCCN) metastatic breast cancer guidelines and impact on overall survival

Rocque GB B, Williams CP P, Jackson BE E, Halilova KI I, Pisu M, Andres F and Smita B. University of Alabama at Birmingham, Birmingham, AL.

Body: Introduction: Payers are implementing reimbursement restrictions for non-guideline based care. Limited information exists regarding real-world concordance with guidelines for metastatic breast cancer (MBC) treatment. Further, the impact of non-concordance on mortality is unknown. We address these gaps by using the Surveillance, Epidemiology, and End Results (SEER) Program-linked Medicare database to evaluate national concordance with NCCN guidelines and the association between concordance and mortality.

Methods: From 2007 to 2013, women with de novo (n=988) or recurrent metastatic breast cancer (n=5651) were evaluated for concordance of first-line systemic therapy (hormonal therapy, chemotherapy, and Her2-targeted therapy) with NCCN guidelines. Concordance was defined as receipt of single agent or combination treatments listed on NCCN guidelines. Non-concordant treatments were grouped into 5 categories: single-agent HER2-targeted therapy (33%), adjuvant regimens used in the metastatic setting (12%), therapy mismatched with ER/HER2 status (12%), non-approved bevacizumab regimens (10%), and other miscellaneous reasons (33%). Multivariable logistic regression was used to identify predictors of non-concordance. Hazard ratios (HR) and 95% confidence intervals (CI) were estimated using Cox regression to compare all-cause mortality associated with non-concordant vs. concordant treatment adjusted for receptor status, comorbidities, age, race, poverty level, entitlement reason, and treatment year.

Results: Mean age at MBC diagnosis was 69y; 77% were white. Median follow-up was 1.2 years. The prevalence of non-concordant first-line systemic therapy was 19% for de novo MBC and 18% for recurrent MBC. Younger age, hormone-receptor negative status, and Her2-positive status were associated with non-concordant treatments for Stage IV and recurrent MBC patients (p<0.001). Higher poverty by census tract was associated with non-concordance in recurrent MBC (p<0.05). The most frequent category of non-concordant treatment in de novo MBC was use of adjuvant regimens in Stage IV MBC (43%) and use of single-agent HER2-targeted therapy (31%) in recurrent MBCs. Adjusted overall survival was similar for patients with de novo MBC receiving concordant and non-concordant treatments (HR 0.88, CI 0.72-1.65). Mortality was modestly increased for patients with recurrent MBC receiving non-concordant care (HR 1.12, CI 1.02-1.22); however, substantial differences were noted by category of non-concordance. Compared to concordant treatment, single-agent HER2-targeted therapy was associated with decreased risk of mortality (HR 0.78, CI 0.68-0.91). Increased mortality was observed for non-approved bevacizumab use (HR 1.79, CI 1.44-2.22) and other miscellaneous regimens (HR 1.42, CI 1.26-1.60). Mortality for therapy mismatched with ER/HER2 status was similar to concordant treatment (HR 1.13, CI 0.88-1.44).

Conclusions: In the first-line setting, treatment inconsistent with NCCN guidelines remains common (18%). Overall mortality was not substantially higher among non-concordant patients. However, mortality risk varied (in both directions) by category of non-concordance. These findings may provide an opportunity for considering refinement of NCCN guidelines.
2016 San Antonio Breast Cancer Symposium

Publication Number: P2-07-03

Title: Insulin and breast cancer risk: Novel insights from mammographic density analyses

Borgquist S, Rosendahl AH H, Czene K, Bhoo-Pathy N, Dorkhan M, Hall P and Brand JS S. Lund University, Lund, Sweden; Karolinska Institutet, Stockholm, Sweden and Julius Centre University of Malaya, Kuala Lumpur, Malaysia.

Body: Background: Insulin has been suspected to influence breast cancer risk because of its mitogenic effects and impact on sex hormone levels. Epidemiological studies investigating breast cancer occurrence in insulin-treated patients with diabetes have produced conflicting results, but were often underpowered and lacked adequate control for important confounders.

Purpose: To investigate the impact of insulin treatment on mammographic density (MD) as intermediate phenotype for breast cancer risk, and to further explore causation by analyzing associations with a polygenic risk score (PRS) incorporating 18 single nucleotide polymorphisms (SNPs) associated with fasting insulin levels.

Design: We conducted a matched cohort study within a Swedish screening-based cohort including insulin-treated type 1 (T1D, N=122) and type 2 (T2D, N=237) diabetes patients and up to 5 non-diabetic women matched on birth year (N=1,780). Associations between diabetes status and duration of insulin use with volumetric mammographic density were analyzed using general linear models adjusting for a comprehensive set of potential confounders. PRS analyses were performed in an independent sample of non-diabetic women (N=9,437) from the same cohort.

Results: In multivariable analyses, T1D patients had higher percent (11.2 vs. 8.8%; P<0.001) and absolute dense volumes (66.6 vs. 60.8 cm$^3$; P=0.09) and a lower absolute non-dense volume (513.2 vs. 617.7 cm$^3$; P<0.001) compared to age-matched non-diabetics. Percent- and absolute dense volumes increased with increasing T1D duration, while no such trend was observed for the absolute non-dense volume. Similar associations but of smaller magnitude, were found in insulin-treated T2D patients. Genetically predicted higher fasting insulin levels among non-diabetes women were associated with increased percent and absolute dense volumes (% change per sd increase in PRS = 0.8 (0.0-1.6) and 0.9 (0.1-1.8) respectively), but no difference in absolute non-dense volume.

Conclusions: Our results demonstrate higher mammographic density among insulin-treated diabetes patients, and genetic analyses support an effect of insulin on volumetric mammographic density. Further studies into how the observed MD differences translate into breast cancer risk are warranted.
Title: Risk of primary and contralateral breast cancer in BRCA1/2 mutation carriers previously affected with ovarian cancer

Body: Introduction: BRCA1/2 mutation carriers are at increased risk of developing breast cancer (BC) and ovarian cancer (OC). However, for BRCA1/2 mutation carriers previously affected with OC, primary BC (PBC) and contralateral BC (CBC) risks might be lowered due to OC treatment, but data hereon are limited. Accurate BC risk estimates are essential for counseling and optimal decision making on BC surveillance and risk-reducing mastectomy (RRM) after diagnosis of BRCA1/2-associated OC. Methods: From the national HEBON cohort study, we selected female BRCA1/2 mutation carriers born from 1940 and at risk of PBC (n=2019; 1194 BRCA1, 825 BRCA2) or at risk of CBC (n=1276; 839 BRCA1, 437 BRCA2). Eligibility criteria for the PBC risk analyses included no history of PBC and both breasts in situ at DNA testing. For the CBC risk analyses, CBC before DNA testing was not allowed and the contralateral breast had to be unaffected at DNA testing. To estimate the association between OC and BC risk, we used the Fine and Gray regression model, with OC as a time-dependent variable and death as competing risk event. The observation started at the age of DNA testing, age 35, or – for the CBC risk analyses – age at PBC diagnosis, whichever came last. Censoring events were RRM, study closing date (i.e. 2014-12-31), and – for the CBC risk analyses – ipsilateral BC recurrence. All analyses were performed separately for BRCA1 and BRCA2 mutation carriers. Results: For the PBC analyses, we selected 236 BRCA1/2 mutation carriers with OC and 1783 BRCA1/2 mutation carriers without OC (median age at start study 53 and 41 years, respectively). During a mean follow-up (FU) of 5.2 years, 15 (6%) OC patients developed PBC after OC, while PBC was diagnosed in 262 (15%) women without OC. OC diagnosis was associated with a lower PBC risk in BRCA1 mutation carriers (HR, 0.27; 95% CI, 0.14–0.53) but not in BRCA2 mutation carriers (HR, 0.88; 95% CI, 0.34–2.27). The cumulative PBC incidence at age 70 in BRCA1 mutation carriers was 25% for OC patients and 66% for women without OC, and in BRCA2 mutation carriers 49% for OC patients and 53% for women without OC. For the CBC analyses, we selected 99 BRCA1/2 mutation carriers affected with PBC and OC, and 1177 BRCA1/2-associated PBC patients without OC (median age at start study 54 and 46 years, respectively). During a mean FU of 3.5 years, 8 (8%) PBC/OC patients developed CBC after OC, while CBC was diagnosed in 131 (11%) PBC patients without OC. In BRCA1 mutation carriers, OC diagnosis was non-significantly associated with a lower CBC risk (HR, 0.44; 95% CI, 0.19–1.03). For BRCA2 mutation carriers the HR was 1.65 (95% CI, 0.34–8.04). The cumulative CBC incidence at age 70 in BRCA1 mutation carriers was 40% for OC patients and 68% for patients without OC; for BRCA2 mutation carriers the number of CBCs was too small to obtain meaningful estimates. Conclusion: For BRCA1 mutation carriers affected with OC the risk of developing subsequent BC is lower than for BRCA1 mutation carriers without OC. Our data suggest that the current BC prevention strategies should be reconsidered for OC patients carrying a BRCA1 mutation, possibly including less intensive BC surveillance, and RRM being indicated only for a subgroup of OC patients.
Title: Risk of metachronous contralateral breast cancer: Systematic review and meta-analysis

Akdeniz D, Schmidt MK K, McCool D, van den Broek AJ J, Hauptmann M, Seynaeve CM M, Steyerberg EW W and Hooning MJ J. Erasmus MC Cancer Institute, Rotterdam, Netherlands; Erasmus MC – University Medical Center Rotterdam, Rotterdam, Netherlands; Netherlands Cancer Institute, Amsterdam, Netherlands and Netherlands Cancer Institute, Amsterdam, Netherlands.

Body: Introduction
Over the last 2 decades, an increasing number of primary breast cancer (PBC) patients opted for a risk reducing contralateral mastectomy, to minimize risk of subsequent contralateral breast cancer (CBC). Therefore, accurate risk estimates of CBC are important for patient tailored counseling and decision making regarding treatment. Currently, CBC risk estimates are determined by \(BRCA1/2\) mutation status, age at PBC diagnosis and family history. For other risk factors, results are inconclusive. We therefore aimed to quantify the association with CBC risk for patient, tumor and treatment related factors as reported in the literature.

Methods
Medline was searched for publications on CBC risk by one reviewer (DA). We focused on associations between CBC risk and \(BRCA1/2\) and \(CHEK2*1100delC\) mutations, SNPs, risk-reducing salpingo-oophorectomy and various factors at PBC diagnosis: family history of breast cancer (BC), age, BMI, menopausal status, mammographic density, TNM-stage, receptor status, morphology, administered radiotherapy and adjuvant systemic treatment.

Eligible papers were published in English between 01-01-1990 and 01-04-2015, investigated female patients with invasive early BC and reported relative risk (RR) estimates (i.e., hazard ratios, relative risks or odds ratios).

We combined RR estimates using a random effects model. Heterogeneity was assessed using the \(I^2\) statistic. Forest plots for crude and adjusted estimates were generated stratifying for mutation status (i.e., \(BRCA1\), \(BRCA2\), \(CHEK2*1100delC\), non-carriers and unselected patients (i.e., population/hospital based cohorts).

Results
After screening of 1,423 papers for title and abstract, 173 eligible papers were fully read, and 96 papers fulfilled the inclusion criteria.

Both in the unselected group and in the \(BRCA1\) and \(BRCA2\) groups, administration of adjuvant endocrine therapy (vs. not), was associated with decreased CBC risk (RR, 0.62 (95% CI 0.55-0.69), 0.55 (95% CI 0.39-0.77), and 0.62 (95% CI 0.40-0.95), respectively). Adjuvant chemotherapy was associated with reduced CBC risk in unselected patients (RR 0.73; 95% CI 0.62-0.86). CBC risk was increased in unselected patients who received radiotherapy at age<40 years (vs. not) (RR 1.33; 95% CI 1.18-1.49), had a lobular (vs. ductal) PBC (RR 1.70; 95% CI 1.33-2.16), had a T2/T3 (vs. T1) PBC (RR 1.15; 95%CI 1.01-1.30), with BMI \(\geq 30\) (vs. <25) at PBC (RR 1.50; 95% CI 1.27-1.76) or had a positive family history for BC (vs. not) (RR 1.82; 95% CI 1.35-2.46). For the other factors of interest we did not observe any effects on CBC risk.

For \(CHEK2*1100delC\) mutation carriers and non-carriers, information on factors affecting CBC risk was scarce. In non-carriers, the RR for adjuvant chemotherapy was 0.60 (95% CI 0.53-0.68).

Conclusions
In unselected patients, adjuvant systemic treatment for PBC decreases CBC risk while a lobular morphology of PBC, high BMI, and a family history of BC increase the risk of CBC. Data is scarce for carriers of a \(BRCA1/2\) or \(CHEK2*1100delC\) mutation and non-carriers. This review identifies prognostic factors to consider for individualized CBC risk estimation which may support medical decision making in BC patients.
Title: Obesity, dyslipidemia, and diabetes as risk factors for trastuzumab-related cardiotoxicity in breast cancer patients

Aseyev O, Johnson C, Turek M, Stadnick E, Law A, Gosh N and Dent S. The Ottawa Hospital Cancer Center / The University of Ottawa, Ottawa, ON, Canada.

Body: Background. Clinical trials have demonstrated an increased risk of cancer treatment related cardiac dysfunction (CTCD) during trastuzumab (H) therapy. Diabetes, dyslipidemia, and obesity are also known risk factors for cardiovascular disease. The primary objective of this study was to evaluate the incidence of asymptomatic drop in left ventricular ejection fraction (AD-LVEF) and symptomatic CTCD (S-CTCD) in women with BC and co-morbidities receiving H, referred to a dedicated cardio-oncology clinic (COC).

Methods. This was a retrospective cohort study of women with BC (all stages) referred to The Ottawa Hospital COC between 2008 and 2015, who received chemotherapy (CT) and H. Data collected included: demographics, reason for referral, cardiac testing (MUGA/ECHO) co-morbidities (diabetes, dyslipidemia) and cardiac outcomes. Obesity defined as body mass index > 30. Symptomatic CTCD include SOB, PND, orthopnea, peripheral edema, congestive heart failure. Asymptomatic drop in LVEF defined as decrease of at least 15% from baseline; normal LVEF, or a decrease of at least 10% in LVEF, less than 53%.

Results. Chemotherapy (A-CT) followed by H, 62 received H without A-CT. 139 patients with no history diabetes, dyslipidemia, or obesity, referred with AD-LVEF (68%), with S-CTCD (30%), pre-CT assessment (2%). Obesity (O) pre-existing co-morbidity in 63 (26%) patients, (20 (32%) with S-CTCD, 40 (63%) referred with AD-LVEF, 3(5%) referred for pre-CT assessment). Dyslipidemia (L) – 52 (21%); referred with S-CTCD 15; 29%), with AD-LVEF 31 (60%), pre-CT assessment 6 (11). Diabetes (D) – 29 (12%) - (6 (21%) with S-CTCD, 19 (66%) referred with AD-LVEF, 4(13%) referred for pre-CT assessment). Combination of two or three conditions significantly increase incidence of S-CTCD: O+L – 67%, O+D – 69%, O+L+D – 72%. Combination of obesity and other conditions significantly increase incidence of S-CTCD: O+L – 67%(Relative Risk -2.2, p=0.04), O+D – 69% (RR-2.3, p=0.02), O+L+D – 72% (RR-2.4, p=0.08).

Conclusion. The combination of two or three co-morbidities significantly increases the incidence of S-CTCD. BC patients experiencing CTCD with pre-existing history of diabetes, dyslipidemia, and obesity may require more proactive strategies for prevention, detection and treatment of cardiotoxicity during trastuzumab-based treatment.
Title: Comparison of survival and clinicopathological features between patients with breast cancer and HIV infection versus breast cancer without HIV infection

Body: Background:
Breast cancer (BCA) is the most common malignancy and the most common cause of death among females worldwide. The use of antiretroviral therapy prolonged life expectancy and increased the incidence of age-related malignancies in patients with the human immunodeficiency virus (HIV). Data regarding the protective versus deleterious effect of HIV in the presentation, clinical course and mortality of patients with BCA is limited.

Objective: To compare the median overall survival between patients with and without HIV diagnosed with breast cancer between 2000 and 2014 at Montefiore Medical Center.

Methods: Patients with HIV infection and breast cancer diagnosed between 2000 and 2014 were identified. Controls were randomly selected from a pool of 5552 patients with BCA without HIV using stratified sampling by year of breast cancer diagnosis with a ratio of 3 controls per case. Patients were followed up for a median of 52 months. Median overall survival and clinicopathological characteristics were compared among groups.

Results: A total of 42 cases of BCS with HIV infection were identified. Of 126 selected controls; 15 were excluded after chart review. Patients with HIV were diagnosed with breast cancer at significantly younger ages compared to non-HIV patient (50.6 vs 64.8, P <.001), had lower BMI (26 vs 30.1, p<0.001) and had higher frequency of Not-hispanic Black (NHB) (64.3% vs 41.4%). Breast cancer stage, grade, histological type and hormonal status as well as surgery, chemotherapy and hormonal therapy were not significantly different between the groups; but the HIV group had a tendency towards less hormonal therapy. There was no difference in the rate of mortality; however overall median survival was higher in patient with HIV. This difference was not statistically significant (106 vs 72, p=0.78)

Conclusion: Patients with HIV are diagnosed with breast cancer at younger ages than the general population. Closer monitoring in this population was suggested by other authors; however the rate of stage I disease is similar between both groups. Despite similar rates of surgery and chemotherapy, higher rates of NHB and less hormonal therapy, mortality rates were similar in both groups and median overall survival was higher in patient with HIV.

**Title:** Neuroleptics in breast cancer risk

Johnston A, Garcia S, Hein S, Bu W and Yi L. Baylor College of Medicine, Houston, TX.

**Body:** Psychiatric medications are among the most widely prescribed class of drugs in the U.S.; the main mechanism of action for a majority of both class 1 and 2 of antipsychotics is blockade of the dopamine receptors in the brain. Dopamine signaling blocks the release of prolactin in the hypothalamus; thus, a common side-effect of anti-psychotic medications is hyperprolactinemia, which causes breast swelling and lactation unrelated to a pregnancy. Elevated serum prolactin levels are associated with increased breast cancer risk. Prolactin-stimulated PRLR/JAK/STAT signaling suppresses cell apoptosis and promotes mammary early lesion progression to cancer. However, it is not yet known whether these dopamine receptor-blocking antipsychotics increase breast cancer risk, and evidence-based research on this topic remains limited. We found that treatment of mice bearing precancerous early lesions with either pimozide (a class 1 antipsychotic) or risperidone (a more commonly prescribed class 2 antipsychotic) caused hyperprolactinemia, activated STAT5 and, unexpectedly, STAT3 in these early lesions, suppressed cell apoptosis, and increased the early lesion load. Furthermore, we observed that continual risperidone treatment, which mimics the treatment scheme of a great majority of patients on this type of medication, accelerated the progression of these early lesions to cancer. Additionally, we found that a short-course of ruxolitinib, an FDA-approved JAK1/2 inhibitor, prevented the cancer-promoting effects of risperidone. Collectively, these data suggest that hyperprolactinaemia-inducing antipsychotics lower the apoptotic anticancer barrier in precancerous lesions and increases breast cancer risk, and prophylactic treatment with ruxolitinib can lower the risk of breast cancer in women on these neuroleptics. RRPA and other genetic experiments have led to potential mechanisms underlying the weakened apoptotic anticancer barrier in these antipsychotic-treated mice.

Title: CPM rate among individuals with breast cancer who underwent multiplex gene testing for hereditary cancer: Single institution experience

Elsayegh N, Gutierrez Barrera AM M, Kuerer HM M, Hernandez ND D, Litton JK K and Arun BK K. UT MD Anderson Cancer Center, Houston, TX.

Body: Background: Availability of multiplex gene (MPG) testing for hereditary cancer has led to increase use of panel testing versus single gene testing for hereditary cancer. These panels include high, but also moderate penetrance genes. For some of these genes, associated cancer risk and risk management guidelines do not exist. Furthermore there is a high rate of variant of unknown significant (VUS) findings in non-BRCA genes. Currently, in the absence or minimal available data, health care providers and patients are faced with important risk management decisions, especially regarding preventive surgeries, such as prophylactic mastectomy. Currently, there is no data regarding prophylactic mastectomy rate among patients with breast cancer who underwent (MPG) testing. Therefore, our aim was to evaluate the rate of contralateral prophylactic mastectomy (CPM) in a cohort of individuals who underwent multiplex gene testing. Methods: Eight hundred thirty five patients with breast cancer who underwent MPG testing between the years 2013 and 2016 were identified using Institutional Clinical Cancer Genetics Database. Patients with pathogenic, likely pathogenic variants or who had a VUS were included in the analysis. Results: Of 835 patients with a diagnosis of breast cancer; 105 (13%) had a pathogenic or likely pathogenic mutation: 29 (28%) BRCA1, 26 (25%) BRCA2, 11 (11%) ATM, 2 (2%) BARD1, 3 (3%) BRIP, 9 (9%) CHEK2, 1 (1%) MSH2, 1 (1%) NBN, 5 (5%) PALB2, 4 (4%) PTEN, 1 (1%) RAD51C, 5 (5%) TP53, 4 (4%) CDH1, 2 (2%) MUTYH, 1 (1%) PMS2, 1 (1%) APC (1). A total of 102 (12%) VUS were found. Average age of diagnosis was 44 (Range 21-81). CPM rate was 32% (n=66) for the total cohort. Twenty nine % (n=19) of patients with non-BRCA mutations, 24.2% (n=16) with VUS and 46% (n=31) with BRCA mutations opted for CPM. Conclusion: Overall 32% of breast cancer patients with germline mutations or VUS opt for CPM at our institution. The rate for CPM in non-BRCA mutations carriers is high despite no available data regarding contralateral breast cancer risk and benefit of CPM. This finding should be validated in larger cohorts, including identification of reasons behind decision for CPM in these cohorts.
Breast health behaviors of women under 40 accessing the Avon breast health outreach program

Body: Background
Breast cancer is the most common cancer among women, and tends to be more aggressive when diagnosed in women <40 years. However, limited research exists on breast health behaviors of women <40. This study analyzes trends in breast health behaviors and diagnostic data among women <40 served by the Avon Breast Health Outreach Program (BHOP) which links medically underserved women to breast health education and screening services.

Methods
Confidential client intake records of female clients (n= 192,296) of Avon BHOP grantees continuously-funded from 2011-2015 were analyzed, along with breast cancer diagnosis data from a select number of clients (n=82) from January-March 2016.

Results
Approximately 7% of Avon BHOP clients from 2011-2015 were <40 years (n=12,872). Women <40 had a significantly lower odds of having been taught breast self-exam (BSE), knowing about mammograms before their visit, having had a clinical breast exam (CBE) in the past 2 years, and having had a mammogram in the past 2 years compared to women ≥40. Over 80% of women <40 reported being taught BSE and knowing about mammograms before their visit, compared to 94% among women ≥40. The percent who reported a CBE in the past 2 years increased by approximately 5% among both <40 and ≥40 women, to a high of 64.6% and 78.2%, respectively, in 2015. Reporting a mammogram in the past 2 years also increased by approximately 5% in both groups, to a high of 25.9% and 70.3%, respectively, in 2015.

Women <40 had a significantly higher odds of having breast-related symptoms (OR=7.64) and a relative diagnosed with breast cancer (OR=1.23) compared to women ≥40. For women <40, the adjusted odds of having had a mammogram in the past 2 years were 1.34 times higher (p<0.001) among those who had a relative diagnosed with breast cancer compared to those who did not, while the odds were 1.09 (p<0.001) among women ≥40.

From January-March 2016, 10 breast cancer cases in women <40 were reported by 7 Avon BHOP grantees; 38 cases were reported in women ≥40. Of the 10 diagnosed cases, the majority were Hispanic (70%) and 30% were Stage IV compared to 6% among women ≥40, however the difference was not statistically significant (p=0.096).

Discussion
In 2015 the American Cancer Society estimated that 4.2% of breast cancer cases were diagnosed in women <40. While the Avon BHOP diagnosis data is limited, the results nonetheless demonstrate a higher rate of breast cancer in this age group. Additionally, the association between being <40 and having a later stage diagnosis compared to those ≥40 appears to be a meaningful trend, and, while not significant in our preliminary data, we anticipate the finding to persist.

While Avon BHOP clients <40 had a significantly lower odds of knowing about screening behaviors compared to ≥40, a large percentage had knowledge of breast health, and increasingly reported higher rates of screening behaviors. There was also a greater positive association between having a relative with breast cancer and having had a mammogram in the past 2 years in women <40 compared to ≥40.

These findings suggest that Avon BHOP clients <40 increasingly understand their breast cancer risk and seek screening services accordingly. It is important to provide clear screening guidelines for this population.
The association between angiotensin receptor blockers usage and breast cancer characteristics

Background: Data regarding the impact of angiotensin receptor blockers (ARB) on breast cancer are inconsistent. We evaluate the association between ARB usage and breast cancer characteristics and outcomes.

Methods: All patients who were treated in our institute for estrogen receptor positive, human epidermal growth factor receptor 2 negative early breast cancer between 4/2005 and 3/2012 and whose tumors were sent for Oncotype-DX analysis were included. Medical records were retrospectively reviewed for clinical-pathological parameters, related comorbidities, treatment and outcomes. Data regarding ARB usage was retrieved. Usage of several pre-specified medications for hypertension including angiotensin converting enzyme inhibitors (ACEI), mineralocorticoid receptor antagonists (MRA), and β-blockers (BB) was also evaluated. Each medication group was compared to the rest of the study population.

Results: 671 patients were included in the study cohort. Forty six (7%) were treated with ARB, 93 (14.2%) with ACEI, 14 (2.1%) with MRA, and 115 (17.5%) with BB. ARB usage was associated with different histological subtype distribution (P=0.009), higher incidence of macroscopic nodal involvement (P<0.001) and more advanced stage at diagnosis (p<0.001). These findings remained significant on multivariate analysis. Patients treated with ARB had worse 5-year breast cancer specific survival (94.7% vs. 98.8%, P=0.024) and worse 5-year overall survival (94.6% vs. 98.8%, p=0.015), but these differences were not demonstrated on multivariate analysis (p=0.251 and p=0.441, respectively).

Conclusions: Patients treated with ARB presented with more advanced breast cancer disease and some distinct histological features. Further research is required to elucidate the effect of ARB treatment on breast cancer.

IDC- invasive ductal carcinoma, ILC- invasive lobular carcinoma
Body: Background
There are studies suggesting significant association between the patient's comorbidity and perioperative outcomes. In breast cancer, patient comorbidity can also influence the oncologic outcome by affecting the decisions regarding adjuvant treatments. In this study, we examined the long-term oncologic outcome in breast cancer patients who underwent curative surgery according to their pre-existing comorbid conditions.

Methods
The medical records of 2,501 patients who underwent surgery for primary breast cancer from June 2006 to June 2010 were reviewed retrospectively. The patients were classified into three groups (ASA 1, 2, 3) according to preoperative ASA status determined by the anesthesiologists. Clinico-pathologic characteristics and survival outcomes of the patients were compared among the different co-morbidity groups.

Result
There were 1,792 (71.6%), 665 (26.6%), and 44 (1.8%) patients in ASA 1, 2, and 3, respectively. Total 95 (3.8%) deaths and 269 (10.8%) recurrences (loco-regional and distant) occurred during the median follow-up period of 71 months. Patients with high comorbidity showed significantly higher rate of death (51 (2.8%), 38 (5.7%) and 6 (13.6%) deaths in ASA 1, 2 and 3 group, respectively, p<0.001). The ASA 3 patients also showed significantly higher rate of breast cancer recurrence when compared to other groups (180 (10.0%), 80 (12.0%) and 9 (20.5%) in ASA 1, 2 and 3, respectively, p=0.041). Cox multivariate analysis demonstrated that high ASA score (ASA 3) was an independent prognostic factor in DFS, OS and BCSS (95% confidence interval [CI], 1.661-6.780; p=0.001, 1.753-11.321; p=0.002 and 2.222-18.429; p=0.001). Fewer patients in the high co-morbidity group received adjuvant therapies (77 (4.3%), 44 (6.6%) and 8 (18.2%) in ASA 1, 2 and 3, p<0.001). The increased recurrence of breast cancer in the high morbidity group was most seen in patients who did not receive adjuvant therapies. The incidence of serious adverse effect during the adjuvant therapy did not differ according to the co-morbidity conditions.

Conclusion
In this study, high comorbidity was related to increased risk of death and recurrence in breast cancer. The increased risk of recurrence in high co-morbidity group was mostly seen in patients who did not receive adjuvant therapies. In patients who underwent the adjuvant therapies, the incidence of serious adverse effects did not differ according to the co-morbidity status.
Title: TP53 gene polymorphisms (c.[215G>C]) in breast cancer patients and predisposition to family cancers- Single center experience

Huszno J, Grzybowska E, Nycz Bochenek M, Pamula Pilat J, Tecza K and Nowara E. Maria Skłodowska-Curie Memorial Cancer Center and Institute of Oncology, Gliwice Branch, Gliwice, Silesia, Poland; Center for Translational Research and Molecular Biology of Cancer, Maria Skłodowska-Curie Memorial Cancer Center and Institute of Oncology, Gliwice Branch, Gliwice, Silesia, Poland; Genetic Outpatient Clinic. Maria Skłodowska-Curie Memorial Cancer Center and Institute of Oncology, Gliwice Branch 44-101 Gliwice, Gliwice, Silesia, Poland; Center for Translational Research and Molecular Biology of Cancer, Maria Skłodowska-Curie Memorial Cancer Center and Institute of Oncology, Gliwice Branch, Gliwice, Silesia, Poland; Center for Translational Research and Molecular Biology of Cancer, Maria Skłodowska-Curie Memorial Cancer Center and Institute of Oncology, Gliwice Branch, Gliwice, Silesia, Poland and Maria Skłodowska-Curie Memorial Cancer Center and Institute of Oncology, Gliwice Branch, Gliwice, Silesia, Poland.

Body: Introduction: Somatic mutations in the TP53 gene are one of the most frequent alterations in human cancers, and germline mutations are the underlying cause of Li-Fraumeni syndrome, which predisposes to a wide spectrum of early-onset cancers. The aim of this study was to evaluate the association between TP53 gene polymorphisms (c.[215G>C]) and predisposition to family cancers. Methods: We reviewed the medical records of 89 (21% TP53 gene homozygotes and 79% heterozygotes) breast cancer patients who were diagnosed and treated in COI in Gliwice. The history of family cancers was collected from medical history. Mutation profile was assessed by RFLP-PCR technique. We evaluated the presence of polymorphism TP53 (c.[215G>C]). Statistical analysis was carried out using STATISTICA 7 software. Results: Cancers in family history were detected in 72% of pts with TP53 polymorphisms and they were observed insignificantly more often in heterozygotes than in homozygotes (76% vs. 58%, p=0.153). The most frequently reported cancers were: breast cancer (33%), lymphoma (17%), colorectal cancer (9%), OUN cancer (8%), gastric cancer (8%), pancreatic cancer (7%), ovarian cancer (6%) and renal cancer (3%). In analyzed group, renal cancers in family were detected more frequently in TP53 homozygotes than in heterozygotes (16% vs. 0, p=0.008). Similarly, there was also observed tendency to the presence of colorectal cancer in TP53 homozygotes (11% vs. 0, p=0.193). Ovarian cancers and cholangiocarcinomas in family were also observed insignificantly more often in homozygotes than in heterozygotes (7% vs. 0, p=0.580) and (5% vs. 1%, p=0.383). There was no association between number of cancers in family and TP53 polymorphisms (47% vs. 43%, p=0.797). Conclusion: TP53 polymorphism (c.[215G>C]) predisposed to development renal and colorectal cancers (TP53 homozygotes) and ovarian cancer or cholangiocarcinoma (TP53 heterozygotes) in family.

Title: Geographic variation in the female breast cancer mortality rates across counties in United States

Sagiraju HKR, Chien L-C, Valerio MA A, Jatoi I and Gimeno D. UT Health Science Ctr Houston- School of Public Health, San Antonio Regional Campus, San Antonio, TX and UT Health Science Centre San Antonio- School of Medicine, San Antonio, TX.

Body: Background: Few studies have examined geographic disparities in breast cancer mortality at smaller geographical areas in the United States (U.S.) taking into account geographical details and spatial auto-correlations. Though these have identified counties with high breast cancer mortality risk, county-level socioeconomic attributes which are proven to be risk factors for breast cancer mortality were not examined and accounted for. The aim of this study is to efficiently map the spatial variation in the female breast cancer mortality rates across the counties of U.S., and to identify the high risk geographical clusters while adjusting for the county attributes, such as ethnic distribution of the population, educational attainment, poverty, unemployment and health care access.

Methodology: County-specific age standardized rates for breast cancer mortality for women aged ≥ 20 years in the U.S. were obtained for 3,109 counties from Surveillance Epidemiology and End Results (SEER) program from 1990-2012. We gathered county attributes from American Community Survey, such as the percentages of Hispanic white, Non-Hispanic white, Non-Hispanic black, < high school education, below 200% poverty, urban, foreign born, language isolation, women aged ≥ 40 years with mammography within last 2 years, and median household income. Then, we applied factor analysis to condense county attributes into three factors as covariates namely Hispanic immigrants, health care access among urban & high income groups, and non-Hispanic black unemployment. Spatiotemporal analysis was carried out by the structured additive regression model to incorporate spatial functions and Bayesian inference using Markov Chain Monte Carlo simulation techniques. Deviance Information Criteria was used for model comparisons and selections.

Results: Moran’s index for the age standardized breast cancer mortality rate was 0.12 (p-value < 0.001) suggesting the existence of spatial dependence for the breast cancer mortality among the counties of U.S. Estimated effects [Mean (95%CI)] of spatial estimates for the factors were 0.03(0.02-0.05) for Hispanic immigrant culture, 0.06(0.04-0.09) for health care access among urban & high income groups and 0.41(0.31-0.51) for the non-Hispanic black unemployment. Counties in the Southwest region, Rocky mountain region and those in the western border of Midwest region of U.S with more Hispanic immigrants, have significantly lower mortality rates, a finding that can attributed to the lower incidence of breast cancer among Hispanics. As the mammography screening among urban and high income areas of the counties in the Mid-west region increase, the risk of breast cancer mortality increase significantly above the national average. And as the non-Hispanic black unemployment rates increase, the counties of Mid-West and those of South-West were at higher risk of mortality compared to national average. The percentage of counties with significant positive spatial function were 3.8% for the health care access factor and 6.3% for non-Hispanic black unemployment factor.

Conclusion: These initial results might explain social, cultural, and other reasons for the observed geographic variations, and in turn, could support a stronger theoretical basis for public health policy.
Economic impact of breast cancer in Mexico

Sherwell-Cabello S, Maffuz-Aziz A and Rodríguez-Cuevas S. Instituto de Enfermedades de la Mama, FUCAM AC., Mexico, Mexico.

**Body: Background:** Breast cancer is the most prevalent cancer in Mexico and is the leading oncologic death cause among women older than 25 years-old. Its incidence has steadily increased during the last decades. Unfortunately, most of the patients are diagnosed in advanced stages, increasing the cost of the treatment and mortality. Through this study, we analyse the annual economic impact of breast cancer in Mexico.

**Materials and methods:** Data from Mexican official statistics from 2014 were obtained. The rate of population covered by the public health system, the mean income per capita, the age for retirement, the funds used in public hospitals according to clinical stages, the mean age for diagnosis and the mean age of death by breast cancer in Mexico and the mean cost of a funeral service were obtained.

We calculate the direct costs including the funds used for diagnosis and treatment of the patients with breast cancer in the public hospitals. The indirect costs were obtained calculating the mean per capita income lost due to death by breast cancer, the number of deaths before 65 years-old (Age for retirement in Mexico) and the mean cost for funeral services. Costs for breast cancer treatment were also obtained according to the funds for early stages (0 – IIA), locally-advanced stages (IIB – IIIC) and metastatic stages (IV). Results were compared between groups.

**Results:** In 2014, around 20,500 new cases of breast cancer were diagnosed in Mexico. Among them, 15,826 patients (77.2%) were treated in public health institutions. From these patients, 38.7% were diagnosed in early stages, 51% in locally-advanced stages and 9.6% in stage IV. Only 22% were diagnosed during screening mammography.

In 2014, funds for early stages amounted to US $44,077,959; for locally-advanced stages to US $120,727,505 and for metastatic stages to US $192,623,862. The total fund for breast cancer, including diagnosis and treatment, was US $304,747,165. Treatments for locally advanced stages were 107.8% higher compared to early stages (US $14,958 / 7,197).

It has been demonstrated that the mean age of breast cancer diagnosis in Mexico is 53 years-old, while the mean age of death due to this disease is 58 years-old. Age for retirement is 65 years and 76% of the breast cancer patients appeared in this group of age or younger. The mean per capita income is US $22 and the cost for funeral was US $1,968 approximately. The mean Overall-Survival rate for breast cancer in Mexico is 83.1%, so the mortality rate is 16.9%, so 2044 patients died due to breast cancer in 2014. The economic loss for the families amounted to US $120,647,834; US$116, 624,822 for the loss of the per capita income and US $4,023,012 for the cost for funeral services.

**Conclusions:** Breast cancer has a great economic impact in both the government and the patient, especially in advanced stages. It is extremely important to improve the mammographic screening programs in Mexico and reduce the time of care. Initiation of annual screening mammography starting at 40 years-old should be a mandatory policy in order to increase the rate of diagnosis of breast cancer at early stages. In the near future, there will not be sufficient economic resources for treating breast cancer in Mexico, if new and strict policies are not carried out.
Title: Alcohol consumption increases mammographic density in women aged ≥55 years

Body: Background: Increased mammographic density is a significant risk factor for breast cancer and decreases the sensitivity of mammography screening. The aim of this study is to examine the factors affecting breast density in Japanese women.

Data sources and methods: Between Apr. 2014 and Mar. 2016, 3492 women were received mammography screening. According to the results of mammography, breast density was categorized as non-dense(BI-RADS 1 and 2, n=1670) and dense(BI-RADS 3 and 4, n=2222). Logistic regression was used to estimate the odds of having dense breasts by age, body mass index(BMI), alcohol consumption, smoking, parity, menopausal status, dysmenorrhea, hormone use, family history of breast cancer, physical activity, fried foods intake, brightly colored vegetables intake, coffee intake and tea or green tea intake. All statistical tests were two-sided.

Results: There was a statistically significant negative interaction of age(OR=0.97, <0.001), BMI(OR=0.78, <0.001), number of live birth (one; OR=0.77, <0.030, two or more; OR0.37, <0.001), post-menopause(OR=0.6, <0.001) on breast density.

. On the other, there was a statistically significant positive interaction of alcohol intake (20g or more a day, OR=1.62, 0.026) in dense breast women aged ≥55 years.

Results of analysis of factors influencing breast density in women aged ≥55 years (n=1382)

- A trend of bone mineral density ≥80% and dense breast was seen in women aged ≥40 years (OR=0.63, <0.086, n=510).

**Conclusion:** Alcohol consumption increase mammographic breast density in women aged ≥55 years. As both of increased breast density and alcohol consumption have been suggested to increase risk of breast cancer, more cautious mammographic screening should be considered for those women aged ≥55 years.
Title: Abstract Withdrawn
Body: BACKGROUND
Improved efficacy was suggested for fulvestrant 500 mg, a selective estrogen receptor degrader (SERD), vs anastrozole as first-line treatment for hormone receptor-positive locally advanced or metastatic breast cancer (LA/MBC) in the open-label Phase 2 FIRST trial. The Phase 3, randomized, double-blind, multicenter FALCON trial (NCT01602380) compared fulvestrant 500 mg with anastrozole 1 mg in patients with hormone receptor-positive LA/MBC who had not received prior hormonal therapy. The primary endpoint of the study was met, such that there was a statistically significant improvement in progression-free survival (PFS) for fulvestrant 500 mg vs anastrozole. We present an analysis of PFS for pre-specified patient subgroups in the FALCON trial.

METHODS
Eligible patients had ER and/or progesterone receptor (PgR)-positive breast cancer, WHO performance status 0–2 and ≥1 measurable/non-measurable lesion(s). Patients were randomized (1:1) to receive fulvestrant 500 mg (IM on Days 0, 14, 28, and each 28 days thereafter) or anastrozole 1 mg daily. The primary endpoint was PFS, assessed via RECIST 1.1, surgery/radiotherapy for disease worsening, or death (any cause). PFS was evaluated in patient subgroups defined by pre-specified baseline covariates. The consistency of effect across patient subgroups was assessed via hazard ratios and 95% confidence intervals using a log-rank test.

RESULTS
Overall, 462 patients were randomized to treatment: 230 received fulvestrant 500 mg and 232 received anastrozole. PFS outcomes in each patient subgroup are presented in the Table.

CONCLUSIONS
This analysis of patient subgroups from the FALCON trial suggests that treatment effects were largely consistent across the subgroups analyzed with some possible exceptions (e.g. patients with visceral vs non-visceral disease). Further work is ongoing to understand the possible treatment effect in these subgroups.

*Data for Asia/non-Asia subgroups are presented in a separate abstract*
Targeting inflammatory pathways: A phase 2 trial of the JAK-inhibitor ruxolitinib in combination with exemestane for aromatase inhibitor-resistant, estrogen receptor-positive breast cancer

Body: Background: In vitro mechanisms link IL-6 to poor outcome in breast cancer via inflammatory pathways, activated JAK/STAT tumor signaling and upregulation of aromatase, leading to an aggressive tumor phenotype. Epidemiological data from our group and others support these mechanisms in women with ER-positive (+) disease. We therefore hypothesized that the JAK inhibitor, ruxolitinib (RUX, INCB018424; Incyte), would enhance activity of exemestane (EXE) in women with ER+ breast cancer who relapsed after non-steroidal aromatase inhibitor therapy, particularly among carriers of a germ-line polymorphism in IL-6, conferring elevated levels of IL-6 in the tumor microenvironment.

Methods: The “JAKEE trial” is a phase II trial to determine the safety and efficacy of RUX + EXE in postmenopausal women with relapsed, ER+ advanced breast cancer. Eligible patients were required to have progressed on a non-steroidal AI and either measurable or bone-only disease. CRP, a putative biomarker of tumor microenvironment inflammation, was measured at baseline and serially during treatment. Using a Simon 2-stage design, we treated 15 patients with RUX at 25 mg BID and EXE at 25mg daily on a continuous 28-day schedule. First stage results were previously presented (AACR, 2014). Accrual proceeded to second stage after no patient met the pre-defined stopping rule of grade (G) 3/4 toxicity requiring discontinuation from the study within the first treatment cycle. Due to the substantial rate of anemia requiring dose reductions, however, RUX dose was reduced to 15 mg BID in second stage.

Results: A total of 25 patients were enrolled; 24/25 had progressed on AI in metastatic setting; 1 relapsed on adjuvant AI. RUX+EXE was well-tolerated overall, with only 2 G4 events (creatinine elevation, hepatic failure); both were due to disease progression. 16% had G3 fatigue, anemia or hypertension; 12% had G3 neutropenia or depression. Other lower grade toxicities in >20% included musculoskeletal pain, increased ALT, and headache. Overall, patients stayed on therapy for a median of 3 cycles (range 2 – 21). There were no CR or PR, but 6/25 (24%) had prolonged disease control (SD> 6 months). Median CRP at study entry was 6.4 (range 0.3-38.9), with 8/25 (32%) having CRP≥10. Achieving SD≥6 months was not associated with baseline CRP (CRP≥10 in 32% with vs. 33% without SD≥6 months, p(exact)=1.0). A novel pharmacodynamic assay to assess STAT3 phosphorylation in peripheral blood mononuclear cells after RUX exposure demonstrated differential effects in patients with response.

Conclusions: Targeting JAK/STAT signaling in AI-resistant breast cancer with RUX+EXE was safe and well-tolerated. 24% of patients had prolonged SD, but baseline CRP level did not predict response. Correlative studies to determine whether host and/or tumor biomarkers predict response to therapy, including germline IL-6 genotype, immune profiles, p-STAT3 and estradiol levels, are currently underway.
Phase 1/2 study of oral seviteronel (VT-464), a dual CYP17-lyase inhibitor and androgen receptor (AR) antagonist, in patients with advanced AR positive triple negative (TNBC) or estrogen receptor (ER) positive breast cancer (BC)

Guca1p A, Bardia A, Gabrail N, DaCosta N, Danso M, Elias AD D, Ali H, Lemon SJ J, Riley EC C, Eisner JR R, Fleming RA A, Kurman MR R, Moore WR R and Traina TA A. Breast Medicine Service, Memorial Sloan Kettering Cancer Center, Chapel Hill, NC; Massachusetts General Hospital Cancer Center, Harvard Medical School, Boston, MA; Gabrail Cancer Center, Canton, OH; North Shore Hematology Oncology Associates, East Setauket, NY; Virginia Oncology Associates, Norfolk, VA; School of Medicine, University of Colorado Denver, Denver, CO; Henry Ford Hospital, Detroit, MI; Oncology Associates, Omaha, NE; James Graham Brown Cancer Center, University of Louisville, Louisville, KY and Innocrin Pharmaceuticals, Inc., Durham, NC.

Body: Background:
Seviteronel (Sevi), a CYP17-lyase (L) inhibitor (reduces testosterone (T) and estradiol (E2) biosynthesis) and a competitive AR antagonist, has activity in castration resistant prostate cancer at a dose of 600mg nightly. Sevi potently inhibits the growth of ER(+)AR(+) MCF7, tamoxifen-resistant (TAMR) MCF7, and ER(-)/AR(+) MDA-MB-453 cells. In a TAMR xenograft BC model, Sevi decreases tumor growth greater than enzalutamide (Enza), an AR antagonist (Ellison et al, SABCS 2015). Nearly all subtypes of BC, including AR(+) TNBC, are potential targets for Sevi based on its mechanism of action (MOA). Phase (Ph) 1 of this study established the recommended Ph 2 dose (RP2D) of Sevi in women with BC as 450mg once nightly, based upon preliminary tolerability and pharmacokinetics (PK) (Bardia et al, ASCO 2016). The primary objective of Ph 2 is to estimate the activity of Sevi, as measured by clinical benefit rate (CBR) at 16 and 24 weeks (wks) for AR(+) TNBC and ER(+) BC, respectively. The secondary objectives include an estimation of Sevi tolerability and pharmacodynamics (PD) (NCT02580448).

Methods:
Women with advanced AR(+) TNBC (stratified by prior Enza use) or ER(+) BC were enrolled using 3 parallel Simon's 2-stage designs powered to evaluate CBR. ER(+) BC patients must have had ≥1 prior line of endocrine therapy; no limit to prior treatment for TNBC. AR(+) status was confirmed using central IHC analysis in all patients, with a ≥10% tumor cell nuclear staining cutoff for evaluable TNBC patients. Sevi was administered once nightly with dinner at 450mg (28d cycle). Tumor and blood samples were collected for PK and PD analysis (circulating tumor cells, ctDNA, sex steroids). Response was assessed every 8 wks for 52 wks, then every 12 wks thereafter. Current tolerability and PD results are presented herein for this ongoing Ph 2 study.

Results:
As of June 7, 2016, 17 patients received Sevi at 450mg nightly between Ph1 and Ph2 with 10 in screening. 14 patients are currently on study in Cycles 1-6. The most common adverse events (AEs > 10% regardless of causality or grade) were tremor (24%), pain (18%), fatigue (18%) and dyspnea (18%), nausea (12%), AST increase (12%), ALT increase (12%) and abdominal pain (12%), all of which were Grade 1 or 2 except for Grade 3 dyspnea (n=1; unrelated). No dose reductions were reported and there were no drug-related discontinuations. Nine patients underwent central AR testing (4 AR(+) of 6 TNBC; 3 AR(+) of 3 ER(+) BC). Median AR tumor cell nuclear staining was 90% (15%-100%). Preliminary sex steroid analyses from 6 Ph 1 patients receiving Sevi at 450, 600, or 750mg nightly (n=2 at each dose) for 1 cycle showed a median decline in E2 concentration of 52% (-29 to -87%) to 12.4pmol/L (4 to 33pmol/L) from baseline. There was a similar magnitude of decline for T.

Conclusions:
Sevi was well-tolerated at 450mg nightly with exposures similar to the RP2D in men (600mg nightly). The CYP17-L inhibition activity of Sevi was demonstrated with an early and potent reduction in E2 and T. Sevi’s unique CYP17-L and AR antagonist MOA may provide a new novel treatment option for AR(+) TNBC or ER(+) BC.
2016 San Antonio Breast Cancer Symposium

Publication Number: P2-08-05

Title: Phase I/II trial of palbociclib in combination with bicalutamide for the treatment of androgen receptor (AR)+ metastatic breast cancer (MBC)

Body: Background: Triple negative breast cancer (TNBC) represents 15% of all BCs. Conventional chemotherapy remains the standard, albeit inadequate, option for these patients (pts) as evidenced by poor disease free and overall survival. The androgen-signaling pathway plays a role in BC pathogenesis and emerging evidence suggests the androgen receptor (AR) is a therapeutic target. TBCRC011 established safety and efficacy of inhibiting AR with bicalutamide (B) in patients with AR+/ER/PgR- metastatic BC (MBC). The regimen was well-tolerated and the study met its prespecified efficacy endpoint demonstrating a clinical benefit rate (CBR) of 19% in this population (Gucalp et al. CCR 2013). The rationale for combining palbociclib (P) with AR blockade stems from prior work in ER+ MBC. P is an oral, selective inhibitor of CDK4/6 activity which significantly improved median progression-free survival (PFS) in combination with letrozole compared to letrozole monotherapy for the treatment of postmenopausal pts with ER+ MBC in the first-line setting. Consistent with preclinical data, P has been shown to reduce growth of AR+ ER/PgR- MDA-MB-453 breast cancer cells via reduced Rb phosphorylation. It has been shown that AR+ TNBC expresses a luminal profile and has intact Rb protein, the target of palbociclib activity. Therefore, we hypothesize that P will increase the efficacy of B in pts with metastatic AR+ TNBC. NCT02605486.

Methods: Pts with AR+ (IHC ≥ 1%)/ER any/HER2(-) MBC on central review at MSK were eligible if met following criteria: ECOG ≤2, postmenopausal, no limit to prior regimens. Pts with ER+ BC must have had 1 prior endocrine therapy. Treatment: B orally daily and P orally daily 3 weeks on 1 week off. DLT period = 28 days. Pts are evaluated for toxicity every 2-4 weeks and for response every 8 weeks. Ph I standard 3+3 design with 3 dose escalations. The primary objective of the phase I portion of the study is to determine the recommended phase II dose of P in combination with B. Plasma for PK was collected throughout the study.

Results: As of 6/12/16, 9 pts with AR+ MBC are enrolled. Accrual is complete to the second dose escalation cohort and the final dosing cohort of B 150mg + P 125 mg began enrollment as of 5/24/16. PK analysis is ongoing and data are expected for presentation. Treatment has been well tolerated with no related Grade 4 or 5 AEs. One SAE of Grade 3 anemia (thought to be related to P) and Grade 4 hypercalcemia led to hospitalization deemed related to disease progression.

Conclusions: The combination of B+P has been well tolerated with no unexpected toxicity observed. Updated safety, response, and PK data will be presented.
Title: A phase 1 study of RAD1901, a novel, oral selective estrogen receptor degrader, for the treatment of ER-positive advanced breast cancer

Kaklamani VG G, Kabos P, Elledge R, Harb W, Purandare D, O'Neill A, Garner F and Bardia A.  University of Texas Health Science Center at San Antonio, San Antonio, TX; University of Colorado Denver, Aurora, CO; Horizon Oncology Center, Lafayette, IN; Radius Health, Inc., Waltham, MA and Massachusetts General Hospital, Boston, MA.

Body: Background: The majority of breast cancers are defined as estrogen receptor positive (ER+) breast cancer. Despite availability of standard therapies, such as aromatase inhibitors, many women eventually relapse with aggressive disease due to acquisition of endocrine resistance, including ESR1 mutations. To help address some of the challenges associated with current therapies including exposure limitations and intramuscular administration, we have developed RAD1901, a novel, non-steroidal, oral selective estrogen receptor degrader (SERD). Preclinical studies with RAD1901 have demonstrated a dose dependent degradation of ER consistent with a SERD mechanism of action. In multiple in vivo models of breast cancer, including patient-derived xenograft models that are sensitive or resistant to standard endocrine therapies, RAD1901 has anti-tumor efficacy both as a single agent and in combination with palbociclib and everolimus. Importantly, RAD1901 has shown superior efficacy compared to fulvestrant in a number these models including those harboring ESR1 mutation.

Methods: RAD1901-005 is a Phase 1 study currently enrolling ER+ advanced metastatic breast cancer patients (ClinicalTrials.gov identifier: NCT02338349) with a dose escalation cohort based on a standard 3+3 design followed by a safety expansion cohort at a tolerated dose. Key inclusion criteria include postmenopausal women aged 18 years or older, with advanced ER+, HER2-negative breast cancer, who have received ≤ 2 prior chemotherapy regimens in the metastatic setting and > 6 months of prior endocrine therapy. In addition, circulating tumor DNA (ctDNA) was evaluated to determine ESR1 mutation status and to correlate it with clinical response.

Results: As of the cut-off date in March, 13 patients were enrolled in the dose escalation part of the study (3+3 design) at doses of 200 mg qd, 400 mg qd and 600 mg qd. RAD1901 exposure was dose dependent and the PK profile was comparable to PK data from a previous study in healthy volunteers. RAD1901 was well tolerated with the most common adverse events being low-grade nausea and dyspepsia. No DLTs were observed. A safety expansion cohort (Part B, n=20) was opened. At the cut-off date 4 of the 13 patients had been on study 4 or more months. Updated outcomes and biomarker data, including ctDNA, will be presented at the meeting.

Conclusion: RAD1901, a novel, non-steroidal, oral SERD, is well-tolerated with manageable adverse effects, and is associated with preliminary evidence of clinical activity in patients with advanced ER+ advanced postmenopausal breast cancer, including patients with ESR1 mutant tumors.
Body: Breast cancer is a challenging disease, because resistance invariably develops to front line therapies targeting estrogen receptor (ER, 70% of breast cancers are ER+), and some endocrine therapies have serious side effects, such as bone loss with aromatase inhibitors. Activated ER inhibits inflammatory gene expression via protein-protein interactions that block NF-κB activity in ER+ tissues. Importantly, NF-κB is a primary mediator of resistance in many cancers, including breast cancer. However, all current endocrine treatments (tamoxifen, raloxifene, fulvestrant) block this palliative signaling pathway, along with blocking the desired proliferative pathway. Thus, there is a significant unmet clinical need for novel endocrine treatments for breast cancer that can ameliorate patient outcome in resistant population, be less prone to resistance development, retain the palliative effects that estrogens have on the inflammatory axis, and cause fewer side effects.

We hypothesized that NF-κB selective ERα antagonists will prove effective in treating endocrine-resistant breast cancer in vivo. Through ligand class analysis, we identified a unique binding hotspot in ERα that has allowed us to dial out the gene activation/proliferative signal of ER ligands, while retaining the strong anti-inflammatory properties of estradiol (E2). Using a novel screening approach based upon high-throughput x-ray crystallography, we previously identified a unique ligand scaffold, termed OBHS (for 7-oxa-bicyclo[2.2.1]heptene sulfonate for the prototypical member), which directs a side chain in this hotspot and reduces gene activation through ligand-induced shifts in helix 11 of ER. While SERMs directly reposition helix 12, OBHS compounds indirectly modulate helix 12 by regulating its docking onto helix 11, leading us to call them as indirect antagonists. Compounds in this novel class act in a mechanistically and structurally distinct fashion from the current endocrine therapies. One of the OBHS analogs surpasses the lead as well as estradiol (E2) for its anti-inflammatory activity mediated through ER. We further established GREB1 transcriptional model in our portfolio to predict response to endocrine therapy. GREB1 is likely a key regulator of estrogen-induced breast cancer growth, and has potential as a new biomarker for predicting E2-dependent and anti-E2-responsive breast cancers. OBHS analogs inhibit GREB1 transcription better than the OBHS parent lead. We are presently carrying out selective estrogen-receptor modulator (SERM)-like modifications to further improve anti-proliferative activity. To aid optimization, a computational workflow, based upon induced fit docking, has been developed.

The ultimate impact of this research will be the development of novel anti-proliferative/anti-inflammatory ligands with unique and persistent efficacy as therapeutics for endocrine-resistant breast cancer, both in adjuvant and advanced disease settings.
**Title:** A phase 1 study of RAD1901, an oral selective estrogen receptor degrader, to determine changes in the $^{18}$F-FES uptake and tumor responses in ER-positive, HER2-negative, advanced breast cancer patients

de Vries EGE GE, Venema CM M, Glaudemans AWJM WJM, Jager A, Garner F, O'Neill A, Patki A and Menke-van der Houven van Oordt CW. University Medical Center Groningen, Groningen, Netherlands; Erasmus Medical Center, Rotterdam, Netherlands; Radius Health, Inc., Waltham, MA and Free University Medical Center, Amsterdam, Netherlands.

**Body:** Approximately 75% of the tumors from breast cancer patients express the estrogen receptor (ER) at diagnosis. Since patients with ER-positive tumors respond to endocrine therapy, determination of the ER status of a patient has important consequences for treatment decision making. The current standard practice to assess ER status is by using immunohistochemical staining of a tumor biopsy. However, the ability to collect serial tumor biopsies during treatment to determine a patient's response to endocrine therapy is limited by the feasibility of performing multiple biopsies. $^{18}$F-fluoroestradiol positron emission tomography (FES-PET) is an imaging modality which can measure ER levels based on FES uptake and has been previously utilized to assess patients' response to endocrine therapies. Serial imaging of tumor FES uptake during treatment with the selective ER degrader (SERD) fulvestrant, demonstrated that significant residual FES uptake in tumor lesions was associated with early disease progression in patients with metastatic breast cancer (van Kruchten et al, Cancer Discov2015;5:72-81).

RAD1901 is a novel, orally available SERD that binds to both ER mutant and wild type forms leading to ER degradation in preclinical models of breast cancer. A prior clinical study of RAD1901 in healthy postmenopausal women demonstrated decreased FES uptake in the uterus after RAD1901 treatment, further supporting the hypothesis that FES-PET imaging can provide an early indication of target effect with this agent.

RAD1901-106 is a Phase 1 study of RAD1901 in metastatic breast cancer patients to explore the use of FES-PET imaging as an early indicator of clinical response to RAD1901 treatment. Key inclusion criteria include postmenopausal patients with advanced ER-positive, HER2-negative breast cancer, who have received $\leq$ 3 prior line of endocrine therapy in the metastatic setting. Serial FES-PET imaging performed pre-treatment and after 14 days on therapy is used to evaluate the effect of RAD1901 treatment on the availability of ER binding sites in tumor lesions. Patients may continue on RAD1901 therapy until tumor progression. Patient enrollment started in early 2016 and is ongoing. FES-PET tumor imaging and preliminary clinical data from patients enrolled in the study will be presented.

ClinicalTrials.gov identifier: NCT02650817.
Progression-free survival results in postmenopausal Asian women: Subgroup analysis from a phase 3 randomized trial of fulvestrant 500 mg vs anastrozole for hormone receptor-positive advanced breast cancer (FALCON)

Shao Z, Ellis MJ J, Robertson JFR FR, Grinsted LM M, Fazal M and Noguchi S.  Fudan University Shanghai Cancer Center, Shanghai, China;  Lester and Sue Smith Breast Center, Baylor Clinic, Baylor College of Medicine, Houston, TX;  University of Nottingham, Royal Derby Hospital Centre, Derby, United Kingdom;  AstraZeneca, Cambridge, United Kingdom;  AstraZeneca, Gaithersburg, MD and  Osaka University Graduate School of Medicine, Osaka, Japan.

Body: BACKGROUND
Fulvestrant is a selective estrogen receptor degrader (SERD) with no known agonist effects. In the open-label Phase 2 FIRST study, fulvestrant 500 mg suggested improved efficacy as first-line treatment vs anastrozole in patients with hormone receptor-positive locally advanced or metastatic breast cancer (LA/MBC). The Phase 3, randomized, double-blind, multicenter FALCON trial (NCT01602380) compared fulvestrant 500 mg with anastrozole 1 mg in patients with hormone receptor-positive LA/MBC who had not received prior hormonal therapy. The primary endpoint of the study, progression-free survival (PFS) assessed via RECIST 1.1, surgery/radiotherapy for disease worsening, or death (any cause), was met, as shown by a statistically significant improvement in PFS for fulvestrant 500 mg vs anastrozole. This analysis evaluated PFS in the Asian patient subgroup, which included all randomized patients from centers in China, Japan, and Taiwan.

METHODS
Eligible patients had ER and/or progesterone receptor-positive breast cancer, WHO performance status 0–2, and ≥1 measurable/non-measurable lesion(s). Patients were randomized (1:1) to receive fulvestrant 500 mg (IM on Days 0, 14, 28, and each 28 days thereafter) or anastrozole 1 mg daily, and were stratified according to LA or MBC; prior or no prior treatment with chemotherapy for LA/MBC; and measurable or non-measurable disease. The consistency of effect across patient subgroups was assessed via hazard ratios and 95% confidence intervals using a log-rank test.

RESULTS
In total, 462 patients were randomized (n=230 fulvestrant 500 mg; n=232 anastrozole). The Asian subgroup comprised 67 patients (n=34 fulvestrant 500 mg; n=33 anastrozole). PFS outcomes for the Asian and non-Asian subgroups are presented (Table). The most commonly reported adverse event (AE) was arthralgia (18.2% vs 12.1% of patients with fulvestrant 500 mg and anastrozole, respectively). The rate of AEs leading to discontinuation of treatment was 3.0% and 3.0%, respectively.

CONCLUSIONS
Based on a preliminary assessment of 67 patients, the treatment effect in the Asian patient subgroup from the FALCON trial appears to be broadly consistent with the non-Asian population.

Title: Time-evolution of the efficacy of first line aromatase inhibitors (AI) in hormone receptor positive (HR+) advanced breast cancer (ABC): A moving target

Debiasi M, Reinert T, Bines J and Barrios C. LACOG - Latin America Cooperative Oncology Group, Porto Alegre, RS, Brazil; Hospital do Cancer Mae de Deus, Porto Alegre, RS, Brazil; Instituto Nacional de Cancer, Rio de Janeiro, RJ, Brazil and PUCRS School of Medicine, Porto Alegre, RS, Brazil.

Body: INTRODUCTION. Recently presented studies suggest significant improvements in efficacy of endocrine therapy trials addressing HR+ ABC. Overall, progression-free survival (PFS) has consistently improved when we analyze first line endocrine trials. This study aims to evaluate the evolution of the PFS obtained with first line AI monotherapy in patients with HR+ ABC.

METHODS. We performed a systematic review of the literature searching for randomized clinical trials of endocrine therapy in HR+ ABC. All trials published since 2000 that involved a first line AI single agent arm were included. Median PFS, year of publication, sample size and population characteristics such as previous endocrine therapy exposure and presence of visceral metastases were extracted from each study and linear correlation used to access the trend of PFS along time.

RESULTS. 13 studies were identified accounting for 3,446 postmenopausal patients that received monotherapy with an AI as first line treatment for HR+ ABC. The year of publication/presentation ranged from 2000 to 2016. A total of 14 treatment arms exploring AI monotherapy were identified and analyzed. One study compared exemestane to anastrozole. The other 12 studies compared AIs as single agents to other endocrine strategies. Single agent anastrozole was used in six studies while letrozole was used in five and exemestane in one trial. PFS ranged from 8.2 months in the experimental arm treated with anastrozole in a trial published in 2000 to 15.6 in the control group treated with letrozole monotherapy in a study published in 2015. Linear regression showed a significant improvement in PFS over time (p = 0.034).

CONCLUSION. A combination of improved medical care and patient selection factors probably explain most of this progressive...
improvement in PFS obtained with the same therapeutic strategy. While in general, entry criteria have not changed significantly over time, more recent clinical trials addressing first line treatment of HR+ ABC are probably including a different population of patients. Exclusion of HER2 positive tumors and of unknown hormone receptor status patients as well as the percentage of patients without previous adjuvant exposure to endocrine therapy, for example, should be taken into account as they select for a more endocrine sensitive group of patients. This observation has implications in the planning of future studies, the estimation of sample size based in expected efficacy as well as the interpretation and generalization of the results to clinical practice.
Title: An orally bioavailable selective estrogen receptor downregulator

Body: Orally bioavailable selective estrogen receptor downregulators (SERDs) may offer greater systemic drug exposure, improved clinical efficacy, and more durable treatment outcome for breast cancer patients with disease progression following antiestrogen or aromatase inhibitor therapy. We report the design and synthesis of ZB716, a C-3 position boronic acid modified fulvestrant, which behaves as a steroidal SERD suitable for oral administration. ZB716 binds to ERa competitively at an IC\textsubscript{50} of 4.1 nM as compared to 3.9 nM for fulvestrant, and it effectively downregulates ERa (IC\textsubscript{50}=12.7 nM) in both tamoxifen-sensitive (T47D) and tamoxifen-resistant (T47D/PKCa) breast cancer cells. It acts as an antiestrogen that exerts potent antiproliferative effects on tamoxifen-resistant breast cancer cells (MCF-7/TamR, T47D/PKCa, and T47D/Y537S). When orally administered to mice, rats, and Beagle dogs, ZB716 demonstrates superior oral bioavailability in all animal-based pharmacokinetic studies when compared to fulvestrant administered by subcutaneous injection. More importantly, orally administered ZB716 was found to potently inhibit xenograft tumor growth in mice. These pre-clinical data strongly suggest that ZB716 is a promising SERD drug that could offer significant improvement over existing SERD regimen of Faslodex. ZB716 is being prepared in an IND application for phase 1 clinical trial in ER+, HER2- advanced breast cancer patients.
True effect of aromatase inhibitor (AI) treatment on global gene expression (expr) changes in postmenopausal ER+ breast cancer (BC) patients: A POETIC study (CRUK/07/015)

Gao Q, López-Knowles E, Cheang MCU Chon U, Morden J, Martin L-A, Sidhu K, Evans D, Martins V, Dodson A, Skene A, Holcombe C C, Mallon E, Abigail E, Bliss J, Robertson J, Smith I and Dowsett M. The Institute of Cancer Research, London, United Kingdom; The Royal Marsden Hospital, London, United Kingdom; Royal Bournemouth Hospital, Bournemouth, United Kingdom; Royal Liverpool University Hospital, Liverpool, United Kingdom; Queen Elizabeth University Hospital Glasgow, Govan, United Kingdom; Poole Hospital NHS Foundation Trust, Dorset, United Kingdom and University of Nottingham, Derby, United Kingdom.

BACKGROUND Gene expression (expr) analyses are increasingly used for characterising the pharmacodynamic response of primary BC. This includes assessing ER+ BC’s dependence on estrogen (E) by measuring gene expr changes after AI-treatment. However, differences in tissue sampling and other preanalytic procedures between samples taken at diagnosis (D) and surgery (S), may lead to systematic artifactual changes that are falsely ascribed to the intervention. To identify genes whose expr is truly affected by AI, we measured global gene expr changes from paired core-cut biopsies at D and S from patients in the POETIC presurgical window trial.

METHODS In POETIC, 4486 postmenopausal women with primary ER+ BC were randomised 2:1 to receive perioperative AI (2 weeks pre + 2 weeks post surgery, termed Tr) or no perioperative treatment (termed Con), allowing gene expr changes to be compared between Tr and Con. RNA was extracted from paired RNA-later stored core-cuts of 56 Con and 157 Tr patients and arrayed on Illumina whole genome expr BeadChips. Raw data was extracted, transformed, normalised and batch-corrected. Probes not detected (p>0.01) in >=25% of samples were discarded. Impact of AI on genes was evaluated based on difference of the expr mean changes (log$_2$(S/D)) of the Tr and Con samples.

RESULTS In the Con group, expr of 73 genes significantly changed (FDR<5%); 70 of these changed by a similar magnitude in the Tr group, indicating their change was independent of AI therapy but would have been artfactually discovered as changed by AI in the absence on Con. The 8 genes most up-regulated in Tr were all among the 20 genes most up-regulated in Con: many were early-response or stress-associated genes. Three of the 8 most down-regulated in AI were the most down-regulated in Con: all were haemoglobin-related. Expr of some genes was changed in Con (eg MYC increase) but was unaffected in Tr. Such artifactual gene changes in Con tumors conceal true AI-induced changes that would not be detected in the absence of comparison with Con.

615 genes were down-regulated and 472 up-regulated in Tr but not Con. The majority of down-regulated genes were cell cycle or proliferation-associated or E-regulated, including ESR1, PDZK1, GREB1, HSPB1. Functional mapping showed changes in the regulation of cyclins and cyclin dependent kinases impacting on G1/S and G2/M. Of note, up-regulated genes included CDK6 (target for CDK4/6 inhibitors) and CCND2, involved in G1/S checkpoint regulation; SNAI2, TGFβ3, TGFβR2, associated with tumour invasion and metastasis; and other genes involved in aryl hydrocarbon receptor, Glioblastoma Multiforme, HIPPO and p53 signalling.

CONCLUSION Expr of certain genes is altered by processes involved in presurgical window studies. In the absence of a Con group, these may be wrongly ascribed to an experimental intervention or wrongly considered as unaffected by the intervention (eg MYC in this study). Down-regulation of E-responsive and proliferation genes was an expected response to AI but increased expr of genes such as SNAI2, CCND2 and CDK6 indicates immediate tumour re-wiring and provides mechanistic support for benefit from combination therapy with a CDK4/6 inhibitor.
Body: Background: Previous reports from the Anastrozole Tamoxifen Alone or in Combination (ATAC) trial have shown significantly prolonged disease-free survival, lower rates of recurrence and distant recurrence, and reduced contralateral breast cancer in patients treated with anastrozole compared to tamoxifen (Cuzick et al., Lancet, 2010). Here, we compare the long-term effects of anastrozole versus tamoxifen in patients randomised to either monotherapy arm in the ATAC trial.

Methods: Postmenopausal women with hormone receptor positive breast cancer randomised to anastrozole or tamoxifen in the main ATAC trial were eligible for the LATTE observational study. The primary objective was to compare the long-term effects of tamoxifen and anastrozole on time to recurrence and death beyond 10 years after randomisation. Secondary objectives included time to distant recurrence, cancer-specific survival, new breast primaries, other cancers, fractures, and cardiac/cerebrovascular events. Cox proportional hazard methods were used to compute hazard ratios (95% CI) for recurrence from the time of last publication (10 years median follow-up).

Results: 2452 women from 11 countries were entered into the LATTE study. 40 women withdrew consent and 759 women died or had a recurrence within 10 years, which left 1653 women for analysis (838 anastrozole vs. 815 tamoxifen). A total of 118 breast events (69 anastrozole (8.2%) vs. 49 tamoxifen (6.0%)) were reported. No significant difference between the two treatment arms were observed (HR=1.36 (0.94-1.97), P=0.098). 57 women had a distant recurrence (33 (3.9%) vs. 24 (2.9%)), 41 reported a loco-regional recurrence (23 (2.7%) vs. 18 (2.2%)), and 26 contra-lateral breast cancer were recorded (17 (2.0%) vs. 9 (1.1%)). None of the treatment comparisons were statistically significant. 305 deaths were recorded (147 (17.5%) vs. 158 (19.4%)), of which 31 were due to breast cancer. Significantly fewer gynaecological cancers were recorded with anastrozole (7 vs. 16; OR=0.42 (0.15-1.09), P=0.05), but overall the effect on other cancers was not significant (54 (6.4%) vs. 64 (7.9%). Fractures, cardiovascular, and cerebrovascular events were evenly distributed between the treatment arms.

Conclusions: Although anastrozole was associated with significant fewer recurrences compared to tamoxifen in the first 10 years of follow-up, in this analysis, with limited number of patients, we could not find a significant difference between the two treatment arms.
Title: 12 years’ median follow up (MFU) of BIG 1-98: Adjuvant letrozole, tamoxifen and their sequence for postmenopausal women with endocrine responsive early breast cancer

Body: Background
The Breast International Group (BIG) 1-98 study is a randomized, phase 3, double-blind trial that compared five yrs of adjuvant treatment with letrozole, tamoxifen, or their sequence in postmenopausal women with hormone-receptor–positive early breast cancer. The study is conducted by the International Breast Cancer Study Group (IBCSG) on behalf of BIG. 8010 patients (pts) were enrolled between March 1998 and May 2003, and first results demonstrating a significant DFS benefit favoring letrozole compared with tamoxifen were reported in 2005 at 25.8 months’ MFU. Subsequent updates showed continuing DFS benefit and updated results published in 2011 at 8.1 yrs’ MFU showed OS benefit. Industry-sponsorship of the original BIG 1-98 ended in 2010; IBCSG launched an observational, non-interventional long-term follow-up study (BIG 1-98 LTFU) to collect survival, disease status and adverse events for an additional 5 yrs. We report results from BIG 1-98 LTFU at 12 yrs’ MFU.

Methods
The original trial includes the 8010 patients enrolled. The potential BIG 1-98 LTFU cohort consisted of 148 academic medical centers with a maximum of 6843 pts who were alive and continuing follow-up when the original study ended. Response bias was addressed using weighting class adjustments estimated using multivariable logistic regression. Unadjusted incidence rates are reported here per 1000 pt-yrs with 95% Poisson confidence intervals. An updated abstract will include adjusted incidence rates, as well as estimates of OS and DFS based on a weighted Kaplan-Meier approach. The database will close in July 2016.

Results
As of May 2016, 81 centers participated in the BIG 1-98 LTFU study, contributing data from approximately 3900 pts (57%) and extending MFU to 12 yrs. Compared with the potential cohort of 6843 pts who were alive and continuing follow-up when the original study ended. Response bias was addressed using weighting class adjustments estimated using multivariable logistic regression. Unadjusted incidence rates are reported here per 1000 pt-yrs with 95% Poisson confidence intervals. An updated abstract will include adjusted incidence rates, as well as estimates of OS and DFS based on a weighted Kaplan-Meier approach. The database will close in July 2016.

</tbody>
</table>

Overall 1845 deaths were reported; the unadjusted incidence of death was lower in the original study compared with during LTFU (21.9 vs. 26.6/1000 pt-yrs); incidence remained relatively stable for pts assigned to tamoxifen (24.9 vs. 25.2/1000 pt-yrs), and increased for pts assigned to letrozole (22.0 vs. 27.1/1000 pt-yrs).

Conclusions
The BIG 1-98 LTFU study has been successfully conducted. The additional data from the BIG 1-98 LTFU study provides important long-term clinical information about OS, DFS and adverse events.
Addition of ovarian function suppression to endocrine therapy in premenopausal women with early breast cancer: A meta-analysis

Chlebowski R, Pan K and Col NF F. Los Angeles BioMedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA and University of New England, Portland, ME.

Body: Introduction
The Suppression of Ovarian Function Trial (SOFT) and the Tamoxifen and EXemestane Trial (TEXT), together with the Austrian Breast Cancer Study Group (ABCSDG-12) and the Eastern Cooperative Oncology Group 3193 (E-3193 trials, have examined adding ovarian function suppression (OFS) using gonadotropin–releasing hormone (GnRH) agonists to endocrine therapy in premenopausal women with early stage breast cancer. However, OFS with GnRH agonist plus aromatase inhibitor has subsequently been found to not consistently reduce estradiol levels to optimal target in the SOFT-EST study (JCO 2016; 34:1584) and implications of these study findings for clinical practice are controversial. Therefore, to further examine this issue, we conducted a systematic literature review and meta-analysis of available evidence.

Methods
We updated a recently published literature review of randomized clinical trials (JCO 2016; 34:1689) through June 1, 2016 using the keywords “breast cancer,” “ovarian function suppression,” “tamoxifen,” and “aromatase inhibitor”. Of 683 of records identified through database searching, the 4 studies named above met inclusion criteria and were included in the quantitative synthesis. Information on disease-free survival (DFS) and overall survival was examined using hazard ratio (HR) and 95% confidence interval (CI). Because of significant heterogeneity in one performed meta-analyses, the random-effects (DerSimonian and Laird) method was used to estimate the combined RR for studies (Open MetaAnalyst).

Results
Combining ABCSG-12, SOFT and TEXT trial findings, OFS addition to aromatase inhibitor resulted in 65 fewer DFS events across the 3 trials compared to OFS addition to tamoxifen (350 DFS events vs. 415 DFS events, respectively, HR 0.89, 95% CI 0.57-1.39, P=0.62, Tau² =0.09, heterogeneity P<0.01). In contrast, 30 more deaths were seen with OFS plus aromatase inhibitor use (155 deaths vs. 125 deaths, respectively, HR 1.31, 95% CI 0.93 -1.84, P=0.12, Tau² =0.03, heterogeneity P=0.18).

Combining SOFT and E-3193 trials to compare OFS addition to tamoxifen to tamoxifen alone use, more concordance between DFS events and overall survival is seen. There were 24 fewer DFS events across the 2 trials with OFS addition to tamoxifen compared to tamoxifen alone (160 DFS events vs. 184 DFS events, respectively, HR 0.83, 95% CI 0.67-1.03, P=0.09, Tau² =0, heterogeneity P=0.94) and there were 14 fewer deaths in the OFS plus tamoxifen compared to tamoxifen alone group (58 deaths vs. 72 deaths, respectively, HR 0.76 95% CI 0.53 -1.07, P=0.12, Tau² =0, heterogeneity P=0.78).

Conclusion
In conclusion, the apparent discordance between DFS and overall survival in the aromatase inhibitor and OFS trials and the results suggesting incomplete and/or intermittent estrogen suppression with GnRH analogs in the SOFT-EST trial suggest that adoption of OFS plus aromatase inhibitor use as adjuvant therapy in premenopausal women with early stage breast cancer may be premature. Longer term survival analyses of the endocrine therapy trials are needed before reliable risks and benefits of aromatase inhibitor plus OFS and tamoxifen plus OFS use as adjuvant therapy can be determined.
Title: Drugs don't work if people don't take them: Non-initiation of endocrine therapy in young women

Rosenberg SM M, Gelber S, Ruddy KJ J, Tamimi RM M, Schapira L, Borges VF F, Come S, Meyer ME E and Partridge AH H. Dana-Farber Cancer Institute, Boston, MA; Mayo Clinic, Rochester, MN; Brigham and Women’s Hospital, Boston, MA; Massachusetts General Hospital, Boston, MA; University of Colorado Cancer Center, Denver, CO and Beth Israel Deaconess Medical Center, Boston, MA.

Body: Background: Despite the well-established survival benefit associated with adjuvant hormonal treatment, younger women with hormone receptor positive (HR+) breast cancer (BC) are less adherent to endocrine therapy (ET) as prescribed, compared to their older counterparts, and may have unique issues that contribute to ET non-adherence. In an effort to identify factors that can be targeted to improve ET uptake and adherence, we sought to evaluate ET initiation in young women with BC.

Methods: As part of a multi-center, prospective cohort enrolling women with newly diagnosed BC at age ≤40 years between 2006-2016, we identified 657 women with HR+, Stage 0-III BC. Participants complete serial surveys that included questions about socio-demographics, fertility concerns, and treatment. Women who did not report taking tamoxifen or an aromatase inhibitor (AI) at least once in the 18 months after diagnosis (dx) were classified as non-initiators. Variables significant at p<0.20 in univariable models were entered into a multivariable logistic regression model to identify independent (p<0.05) predictors of non-initiation.

Results: By 18 months post-dx, 15% (99/657) had not initiated ET; among women with Stage 0 BC, 77% (51/66) had not initiated vs 8% (48/591) with invasive BC (p<0.0001). Among initiators (N=558), 93% were on tamoxifen, with 7% reporting AI alone or in addition to tamoxifen; 97% started ET within 12 months of dx. Among women with invasive BC (Table), non-initiation was associated with having less than a college degree (OR: 2.49 95% CI: 1.25-4.94), non-Caucasian race (OR: 2.58 95% CI: 1.18-5.64) and non-receipt of radiation (OR: 0.40 95% CI: 0.21-0.75).Age at dx, marital status, having children, employment, perceived financial comfort, fertility concern, stage, surgery, and chemotherapy were not significantly associated with non-initiation.

Conclusion: Most young women with HR+ DCIS do not take adjuvant ET despite the potential benefits (substantially reduced risk of local recurrence and contralateral BC) and very low risk of serious toxicity. Among young women with invasive HR+ BC, a significant minority fails to start ET within 18 months of dx. Adjuvant ET non-initiation may contribute in part to the racial and SES outcomes disparities that have been observed. Further study is needed to elucidate barriers to initiation with the goal of developing targeted interventions that will enhance ET initiation and adherence in general.

Table. Predictors of ET non-initiation in women with invasive BC (N=577*)

Title: Safety assessment of extended adjuvant endocrine therapy with letrozole; results of the randomized phase III IDEAL trial (BOOG 2006-05)

Blok EJ J, Kroep JR R, Meershoek-Klein Kranenbarg EM M, Duym-de Carpentier M, Putter H, van den Bosch J, Maartense E, van Leeuwen-Stok AE, Liefers G-J, Nortier JWR WR, Rutgers EJT JTh and van de Velde CJH JH. Leiden University Medical Center, Leiden, Netherlands; Leiden University Medical Center, Leiden, Netherlands; Leiden University Medical Center, Leiden, Netherlands; Albert Schweitzer Hospital, Dordrecht, Netherlands; Reinier de Graaff Hospital, Delft, Netherlands; Dutch Breast Cancer Research Group, Utrecht, Netherlands and Netherlands Cancer Institute, Amsterdam, Netherlands.

Body: The implementation of adjuvant aromatase inhibitors (AI) has contributed significantly to an ongoing improvement in survival of early breast cancer patients, but the impact of extended AI on toxicity after use in the initial 5 years has not yet been studied. Earlier, it was established that even after 5 years of adjuvant tamoxifen, extended letrozole for 5 years was comparable to the earlier reported toxicities, without an effect on overall quality of life. The aim of the current study is to assess the reported toxicity in the IDEAL trial, investigating extended letrozole after 5 years of endocrine therapy.

The Dutch phase III IDEAL trial was designed to study the optimal duration of extended adjuvant letrozole, by randomizing to either 2.5 or 5 years of letrozole after the completion of 5 years of any endocrine therapy. All patients were disease-free at the time of randomization. The primary outcome of this study, disease free survival after extended endocrine therapy, will be reported separately. Toxicity data were collected every 6 months in the first year, and annually thereafter until study completion. 1824 patients were included in the trial, of which 26 patients never started with therapy (n=1798). In total, 3434 adverse events were reported by 1283 patients, causing 360 (20%) patients to stop therapy due to these events. In total, 643 patients randomized to 5 years of therapy reported 1834 AEs (71.2%), whereas 640 patients on 2.5 years of therapy reported 1587 events (71.5%). In the 5 year AI group, 1456 (80%) of the AEs were reported within the initial 2.5 years causing 177 patients to stop therapy in this period, versus 29 patients who stopped due to toxicity after the therapy extension beyond 2.5 years. There was no significant difference in the proportion of grade 3/4 events between both groups (2.5yr: 9.8%, 5yr: 9.7%, $X^2$ p=0.52). Most reported AEs were arthralgia (n=248, 13.8% of all patients, 8.9% grade 3/4), hot flushes (n=215, 12%, 6.5% grade 3/4), osteoporosis (n=181, 10%, 2.2% grade 3/4), fatigue (n=156, 8.7%, 5.1% grade 3/4) and a decrease in joint function (n=114, 6.3%, 3.5% grade 3/4). In total, only one grade 5 AE was reported, which was unrelated to the treatment (bleeding and sepsis after cholecystectomy).

Although the toxicity pattern is comparable to regular AI based adjuvant therapy, the percentage of specific adverse events like arthralgia and hot flushes is lower than expected. This observation is possibly a selection bias, since patients who encountered side effects during regular adjuvant therapy could have been less willing to participate in this trial. Remarkably, low numbers of AEs and therapy refusal due to toxicity were reported after therapy extension beyond 2.5 years. In conclusion, extended adjuvant endocrine therapy shows an acceptable toxicity pattern, and therapy extension beyond 2.5 years up to 5 years is well tolerated and safe.
Title: The effects of treatment-induced symptoms, depression and age on sexuality in premenopausal women with early breast cancer receiving adjuvant endocrine therapy

Body: Background: In premenopausal women with breast cancer any treatment that causes abrupt, premature ovarian failure increases the risk of sexual problems. Randomized-controlled trials in this population reported a worsening in sexual functioning over time irrespective of adjuvant endocrine treatment. We investigated key symptoms related to endocrine therapy, depression and age as predictors of sexual problems in premenopausal women with early breast cancer treated in the IBCSG TEXT/SOFT trials over the first two years of endocrine therapy.

Methods: A subset of patients (pts) enrolled by centers with English as primary language to TEXT (1027 of 2672 pts) and SOFT (1260 of 3066 pts) completed a questionnaire consisting of global and symptom-specific quality of life indicators, the CES-Depression (CES-D) and the MOS- Sexual Problems (MOS-SP) measures at baseline, 6, 12 and 24 months. The analysis considered 5 cohorts of pts according to chemotherapy use (yes/no), trial (SOFT/TEXT) and endocrine treatment assignment (tamoxifen alone [T], T or exemestane [E] with ovarian function suppression [OFS]). Mixed modeling was used to test the effect of the following on changes in sexual problems (MOS-SP total score) over two years: changes in treatment-induced symptoms (hot flushes, vaginal dryness, sleep disturbances, bone/joint pain, troubled by weight gain, tiredness, nausea/vomiting) from baseline to 6 months; depression at 6 months; and age at randomization. The model included severity groups of symptoms, depression (all dichotomized by median) and age (< 40 vs ≥40 years), 5 cohorts, time points (6, 12, 24 months), baseline covariates, and interactions of symptoms, timepoints and cohorts.

Results: Overall across cohorts, pts with more severe worsening of vaginal dryness and sleep disturbances at 6 months reported a greater increase in sexual problems at all timepoints (p<.0001). The effect of vaginal dryness on sexual problems was most pronounced in the cohort of pts who received T+OFS or E+OFS without chemotherapy; the effect of sleep disturbances was most pronounced in the cohort with prior chemotherapy and T alone. All other symptoms had a smaller impact on differences in changes of sexual problems. Significant effects were only seen in the short-term and varied according to cohort. Severity of depression at six months did not predict sexual problems at the later timepoints in the overall population. In the cohort that received T+OFS or E+OFS without chemotherapy, pts who had more severe depression scores at 6 months reported significantly worse sexual problems at all timepoints (p<.05). No differences were found for younger vs. older pts with respect to sexual problems at any timepoint.

Conclusion: Among several key symptoms related to endocrine therapy, only vaginal dryness and sleep disturbances significantly predicted sexual problems during the first two years in pts who received adjuvant endocrine therapy with or without chemotherapy. Depression predicted sexual problems only in the cohort of pts who received combined endocrine treatment without chemotherapy. Early identification of vaginal dryness, sleep disturbances and depression is important for timely and tailored interventions.
Title: A new oral SERD AZD9496 for treatment of hormone dependent postmenopausal breast cancer

Sabnis GJ J, Kazi A, Schech A, Yu S, Golubeva O, Weir H and Brodie A. West Coast University, Los Angeles, CA; University of Maryland, Baltimore, MD; Loyola University Maryland, Baltimore, MD; St. Mary’s College of Maryland, St. Mary’s City, MD and AstraZeneca Oncology, Macclesfield, United Kingdom.

Body: Treatment of hormone sensitive breast tumors with endocrine therapy such as antiestrogens or aromatase inhibitors has improved their clinical outcomes. However, not all tumors respond and the ones that do respond may eventually acquire resistance. One of the proposed mechanisms of resistance to endocrine therapy is overexpression of ERα and cross-talk of ERα with growth factor receptors. Studies including our own have shown that downregulation of ER with pure antiestrogen fulvestrant in combination with AIs may prolong responsiveness of the tumors to endocrine agents. Fulvestrant has been employed as either first or second line treatment for ER positive breast cancers alone or in combination with AIs. Studies have suggested that further escalation of dose may provide further benefit. However, dose escalation of fulvestrant which is administered via intramuscular injection is difficult due to its poor solubility. To overcome this shortcoming of an injectable drug, a novel orally active SERD (selective estrogen receptor downregulator), AZD9496 was developed. In addition to being orally active, AZD9496 is selective for mammary ERα. In the current study, we compared the effect of AZD9496 and fulvestrant on the growth of MCF-7Ca (human estrogen receptor positive MCF-7 cells stably transfected with human placental aromatase gene) xenografts grown in ovariectomized athymic nude mice. Tumors were allowed to form with androstenedione (aromatizable source of estrogen) supplement. When the tumors reached ~250 mm³, mice were grouped such that the mean tumor volumes were not significantly different (p>0.99). Mice bearing xenografts of MCF-7Ca were then treated with fulvestrant (1 mg/d-sc) or AZD9496 (5 mg/kg/d-po), alone or in combination with anastrozole (200µg/d-sc) for 23 weeks. Tumors were measured weekly and growth rate was calculated. AZD9496 was significantly better at inhibiting the growth of tumors compared to control (p<0.001) and anastrozole (p=0.04). AZD9496 was equally effective in inhibiting the growth of tumors compared to fulvestrant (growth rate, p>0.99 and tumor volume on week 23, p=0.99). In the second study, efficacy of AZD9496 was evaluated on against anastrozole resistant MCF-7Ca xenografts. Tumors were treated with anastrozole (200µg/d) for 13 weeks. During this time, the tumors initially regressed but eventually began to grow and had doubled in volume. At this time-point, they were regrouped to receive second line treatment. Single agent AZD9496 was marginally significant compared to continued anastrozole treatment (p=0.07). Nevertheless, second line treatment with AZD9496 was equally effective as fulvestrant (p=0.36). The combination of anastrozole with AZD9496/fulvestrant was more effective in reducing tumor growth compared to continued anastrozole treatment. Next, we measured the effect of AZD9496 on the mouse uterus. Uterine weight of mice treated with AZD9496 was not significantly different from mice that were treated with androstenedione (p=0.99). These results suggest that AZD9496 was selective for tumor ERα and had no effect on the uterine ERα. These results suggest that AZD9496 may be a better alternative to fulvestrant due to its selectivity for mammary ER and same efficacy as fulvestrant obtained upon oral administration.

Title: Metabolite-guided long-term prediction of outcome in tamoxifen treated breast cancer patients

Helland T, Henne N, Bifulco E, Hustad SS, Kristensen VN, Lash T, Borgen E, Janssen EAM, Lien EA, Naume B, Mellgren G and Søiland H. Haukeland University Hospital (HUS), Bergen, Hordaland, Norway; University of Bergen (UIB), Bergen, Hordaland, Norway; Stavanger University Hospital (SUS), Stavanger, Rogaland, Norway; Oslo University Hospital, Oslo, Norway; University of Oslo, Oslo, Norway and Emory University, Rollins School of Public Health, Atlanta, GA.

Body: Background
The genetic polymorphisms of CYP2D6 determine its enzymatic activity thereby the pharmacokinetic velocity by which tamoxifen (tam) is converted into active metabolites. Combined analyses of tam metabolites compared to CYP2D6 type and long-term survival could allow prediction of tam response and personalization of therapies. The clinical importance of defining such subgroups in the era of the new long-term (10-year) tam treatment paradigm is actualized.

Material and Methods
From May 1995 to December 1998, patients were included in an observational micro-metastasis study in the Oslo region and treated according to the national guidelines at the time (1). Serum samples were drawn at 3-year follow-up from 356 relapse-free patients, 106 of these were treated with tamoxifen. The median follow up time for breast cancer death was 16.8 years (3.5-19.4). Serum samples were processed using protein precipitation with acetonitrile. An Aquity UPLC system was used to chromatographically separate 10 tam metabolites using a BEH C18 Phenyl column (100 x 2.1 mm, 1.7 µm particle size) that was developed with a water-methanol gradient containing 0.1% formic acid. The LC system was coupled to a Xevo TQ-S tandem mass spectrometer equipped with an atmospheric pressure photoionization source. The method was validated with respect to linearity, imprecision, accuracy, and functional sensitivity according to FDA guidelines.

Results
The new LC-MS/MS method separated the active Z-isomers of 4OHtam and 4OHNDtam (endoxifen) from its inactive Z'-isomers and E-isomers. Imprecision (intra and inter-day CV %) was within 10 % for target concentrations for all metabolites and accuracies were in the range 95-106%. The method was validated with serum samples from 42 breast cancer patients using 20 mg of tamoxifen. The endoxifen concentrations ranged from 0 to 90 nM, with a median value of 25 nM. The previous observed endoxifen level of 10 nM in poor metabolizers (2) was used as cut-off for the grouping of patients. The nil endoxifen (NE) group (< 0.1 nM, n=14) or low-endoxifene (LE) group (0.1-10 nM, n=8) were grouped together. Univariate survival analysis did not show a significant association between breast cancer specific survival and endoxifen levels. (p=0.15; logrank and p=0.18; Breslow). However, for the period beyond 10-years of follow-up the breast cancer survival differed between the high endoxifene (HE) group and the NE+LE groups. For patients surviving the first 10 years the breast cancer specific survival was 94.2% vs. 77.8% for the HE and NE+LE groups respectively (p=0.020, logrank and p=0.017, Breslow, HR=4.5, CI 95=1.1-17.9). In the multivariate analysis endoxifen ≤/> 10 nM remained the only factor in the final model.

Discussion
We developed a new accurate and precise LC-MS/MS method for the measurement of 10 tamoxifen metabolites. Importantly, the method separates active and inactive isomers of 4OHtam and 4OHNDtam/endoxifen. Despite the low number of patients, we observed a poorer long-term survival beyond 10 years in patients with nil or low serum concentration of endoxifen. A comprehensive analysis is presented addressing the relationship between genotyped based and metabolite based prediction of long-term outcome in tamoxifen treated breast cancer patients.

Title: A single-blind, randomized, placebo-controlled phase II study to evaluate the impact of oral ibandronate on bone mineral density in osteopenic breast cancer patients receiving adjuvant aromatase inhibitors: Final results of the single-center BONADIUV trial

Body: Background. Several randomized trials demonstrated aromatase inhibitors (AI) superiority in terms of disease-free survival compared to tamoxifen treatment for postmenopausal hormone receptor-positive breast cancer (BC) patients. Anyway AI toxicity profile due to estrogen suppression is a concern. Pivotal trials demonstrated a significant bone mineral density (BMD) loss due to AI, with a consistent risk of fractures, thus impacting on patients’ quality of life. Bisphosphonates represent an effective treatment in postmenopausal osteoporosis fractures prevention. Several studies demonstrated that upfront bisphosphonates therapy prevents bone loss in postmenopausal women receiving adjuvant AI for early-stage BC. However an adequate patients selection for adjuvant bisphosphonates treatment during AI endocrine therapy is still a challenge.

We present the final results of the BONADIUV trial, a single-blind, randomized, placebo-controlled phase 2 study designed to evaluate the impact of ibandronate treatment on BMD in osteopenic women taking AI.

Methods. Between January 2011 and May 2014, 561 patients underwent a baseline BMD assessment before starting AI as planned adjuvant treatment. Overall 171 osteopenic patients (lumbar spine [LS] and/or trochanter -1< T-score <-2.5), were randomized in a 1:1 ratio to receive either placebo or oral monthly ibandronate (150 mg). All patients receive oral supplementation of calcium and vitamin D3. Study duration was 2 years. Exclusion criteria were: premenopausal status at time of randomization; comorbidities with increased risk of osteoporosis; body mass index <18; chronic use of steroids; previous use of bisphosphonates; psychiatric disorders. Primary endpoint was the mean BMD difference between the two arms at a 2-year follow up. ClinicalTrials.gov identifier: NCT02616744. A total of 72 patients per arm of treatment were needed to obtain an 85% statistical power in order to detect a 2% BMD mean difference between the two arms. Considering a 10% dropout, at least 158 patients were required.

Results. A total of 171 patients were randomized in the study. Overall 27 patients (15.8%) withdrew the protocol (17 ibandronate vs 10 placebo arm): the final analysis was performed on 144 patients (72 patients per arm). P-value from Wilcoxon test showed no significant difference between arms at baseline both for LS (p=0.94) and trochanter (p=0.83). At 2-year, osteopenic patients treated with ibandronate gained +18.7% and +15.5% at the LS and trochanter BMD, respectively. Patients treated with placebo lost -13.3% at the LS, and gained +2.9% at the trochanter. Trochanter p-value from covariance analysis showed a mean BMD change significantly in favor of ibandronate arm at 1-year (p=0.012), and borderline at 2-year (p=0.087). Concerning LS, the mean BMD change was significantly in favor of ibandronate arm both at 1-year (p=0.002) and 2-year (p<0.0001).

Conclusions. Final results of our study showed that treatment with ibandronate, as compared to placebo, improved BMD change in osteopenic women treated with adjuvant AI, and consistently protected patients' bone loss.

Title: Adverse events rates in a privately insured US population on tamoxifen compared to controls from the MarketScan database

Peterson LL L and Simpson KN N. Washington University, St. Louis, MO and Medical University of South Carolina, Charleston, SC.

Body: Patients with breast cancer (BC) and those at high risk for BC are often reluctant to initiate Tamoxifen (Tam) due to potential adverse events (AEs) such as deep vein thrombosis (DVT), pulmonary embolus (PE), acute ischemic stroke (AIS), myocardial infarction (MI) and endometrial cancer (EC). Some decline this life saving therapy due to fear of AEs. AE rates from RCTs are low, but AE rates in the general population are not well documented.

Methods: The MarketScan database (2010-2013) was searched for patients aged 30-64 with a prescription of Tam active for more than 120 days. Patients with prior DVT, PE, AIS, MI or EC were excluded. ICD-9 codes for DVT, PE, AIS, MI and EC for inpatient and outpatient encounters were used to determine the frequency of AEs while on Tam. Patients taking Tam for prevention, DCIS or invasive cancer were included. Results were stratified by sex, age and time on Tam (in years). A random control group was created from the database utilizing patients age 30-64 with a levothyroxine prescription active for more than 120 days to calculate odds ratios (OR) for the AEs.

Results: 67,887 patients on Tam, including 1622 males, were analyzed, for a total of 93,498 Tam Exposure Years. The control group included 2.4 million patients. The average age of Tam users was 48 (males), 50 (females). The average age of controls was 51 (males), 50 (females). Ages (%) represented in Tam users: 30-34 (2%), 35-44 (20%), 45-54 (52%), 55-64 (26%). The average time on Tam was 1.4 years for females, 1.0 years for males (.33-4.2). DCIS accounted for 17% of Tam use, <1% was for prevention. AE rates and odds ratios (OR) are in the table below.

Conclusions: Despite an increased odds of DVT, PE and EC, AE rates in patients on Tam are remarkably low, especially in the younger age population, the population most likely to be on Tam. The odds of AIS and MI are lower in Tam users than controls. The favorable risk/benefit profile of this drug should be emphasized to patients who would benefit from its use, with the use of actual event rates, not odds ratios, being the focus of discussion with patients. Male sex increases the odds of DVT, PE, AIS and MI. Increasing age and use of Tamoxifen for more than 2 years increase the odds of having an AE. Further analysis will evaluate whether there are differences in AE rates between Tamoxifen patients based on their diagnosis (prevention, DCIS, invasive cancer).
Title: Association between BMI and residual estradiol levels in post-menopausal women using adjuvant letrozole: Results of a prospective study

Cescon DW W, Ennis M, Pritchard KI I, Townsley C, Warr D, Elser C, Rao L, Stambolic V, Sridhar S and Goodwin PJ J. Princess Margaret Cancer Centre, University Health Network, Toronto, Canada; Sunnybrook Odette Cancer Centre, ON, Canada; Lunenfeld Tanenbaum Research Institute, Toronto, Canada; Women's College Hospital, Toronto, Canada; Applied Statistician, Markham, Canada; Mount Sinai Hospital, Toronto, Canada and University of Toronto, Toronto, Canada.

Body: Background: Adjuvant aromatase inhibitors (AI) are the standard of care for post-menopausal women with early breast cancer (BC). Some studies have suggested that women with high BMI have less benefit from some AIs (anastrozole, but not letrozole) vs. tamoxifen. Of concern, a positive correlation between BMI and residual estradiol in women using letrozole has been reported (ALIQUOT Study; JCO 2012). These findings have created uncertainty about the use of AIs in overweight and obese women. We conducted a prospective study to measure estrogen levels in post-menopausal women using adjuvant letrozole, with the primary objective of evaluating the relationship between residual E2 and BMI.

Methods: Post-menopausal women with early BC taking adjuvant letrozole for at least 3 months were recruited at 4 sites in Toronto, Canada. Fasting blood was collected 24 hours after the prior dose at baseline (Day 1, routine use of own letrozole, including generic) and on Day 29, following 28 days of monitored adherence to a provided supply of Femara 2.5 mg/day (Part A). Participants with BMI>25 were treated for a further 28 days (Part B) with a double dose of Femara (5 mg/day). Estradiol and estrone were measured using a high sensitivity liquid chromatography-tandem mass spectrometry assay. Vitamin D and markers of obesity/inflammation were assayed, and symptom/quality of life questionnaires completed at the same time points.

Results: 112 eligible patients were enrolled and completed Part A. Median age was 62 and BMI 24.7 kg/m^2 (range 19.0 to 42.2 kg/m^2). 68% of participants had received adjuvant chemotherapy. Estradiol levels (mean±SD) were 2.81±1.15 pg/mL at baseline (typical use) and 2.69±1.01 pg/mL at Day 29 following monitored Femara use with near-perfect adherence (p=NS). No significant correlation was observed between estradiol and BMI on either Day 1 or Day 29 (r=0.06, p=NS). As previously reported, letrozole 5 mg/day dose did not affect residual estradiol levels at Day 58 for women with BMI>25. Residual estradiol was not correlated with vitamin D or markers of obesity/inflammation (insulin, leptin, CRP).

Conclusion: No association was observed between BMI and residual estradiol in women using letrozole (generic or Femara) at standard doses. These results are consistent with the absence of a treatment-by-BMI interaction in the BIG 1-98 trial and they provide reassurance that letrozole is an appropriate treatment in overweight and obese women.

Title: A multi-institutional, prospective study of incorporating the genomic platform breast cancer index as a tool for decision-making regarding extension of adjuvant endocrine therapy

Sanft T, Berkowitz A, Schroeder B, Hatzis C, Schnabel C, Aktas B, Brufsky A, Pusztai L and vanLonden GJ. Yale School of Medicine; University of Pittsburg Medical Center; Biotheranostics, Inc. and Istanbul Medeniyet University Goztepe Research and Training Hospital.

Background: Extending adjuvant endocrine therapy (AET) for hormone responsive breast cancer (HRBC) from 5 to 10 years is beneficial for many in preventing late relapse. Current decision-making regarding extension relies on a decision-making process that weighs non-personalized recurrence risks against risks and benefits of extended AET. The Breast Cancer Index (BCI, BioTheranostics Inc) has been validated to quantify the risk of late recurrence and to predict likelihood of benefit from AET extension based on an individual's tumor genomic profile. The purpose of this study was to conduct a multi-institutional study to prospectively assess the impact of BCI i) on provider's recommendation using the BCI results; 2) the confidence with decision-making; and 3) patient's satisfaction regarding extension of AET.

Methods: Patients with stage I-III HRBC treated at Yale Cancer Center and University of Pittsburgh Medical Center (UPMC), who had completed at least 3.5 years of AET were eligible. BCI was performed on FFPE samples from the original tumor sample (bioTheranostics Inc.). Patients and physicians completed pre- and post-test questionnaires examining preferences for extending AET, patients also completed anxiety and decision-conflict surveys.

Results: 140 patients [mean age 61, 80% postmenopausal, 73% stage I] were included. No extended AET was recommended for 35.3% patients pre-testing. Reasons physicians did not recommend extended AET were perceived low risk of recurrence (87%), risk of osteoporosis (25%) and side effects (13%). Extended therapy was recommended for 65.7% patients pre-testing. Integration of BCI resulted in a change in physician treatment recommendation in 29% of patients. The recommendation for no extended AET rose to 48% and recommendation for extended AET dropped to 52% (OR=1.76 95% CI 1.08-2.85; p=.003). Of the recommendations that changed (N=41), the majority (73%) was for not extending endocrine therapy. However, 27% of recommendations were to extend endocrine therapy because of high risk or high likelihood of benefit results. More physicians felt strongly confident in their recommendation after the test result (26.4%) than before (9.3%) (OR= 3.5 95% CI 1.77-6.95; p<.0001). Satisfaction of decision increased in 23% of patients (OR=2.72 95% CI 1.66-4.46; p<.0001). Patient reported concerns including the cost, safety and benefit of extended AET decreased from pre- to post-testing (p=.025; p<.0001; p=.0012 respectively)

Conclusions: Overall, incorporation of BCI into clinical practice resulted in significant changes in physician recommendations regarding AET duration, with the majority of recommendations for no extended AET. Physicians reported increased confidence for their recommendation when incorporating the test result. There was also a significant increase in patient satisfaction and decrease in patient reported concerns regarding cost, safety and benefit of extended AET. The BCI is a tool that could be incorporated into decision-making algorithms to enhance physician confidence and patient satisfaction with recommendations for extending AET.
How population-based data complement trial data in the adjuvant endocrine treatment of ER+/HER2+ breast cancers

Dackus GMHE MHE, Joziwak K, Sonke GS S, Van der Wall E, Van Diest PJ J, Hauptmann M, Siesling S and Linn SC C.
Netherlands Cancer Institute, Amsterdam, Netherlands; University Medical Center Utrecht, Utrecht, Netherlands; Netherlands Cancer Institute, Amsterdam, Netherlands; Netherlands Cancer Institute, Amsterdam, Amsterdam, Netherlands; University Medical Center Utrecht, Utrecht, Netherlands; Comprehensive Cancer Organisation, Utrecht, Netherlands and MIRA Institute for Biomedical Technology and Technical Medicine, University of Twente, Enschede, Netherlands.

Body: Background
This study is part of the Netherlands Breast Cancer Project, initiated to address research questions that are unlikely answered by future randomized controlled trials (RCT). Here we investigated whether aromatase inhibitors (AI) are superior over tamoxifen (TAM), in the treatment of Estrogen Receptor (ER) positive Human Epidermal growth factor Receptor 2 (HER2) positive breast cancer, using treatment and outcome data from the population based Netherlands Cancer Registry (NCR). RCTs showed superiority of AI over TAM in postmenopausal ER+/HER2+ patients while a (non-significant) suggestion for worse outcome was observed among premenopausal patients treated with AI in the SOFT/TEXT trial. Perimenopausal women were not considered in these trials.

Methods
Dutch women without a prior malignancy, diagnosed between 2005-2007 with an ER+/HER2+, endocrine treated, non-metastatic, invasive breast cancer, were identified through the NCR and followed until 2013. Since data on menopausal status were lacking, we used age at diagnosis as a proxy to categorize patients as premenopausal (≤45 years), perimenopausal (45-55 years) and postmenopausal (>55 years). A time-dependent variable was calculated indicating whether AI treatment was given for >50% (denoted AI treated) vs. <50% (denoted TAM treated) of endocrine treatment duration. Recurrence-free survival (RFS) and overall survival (OS) were assessed using an extended Kaplan-Meier survival estimator and Cox proportional hazards regression. Hazard Ratios (HR) for the TAM/AI comparison, were adjusted for chemotherapy, trastuzumab, age at diagnosis, lymph node status, grade, clinical T stage, and ovarian ablation.

Results
We included 1158 patients: 326 pre-, 306 peri- and 526 postmenopausal. Of these, 229 received TAM and 929 AI. During follow-up, 239 RFS and 184 OS events were observed. In the TAM treated group, 56 RFS and 45 OS events were observed, in the AI treated group 183 RFS and 139 RFS events were observed respectively. No differences in RFS were observed comparing AI to TAM treated patients in the premenopausal (HR 1.33; 95% CI 0.71-2.49; P=0.378) and postmenopausal (HR 0.84, 95%CI 0.54-1.32; P=0.456) group. However, perimenopausal patients benefitted significantly from AI compared with TAM (HR 0.50; 95% CI 0.27-0.95). Results were similar for OS: no significant benefit from AI when compared to TAM in pre- (HR 1.41; 95% CI 0.62-3.19; P=0.408) and postmenopausal (HR 0.75; 95% CI 0.47-1.22; P=0.245) patients while perimenopausal patients derived significant benefit from AI treatment (HR 0.42; 95% CI 0.20-0.85; P=0.016).

Conclusion
In this population based cohort study we observed superiority for AI over TAM in the treatment of ER+/HER2+ perimenopausal patients. Data were suggestive in favor of AI when compared to TAM for postmenopausal patients while an indication of worse outcome with AI was seen in premenopausal patients, consistent with results of the SOFT/TEXT trial. Although we used age as a proxy for menopausal status, our results are consistent with previous RCTs. Population based data may therefore provide a reliable source of information when new RCTs might not be feasible anymore.
Title: Genomic profiling of residual ER+ breast cancers treated with prolonged neoadjuvant letrozole reveals novel alterations in clinically resistant tumors

Body: Background: Approximately 20% of patients with early ER+ breast cancer (BC) treated with adjuvant antiestrogen therapy eventually relapse with endocrine-resistant metastatic disease. We hypothesized that profiling newly diagnosed ER+ BC that persist following prolonged estradiol deprivation with letrozole would identify genomic alterations associated with endocrine resistance.

Methods: We treated 57 postmenopausal women (median 77 years; range 60-86) with ER+/HER2– BC with neoadjuvant letrozole (median 7.5 months; range 3-36) followed by surgery and adjuvant endocrine therapy. Patients were followed with serial ultrasounds and defined as non-responders if they developed recurrent locally or metastatic disease, or had a preoperative endocrine prognostic index (PEPI) ≥4 (composite score of post-treatment ER, Ki67, T and N status). Post-treatment specimens were profiled by RNA-seq and targeted capture NGS of >300 cancer-related genes. We screened for variants with a high probability of disrupting protein function (GERP score >4) and excluded likely germline variants by filtering out every alteration not present in COSMIC, if the variant had an allele frequency >0.1% as per the ExAC dataset.

Results: Ten patients (17.5%) had a PEPI 0 score, 31 (54%) were PEPI 1-3, and 16 (28%) were PEPI ≥4. After a median follow-up of 50 months (12-100), 9 patients (15.7%) had recurred with metastatic disease (4 with PEPI 1-3, 5 with PEPI ≥4). We identified 294 variants with a median coverage >250x (206 nonsynonymous, 21 nonsense, 58 indels, 8 splice site). Recurrent mutations included PIK3CA (38%), KMT2C (28%), CDH1 (15%), NF1 (12 %), TP53 (10%), MAP3K1 (7%), ERBB2 (7%) and ESR1 (5%). Recurrent amplifications were identified in MCL1 (31%), GNAS (19%), CCND1 (16%), FYN (14%), AURKA (12%), and ERBB2 (10%), while recurrent deletions were found in DUSP4 (12%), NCOR1 (8%) and NF1 (6%). Compared to alterations reported in untreated ER+ breast cancers in TCGA, we observed a significant increase in KMT2C, NF1, MCL1 and FYN alterations (FDR<0.05). MCL1, GNAS and FYN amplifications, DUSP4 deletions, MAP3K1 mutations, and ERBB2 and NF1 alterations were enriched in the non-responder group. Differential expression analysis of the RNA-seq data revealed an enrichment of E2F and MYC target genes, and genes involved in the G2/M checkpoint, TORC1 signaling, EMT and immunosuppression in non-responding tumors. PEPI 0 tumors were enriched with Luminal A subtype tumors, whereas PEPI 4 tumors were enriched with Luminal B, basal and HER2-enriched subtypes. Luminal A tumors exhibited improved disease free survival compared to other subtypes (HR 0.28, 95% CI 0.10-0.64). Gains in the proximal portion of chromosome 1q were associated with poor long-term outcomes as the relapse-free survival rate at 40 months for patients with 1q gains was 89% versus 41% for patients with no 1q gain (p=0.001).

Conclusions: Genomic profiling of residual ER+ breast cancers treated with prolonged neoadjuvant letrozole revealed a different mutational landscape than primary untreated ER+ BC. These alterations may be associated with poor response to estrogen deprivation in early breast cancer and deserve further study.

Title: The impact of intrinsic subtypes and molecular features on aromatase inhibitor induced reduction of proliferation marker of Ki67 in primary ER+ breast cancer: A POETIC study (CRUK/07/015)

Cheang MCU, Morden J, Gao Q, Parker J, López-Knowles E, Detre S, Hills M, Zabaglo L, Tomiczek M, Mallon E, Robertson J, Smith I, Bliss J, Dowsett M and On Behalf of the POETIC Trialists. Institute of Cancer Research, London, United Kingdom; University of North Carolina at Chapel Hill, Chapel Hill, NC; Royal Marsden Hospital, United Kingdom; University of Glasgow and University of Nottingham, United Kingdom.

Body: Background

Neoadjuvant endocrine therapy (NAE) is often a good option for postmenopausal (PM) women with estrogen receptor positive (ER+) breast cancers (BC). Fall in Ki67 is widely accepted as valid for predicting favorable tumor response to NAE and improved outcome. We report our planned correlative study to investigate if intrinsic subtype impacts on Ki67 changes ($\Delta$Ki67) as measured by immunohistochemistry. We also explored the correlation of several ER+ BC relevant molecular features at baseline (B) with $\Delta$Ki67.

Patients and methods

POETIC is a phase III, randomized 2:1 study for 4486 PM patients with ER+ BC to determine whether peri-operative aromatase inhibitor (AI) followed by standard adjuvant therapy improves outcome compared with standard adjuvant therapy alone. The proliferation rate was estimated as percentage (%) of cancer cells staining for Ki67. Primary biological endpoint was defined as two-week (2wk) change in Ki67 (2wk$\Delta$Ki67): ln[(2wk Ki67+0.1)/(B Ki67+0.1)]. Secondary endpoint: “responders”, was % change of Ki67 defined as (2wk Ki67 – B Ki67) *100/B Ki67. “Responder” was defined as follows: reduction <50% as poor (PR), 50-75% moderate and >75% as good responder (GR).

Human whole genome expression (GE) Illumina BeadChips were performed. Data was obtained from 137 paired samples from the treatment group (T) and 49 pairs from the control (C) group with GE data passing quality check and baseline Ki67 ≥ 5% to minimise the impact of extreme values based on proportional $\Delta$Ki67. Intrinsic subtype and risk of recurrence (ROR) groups were calculated using PAM50. GE scores from Oncotype Dx, MammaPrint, p53 mutation/wildtype (Troester 2006), ER+ early response (ERE) (Hatzis 2011), estrogen-regulated genes subtypes (Oh 2006) and markers for 23 different immune cell types (Bindea 2013) were calculated. Associations of GE scores to endpoints of response were determined by Spearman correlation and chi-square tests. Bonferroni correction was used to control error rate with p<0.0005 deemed significant.

Results

At B of the 137 paired T, 64% were Luminal A (LumA), 22% Luminal B (LumB), 9% as HER-2 enriched (HER2-E), 2% as Basal-like (BLBC) and 3% as Normal-like. Subtypes at B were associated with response, with LumA showing the biggest reduction of Ki67 (p=0.0001) and GR. All GE, except ERE, correlated significantly with 2wk$\Delta$Ki67 and response: higher risk groups associated with lowest reduction rate. None of immune cell types correlated with 2wk$\Delta$Ki67, except that tumors enriched with T-helper 1 cell type were associated with PR (p < 0.000001).

Comparing subtypes between time-points, 85% of LumB and 42% of HER2-E were assigned instead as LumA at 2wk regardless of response. Of the 15 ROR defined high-risk group, only 33% were assigned instead as low-risk at 2wk.

Conclusion

Both LumA and LumB are endocrine sensitive. A fall of Ki67 was observed in majority of cases. Most tumors estimated as high-risk by molecular profiling showed less response and most remained moderate or high risk of recurrence on endocrine therapy. Whether molecular profiling at 2wk after starting AI predicts for long-term outcome in PM women with ER+ better than at diagnosis will need to be determined.
Using the 21-gene assay from core needle biopsies to choose neoadjuvant therapy for breast cancer: A multi-center trial

Bear HD, D. Wan W, Robidoux A, Rubin P, Limentani S, White, Jr. RL L, Granfortuna J, Hopkins JO O, Oldham D, Rodriguez A and Sing AP P.  Virginia Commonwealth University, Massey Cancer Center, Richmond, VA; Centre Hospitalier de l'Universite de Montreal, Montreal, QC, Canada; Cone Health Cancer Center, Greensboro, NC; Carolinas Medical Center, Charlotte, NC; Forsyth Regional Cancer Center, Winston-Salem, NC; Lynchburg Hematology Oncology Clinic, Lynchburg, VA; Methodist Hospital, Houston, TX and Genomic Health, Inc, Redwood City, CA.

Body: Neoadjuvant systemic therapy (NST) can facilitate breast conserving surgery (BCS) for large cancers. While hormone receptor positive (HR+) cancers respond to neoadjuvant chemotherapy (NCT), pathologic complete responses (pCR) are unlikely. Neoadjuvant hormonal therapy (NHT) may make BCS possible with less toxicity than NCT. We hypothesized that the Oncotype Dx® 21-gene Recurrence Score (RS), could guide the decision to treat with NHT versus NCT to facilitate BCS. This hypothesis is based on the ability of the RS to identify ER+ patients (pts) likely to benefit from adjuvant CT vs unlikely to benefit, as well as prior studies showing that pts with a low RS have no pCRs when receiving NCT (Yardley, et al 2015).

Methods: This prospective multi-center study enrolled pts with HR+, HER2-negative, invasive breast cancers not suitable for BCS (size ≥ 2 cm). Diagnosis was made by core needle biopsy (bx). Tissue blocks from the bx’s were sent to Genomic Health for RS testing. Pts whose tumors had a RS < 11 were to receive NHT; pts with RS >25 tumors were to receive NCT; pts with midrange RS of 11-25 were randomized to NHT or NCT.

The primary objective was the feasibility of randomizing pts with RS values 11-25 between NHT and NCT. The primary endpoint was whether 1/3 or more of randomized pts would refuse assigned treatment. Secondary endpoints included: clinical partial and complete response (cPR, cCR) rates, overall clinical response rates (CR), pCR in the breast, pCR in the breast and nodes and successful BCS. One-sample binomial test was used to compare the observed refusal rate with 1/3, along with its 95% CI. Fisher's exact test, logistic regression (for a binary endpoint), and/or ordinal regression (for an ordinal endpoint) were used to compare the 4 treatment groups for secondary endpoints.

Results: Seven US and Canadian centers enrolled 64 pts; 5 were excluded (1 delay in RS result, 1 lost block, 1 HR testing discrepancy, 2 not eligible). Of 33 pts with RS 11-25, 5 (15%; 95% CI =2.9% - 27.4%) refused assignment to NCT (2 chose NHT and finished the study). This was significantly lower than the 33% target (binomial test, p=0.0292). Results for other endpoints are shown in the Table (according to treatment received); the total number of pts for the analyses is 55; 1 pt had missing data for clinical response.

Conclusions: This pilot showed the feasibility of using the RS to guide NST, with only a 15% refusal rate of randomly assigned treatment. Of greater interest is the finding that pts with a RS <11 had a high CR rate with NHT and that pts with a RS 11-25 who...
received NHT had a similar rate of BCS success as the pts with RS <11. Conversely, pts with RS>25 treated with NCT had the highest CR (cCR + pCR) and pCR rates. These results demonstrate that conducting a similarly designed larger trial is feasible and suggests that for pts with a low RS, NHT is a potentially effective strategy.
Title: PowerPIINC trial: Changes in tumor proliferation index and quality of life with 7 days of preoperative tamoxifen

Body: BACKGROUND: A decrease in Ki67 has been shown to be a predictor of response to tamoxifen. Previous trials have shown a decreased Ki67 proliferation index in breast tumors with as little as 2 weeks of preoperative tamoxifen. However, shortening the preoperative treatment time in window of opportunity studies increases patient acceptance for trial participation. The POWERPIINC trial examined the effect of 7 days of preoperative tamoxifen on breast tumor proliferation and patient symptoms.

METHODS: Adult women with untreated stage I or II invasive breast cancer that was ER positive (>1%) planning on breast surgery with no contraindications to tamoxifen were enrolled. Women received 20mg of tamoxifen for 7 days up to the day of surgery and for 14 days afterwards. Proliferation was assessed by Ki67 immunohistochemistry before and after 7 days of tamoxifen. The proliferation genes from the PAM50 were also assessed by RT-PCR. Symptoms and QOL were assessed by the FACT-ES, MENQoL, and BMQ.

RESULTS: 52 women were enrolled, and 44 were evaluable for Ki67. The median age was 58.5 years, and the median tumor diameter was 1.2cm. Most women (73%) were post-menopausal. Most tumors were PR positive (88%). Only 8% of tumors were HER2-positive. The Ki67 decreased by a geometric mean of 40% (95% CI 29%-63%), and 73% (95% CI 57%-85%) of women had tumors with decreased proliferation after 7 days of tamoxifen (p=0.0001 by paired t-test). No correlation was seen between the change in Ki-67 and change in FACT-ES or MENQoL scores. Women reported minimal to no bother from psychosocial or physical symptoms at baseline or on the day of surgery. Expression level of individual proliferation genes did not change after 7 days of tamoxifen.

CONCLUSION: Seven days of tamoxifen showed a similar relative decrease in the Ki67 proliferation index as that reported for longer courses. Therefore, short window of opportunity trials can be informative.
The long term outcomes of female patients treated with primary endocrine therapy for non-metastatic breast cancer

Morrow E, Griffard A, Murray J and Lannigan A. Wishaw General Hospital, Wishaw, Lanarkshire, United Kingdom.

Introduction: Primary endocrine therapy is usually prescribed for elderly patients with breast cancer who are considered too frail for surgery. Many respond well but some patients progress requiring either a switch of treatment or, in some cases, surgical intervention for local disease control. This study aimed to look at all patients treated with primary endocrine therapy over a six year period with a particular focus on their survival and how many ultimately required to have surgery performed.

Methods: All female patients treated with primary endocrine therapy in our NHS board, diagnosed with breast cancer between August 2009 and July 2013, were identified from a prospectively collected database. Those with metastatic disease at diagnosis were excluded. Their progress and long term outcomes were detailed from each patient's electronic record.

Results: 171 patients were commenced on primary endocrine therapy for non-metastatic breast cancer during this period. The median age at diagnosis was 81 years (43-99 years). 132 of the tumours were ductal/no specific type, 22 were lobular, 7 mucinous and 10 were of other types. The median ER status was 8 (0-8). In all but two cases the agent used was an aromatase inhibitor. 65 (38%) patients were documented to have clinically and/or radiologically responded to therapy, 8 (5%) had static disease, 41 (24%) had disease progression and 47 (27%) were not followed up in clinic, usually as either a clinician decision based on their frailty or as the patient failed to attend appointments. In 10 cases, follow up appointments had been attended but there was no clear documentation regarding clinical progress. In those patients who had disease progression, the mean time to documented progression was 30 months (2-60 months). In the other patients who had follow up, mean length of follow up at the time of data collection was 27 months (2-84 months). 36 (21%) patients required a switch in endocrine therapy, in 31 cases due to disease progression and in the other 5, because of side effects. 13 (8%) patients ultimately required to have surgery. At the time of data collection, 104 patients had died with their mean survival being 537 days (4-2016).

Conclusions: While some patients treated with primary endocrine therapy for breast cancer had progressive disease requiring a switch of treatment or surgery, the majority of those followed up achieved disease control and tolerated the medication well. It therefore provides an acceptable alternative to surgery in the frail, elderly population.

Body: Background
Nausea and Vomiting due to cancer therapy is still a problem for patients and physicians and therefore an ongoing item of research in oncology. International antiemetic guidelines (ASCO, NCCN, MASCC/ESMO) have been published and new drugs are introduced into the market. The fixed oral combination of the NK<sub>1</sub>-receptor antagonist (RA) netupitant and the 5-HT<sub>3</sub>-RA palonosetron (NEPA) was recently approved in US and EU for the prevention of acute and delayed chemotherapy-induced nausea and vomiting (CINV) in cancer patients receiving cisplatin-based highly emetogenic (HEC) or moderately emetogenic chemotherapy (MEC). The MASCC guidelines 2016 recommend a triple combination of 5-HT<sub>3</sub>- and NK<sub>1</sub>-RA and dexamethasone given on day 1 for patients receiving HEC, anthracycline / cyclophosphamide (AC)-containing chemotherapy as well as for carboplatin-based MEC for the prevention of chemotherapy-induced nausea and vomiting (CINV).

Objectives
The primary endpoint of this non interventional study is the evaluation of quality of life in adult cancer patients receiving NEPA for CINV prevention in MEC or HEC. Secondary endpoints are efficacy and safety of NEPA.

Methods
This non-interventional study evaluates CINV prophylaxis with NEPA and QoL in 2500 cancer patients receiving single day or two day MEC or HEC in an ambulatory setting in German cancer hospitals and specialized cancer practices. NEPA is prescribed in accordance with the EU marketing authorization. Quality of life is recorded by FLIE questionnaires. Efficacy - measured as complete response (CR, no vomiting, no rescue medication) –as well as additional medication, safety and adverse events (AEs) are documented by an online questionnaire filled by the physician and a patient diary. 3 consecutive chemotherapy cycles are documented online using the ODM QuaSi documentation system. All specifications in the online documentation must be verifiable.

Results
700 patients from 175 centers (93 gynaecologic oncology, 79 medical oncology, 3 urologic oncology) are included to date. The majority of patients were women (88.7%). 71% of all patients had breast cancer. 92.6% had an ECOG performance status of 0-1. 77.6% received (neo)adjuvant chemotherapy. Most common chemotherapy regimens were AC-based regimens (53.9%), carboplatin-based regimens (15.9%) and cisplatin-based regimens (12%).

Efficacy data are available for 486 patients in cycle 1 and 350 patients over 3 cycles. During 3 consecutive chemotherapy cycles, 89% of patients had a CR on day 1 as recorded by patient diaries. In the delayed phase (days 2-5), 85% of patients had a CR. 93% recorded no vomiting during the entire 5 days at risk following chemotherapy and 69% reported no or only mild nausea. >90% of the medical staff rated the efficacy of the CINV-prophylaxis with NEPA as good or very good over 3 cycles.

Adverse events (AE), mostly constipation were rare and mild and only of grade 1 or 2. No serious AEs were observed.

Summary
NEPA is a safe and efficacious option for the prophylaxis of nausea and vomiting in highly and moderately emetogenic chemotherapy.
Title: A longitudinal look at toxicity management within a platform trial: Lessons from the I-SPY 2 TRIAL

Paoloni M, Lyandres J, Buxton MB B, Berry DA A, Esserman LJ J, DeMichele A and Yee D. QuantumLeap Healthcare Collaborative, San Francisco, CA; University of California, San Francisco, San Francisco, CA; Berry Consultants, Austin, TX; University of Pennsylvania, Philadelphia, PA and University of Minnesota, Minneapolis, MN.

Body: Background: I-SPY 2 is a multicenter, phase 2 trial using response-adaptive randomization within biomarker subtypes to evaluate a series of investigational agents or regimens when added to standard neoadjuvant therapy for women with high-risk stage II/III breast cancer - investigational agent (I) +paclitaxel (T) qwk, doxorubicin & cyclophosphamide (AC) q2-3 wk x 4 vs. T+/-HP/AC (control arm(s)). Although the primary endpoint is pathologic complete response (pCR) at surgery, a key secondary aim is to evaluate the toxicity profiles of these investigational agents. Distinct aspects of safety monitoring in a platform trial, as well as the specificities of safety management in a potentially curative population make the experiences from I-SPY 2 valuable to the community.

Methods: Inclusion and exclusion criteria are uniformly applied to all women in I-SPY 2. When a new investigational agent/regimen is planned for the trial, agent specific laboratory/hematologic limits or additional required tests are added, as needed. Eligibility criteria remain in the trial for its duration and apply to all investigational and control arms. Laboratory and adverse event data are collected and monitored in real time. The lead investigator of the investigational agent/regimen who chaperones a specific agent/regimen through the trial (“Agent Chaperone”), Medical Monitor, I-SPY 2 Agents Committee, CRO safety group, and an active DSMB that meets monthly oversee the management of toxicities within each investigational agent/regimen of the trial. Toxicity profiles for an investigational agent/regimen are compared to their relevant control. Safety analyses are intention to treat.

Results: From March 2010-May 2016, eleven (11) investigational agents/regimens have opened (and 6 have completed evaluation) and 973 women have been randomized. These agents/regimens span a variety of mechanisms of action including targeted therapies such as small molecule inhibitors and antibodies, as well as immunotherapies. Additions to the trial’s eligibility criteria have been made with new investigational arms. Adverse events of special interest have been monitored for each investigational arm and specific toxicities treated uniformly when applicable. A risk-based monitoring plan has been implemented that focuses on the collection and review of the trial's most critical data elements including serious adverse events and drug specific safety issues, allowing for a more efficient and focused effort. Safety issues have been quickly addressed and requirements updated, when needed, given the importance of limiting (or avoiding) long-term safety complications within this neoadjuvant patient population. Accrual to the trial has (been) maintained over time and the safety of trial participants has been well managed.

Conclusion: A platform trial requires an evolving, and focused safety-monitoring process that adapts as new investigational agents are included. I-SPY 2's infrastructure and team science approach has created a system to manage patients across multiple arms with different risk profiles. These practices will support the safe evaluation of additional new combinations and regimens and serves as a guide for safety management within standing platform trials.
Title: Incidence and severity of diarrhea with neratinib + intensive loperamide prophylaxis in patients (pts) with HER2+ early-stage breast cancer (EBC): Interim analysis from the multicenter, open-label, phase II control trial

Barcenas C, Olek E, Hunt D, Tripathy D, Ibrahim E, Wilkinson M, Hurvitz S, Iannotti N, Kellum A, Manalo Y, Wong S, Hansen V, Alvarez R, Chan A, Gore I, Kendall D, Wade J, Ruiz R, Fang P, Bryce R and Moran S. MD Anderson Cancer Center; Puma Biotechnology Inc.; The University of Texas MD Anderson Cancer Center; Beaver Medical Group; Inova Medical Group; UCLA Hematology/Oncology Clinical Research Unit; Hematology Oncology Associates of the Treasure Coast; North Mississippi Medical Center Hematology and Oncology Services; Coastal Bend Cancer Center; Rutgers Cancer Institute of New Jersey; Northern Utah Associates; Southeastern Regional Medical Center, Inc.; Hollywood Private Hospital; Alabama Oncology, Bruno Cancer Center; Utah Cancer Specialists Research and Decatur Memorial Hospital Cancer Care Specialists of Central Illinois.

Body: **Background:** Neratinib (Puma Biotechnology Inc) is an irreversible pan-HER inhibitor in late-phase development for the treatment of early-stage and metastatic HER2+ BC. Diarrhea, the main toxicity of neratinib, requires active management with loperamide prophylaxis given early in the course of treatment. CONTROL (PUMA-NER-6201) is an international, open-label, phase II study investigating the efficacy of loperamide prophylaxis in the prevention of neratinib-associated diarrhea. CONTROL has recently been expanded to include prophylaxis with loperamide + budesonide, which targets inflammation identified in a preclinical model of neratinib induced diarrhea.

**Methods:** Pts with HER2+ early-stage BC who had completed trastuzumab-based adjuvant therapy were eligible. All pts were to receive oral neratinib 240 mg/day for 1 year + structured loperamide prophylaxis on d1–56 (2 cycles). Adverse events were graded according to NCI-CTCAE, v4.0. Primary endpoint: incidence of grade ≥3 diarrhea. A protocol defined interim analysis (data cut-off July 2016) was performed when ~120 pts had completed ≥2 cycles of neratinib + loperamide prophylaxis. A preliminary analysis of the loperamide + budesonide cohort was also performed at this time. Clinicaltrials.gov: NCT02400476.

**Results:** For the interim analysis, 133 pts received neratinib + loperamide prophylaxis. A further 16 (of 40 planned) pts received neratinib + loperamide prophylaxis (2 cycles) + budesonide (1 cycle). Key results are shown in the table. Incidence of grade ≥3 diarrhea was 27.1% with loperamide prophylaxis and 12.5% with loperamide + budesonide prophylaxis vs 39.9% without protocol-mandated loperamide prophylaxis (ExteNET). Grade 2 diarrhea also decreased (20.3%, 18.8% vs 32.5%, respectively). Grade 3 diarrhea events were uncommon after cycle 1 in all CONTROL cohorts.

<sup>1</sup> Amd 3: Amd 3 not collected on data cut-off.
<sup>2</sup> Protocol amends: no changes in loperamide regimen made.
<sup>3</sup> Amd 3: 2 cycles at protocol-mandated loperamide dose (20 mg od) + 3 cycles at 10 mg od.
<sup>4</sup> ExteNET: ExteNET loperamide prophylaxis prn (protocol-mandated loperamide as needed).
<sup>5</sup> Grade ≥3 diarrhea: all grades 3–5 diarrhea.
<sup>6</sup> Time on study (neratinib), mo: Incidence of grade ≥3 diarrhea is shown across all neratinib cycles.
1. Oral loperamide 4 mg with first neratinib dose, then 2 mg q4h d1–3, then 2 mg q6–8h d4–56.
2. Oral loperamide 4 mg with first neratinib dose, then 4 mg tid d1–14, then 4 mg bid d15–56.
5. Primary endpoint (CONTROL).
6. Cohorts are ongoing.

**Conclusions:** A structured loperamide prophylactic regimen for 2 cycles is associated with a lower incidence and severity of neratinib associated diarrhea, with notably less grade 2/3 diarrhea compared to ExteNET events. There appears to be some adaptation to the effects of neratinib, as higher-grade diarrhea occurs early and does not typically recur. Preliminary data suggest that adding budesonide may further improve outcomes; enrollment into the budesonide cohort continues.
Efficacy and safety of darbepoetin alfa or epoetin beta in 2994 high risk early breast cancer patients participating in the German adjuvant intergroup node-positive study (GAIN)

Body: Background

Reduced quality of life during chemotherapy is often due to fatigue and dyspnea caused by chemotherapy-induced anemia. In breast cancer patients the incidence is estimated to be above 50% and rising during the course of treatment resulting as well in therapy delays. Despite red blood cell transfusion the administration of erythrocyte stimulating factors (ESF) serves as a treatment option. In comparison with conventional chemotherapy intense dose dense regimens have proven to be beneficial in high-risk breast cancer patients, but higher incidences of anemia have been reported. In the GAIN trial two dose dense regimens were evaluated and patients received either Darbepoetin alfa or Epoetin beta. The aim of this subanalysis was to analyse the efficacy and safety of the application of two different ESF during adjuvant chemotherapy for primary node positive breast cancer.

Methods

Patients were randomly assigned to receive three courses each of epirubicin (E), paclitaxel (T), cyclophosphamide (C) all given at 2-week intervals i.v. (idd ETC-regimen) or ddEC followed by paclitaxel weekly (Tw) plus capecitabine (X)(EC-TX-regimen). All patients received either primary prophylaxis with Epoetin beta (Epo) (450IE/kg weekly) or Darbepoetin alfa (D) (4.5µg/kg biweekly). Allocation happened alternately by date of randomization. Patient outcome (rate of anemia and thromboembolic events, disease free survival (DFS), overall survival (OS)), overall and by regimen were compared according to ESF type applied and in subgroups defined by age.

Results

2994 patients were randomized to receive one of the dose dense chemotherapies and of these 1482 patients were given Darbepoetin alfa and 1512 received Epoetin beta. In the trial 84.7% of patients suffered from anemia in the Darbepoetin as well as in the Epoetin group and grade 3/4 anemia was observed in 3.6% vs 3.1% of patients, respectively. In the ETC arm anemia rates, especially grade 3/4 were slightly higher, but there was no significant difference within the treatment arms according to ESF applied (anemia any grade: D 86.1% vs. Epo 87.2%; EC-TX: D 83.2% vs. Epo 82.3%). In the ETC arm anemia was most frequently observed in patients aged 60+ years, but there was no significant difference between the ESF (D 90.5% vs. Epo 89.8%). No significant differences in the incidence of anemia by ESF treatment were observed in various age groups of the EC-TX arm. Thromboembolic events occurred in 9.1% in the Darbepoetin group and in 10.1% of patients treated with Epoetin (p=0.355). Interestingly there were more thromboembolic events in the EC-TX arm compared to the ETC arm (p<0.001), but irrespective of the ESF type (EPC: D 7.0% vs. Epo 7.7%; EC-PX: D 11.3% vs. Epo 12.5%).

OS and DFS analyses showed no difference between ESF treatment overall as well as stratified by chemotherapy regimen.

Conclusion

High risk breast cancer patients treated with two different dose dense chemotherapy schedules have comparable incidences of anemia, thromboembolic events and a similar long term outcome if they receive a preventive treatment with either Darbepoetin alfa or Epoetin beta.

The trial is financially supported by Amgen and Roche.
Title: Safety, immunogenicity and efficacy of proposed biosimilar pegfilgrastim (LA-EP2006) compared with reference pegfilgrastim in breast cancer: Pooled analysis of two randomized, double-blind, phase III trials

Blackwell K, Gascon P, Jones CM, Nixon A, Nakov R, Mo M, Krendyukov A and Nadia H. Duke Cancer Institute, Durham, NC; Fundacio Clinic, Barcelona, Spain; The Jones Clinic, Memphis, TN; Fowler Family Center for Cancer Care, Jonesboro, AR; Sandoz Inc/ Hexal AG, Holzkirchen, Germany; Sandoz Inc, Holzkirchen, Germany and Brustzentrum der Universität München (LMU), Munich, Germany.

Body: Background: Biosimilars are highly similar to a biological reference product with no clinically meaningful differences in terms of efficacy and safety. Here we present the pooled analysis of two randomized trials (PROTECT1 and 2) comparing the efficacy, safety and immunogenicity of proposed biosimilar pegfilgrastim (LA-EP2006) with reference pegfilgrastim (Neulasta®*).

Methods: Two multinational, independent, prospective, double-blind, phase III studies (EudraCT: 2011-004532-58; 2012-002039-28) enrolled adult chemotherapy-naïve women with breast cancer scheduled to receive ≤6 cycles of (neo)-adjuvant chemotherapy with docetaxel 75 mg/m², doxorubicin 50 mg/m² and cyclophosphamide 500 mg/m² (TAC). Patients were randomized to receive a single 6 mg injection of LA-EP2006 or reference on Day 2 of each cycle. Primary endpoint was duration of severe neutropenia (DSN) (number of consecutive days with ANC <0.5x10⁹/L) in Cycle 1. Equivalence was confirmed if the 95% confidence intervals (CI) for the difference in mean DSN between groups were within a pre-defined margin of ±1 day. Secondary efficacy endpoints included incidences of febrile neutropenia (FN), fever and infections, and depth of ANC nadir and time to ANC recovery (≥2x10⁹/L after the nadir) in Cycle 1. Safety was assessed at each visit with follow-up visits at 4 weeks and 6 months (PROTECT1 only) after last administration of pegfilgrastim. Immunogenicity was assessed before the first pegfilgrastim injection, on Day 15 of cycle 6, and 4 weeks and 6 months (PROTECT1 only).

Results: A total of 624 patients were randomized (LA-EP2006: n=314; reference: n=310). Baseline demographics were well balanced (mean age: LA-EP2006: 49.3 years, reference: 49.8; median duration (months) since initial diagnosis: LA-EP2006: 1.33 [0.1–76.0], reference: 1.35 [0.2–11.2]; ECOG status 0: LA-EP2006: 78%, reference: 75%). Mean DSN difference in Cycle 1 was -0.04 days (95% CI: -0.19, 0.11), showing statistical equivalence. FN was reported in 5.7% of patients with LA-EP2006 vs. 8.4% with reference in Cycle 1 (all cycles: 8.0% vs. 10.3%). Across all cycles, frequency of fever (LA-EP2006: 18.5%; reference: 19.7%) and infections (LA-EP2006: 15.6%; reference: 18.1%) were similar in both groups. Mean ANC time courses were almost superimposable in the two groups, with similar time and depth of ANC nadir and median time to ANC recovery was 2 days in both groups in Cycle 1. Treatment-emergent adverse events (TEAEs) were similar across groups (LA-EP2006: 92%; reference: 89%), and TEAEs with a suspected relationship to pegfilgrastim were reported in 22.6% of patients with LA-EP2006 and 21.3% with reference across all cycles, with the most frequent being musculoskeletal and connective tissue disorders (LA-EP2006: 10.2%; reference: 9.7%). Serious TEAEs were reported in 14.3% (LA-EP2006) vs. 17.1% (reference) across all cycles. No neutralizing or clinically relevant anti-pegfilgrastim antibodies were identified.

Title: HER2 positive breast cancer and subclinical cardiotoxicity by echocardiogram 2D Strain, Do chemotherapy sequence matter?

Pérez-Montessoro V, Poblano-Aguilar I, Galindo-Uribe J, Vásquez-Ortiz Z and Armengol-Alonso A. Instituto Nacional de Ciencias Médicas y Nutrición Dr Salvador Zubiran, Mexico City, Mexico and Instituto Nacional de Ciencias Medicas y Nutricion Dr Salvador Zubiran, Mexico City, Mexico.

Body: Background: Even when there are free schemes of anthracyclines, the biological subtype HER2+ can be exposed to cardiotoxic drugs anthracyclines (A) and/or trastuzumab(H). It has been demonstrated that the LVEF is not sensitive to detect early cardiac changes and could be within normal ranges but with irreversible cardiac dysfunction. 2D speckle tracking and cardiac biomarkers (TnI and NT-proBNP) have shown more sensitivity to define early myocardial damage. Adjuvant trial FinHER suggests lower cardiotoxicity (0.5%) when taxanes (T)+H are given before A. Our objectives were: 1)To show higher sensitivity of the longitudinal strain in the echo to detect cardiotoxicity compared to the LVEF 2)To describe if there are any differences in the cardiotoxicity in relation with the chemotherapy sequence used.

Patients and methods: A retrospective cohort of patients diagnosed with breast cancer from February 2008 to January 2016 was obtained, in which 46 patients with HER2 positive breast cancer were included, most in the context of neoadjuvant or adjuvant chemotherapy treated with sequential chemotherapy (A→T+H vs T+H→A), with a cumulative dose of 240 mg/m² of doxorubicin. A basal echo was done, as well at 3, 6, 9, 12 months after the beginning of the chemotherapy to determine LVEF and early cardiac damage parameters, such as longitudinal strain. Cardiotoxicity was determined with a symptomatic HF with a decline of LVEF >5% or LVEF ≤55% or asymptomatic HF with a decline ≥10% or in LVEF or LVEF ≤55%. A fall ≥15% was considered a significant decline of the longitudinal strain.

Results: 1 patient (2.1%) presented symptomatic HF (NYHA III). Asymptomatic cardiotoxicity was present in 9 patients (19.6%), 9 (19.6%), 11 (23.9%), and 13 (28.3%) at the 3, 6, 9, and 12 months respectively. The mean LVEF were (66±6.6), (63±9.0), (65±7.0), (65±6.4), and (63±6.9) at the basal, 3, 6, 9, and 12 months measurements respectively, with a non-significant “p” value. Significant decline in the longitudinal strain was observed in 10 patients (21.7%, p=0.012), in 13 patients (28.3%, p=0.034), in 15 patients (32.6%, p=0.95), and in 18 patients (39.1%, p=0.07), at the 3, 6, 9, and 12 months measurements respectively. When comparing the cardiotoxicity group vs the non cardiotoxicity groups no significant differences were observed with other risk factors as: HTN, dyslipidemia, carbohydrate intolerance, DM, radiotherapy, weight, cumulative doses of A, systolic-diastolic BP, glc levels, HDL, TG, and BMI. In the logistic regression analysis the longitudinal strain decline (≥15%) basal vs 3 months measurement had a OR 7.63 CI 95%(1.04-55.86) and the A→T + H sequence OR 7.7 CI 95%(1.076-55.43), were kept as independent variables for cardiotoxicity.

Conclusions: As reported in literature the decline in the longitudinal strain was more sensitive than the LVEF to predict cardiotoxicity, thus this would allow to identify the highest risk individuals and to start a cardioprotective intervention. Due to the retrospective character of our study, we believe that in the neoadjuvant or adjuvant chemotherapy setting of sequential chemotherapy there is the need of prospective studies that evaluate the subclinical cardiotoxicity with more sensitive parameters to confirm our data.
Title: Duration of fasting before taking lapatinib is associated with skin toxicity in neoadjuvant treatment of HER2 positive breast cancer: A cohort study from JBCRG-16/Neo-LaTH

Tsuda M, Ishiguro H, Toriguchi N, Masuda N, Bando H, Ohgami M, Homma M, Morita S, Yamamoto N, Kuroi K, Takano T, Shimizu S and Toi M. Graduate School of Medicine, Kyoto University, 54 Kawaharacho, Syogoin, Sakyo-ku, Kyoto, Japan; NHO Osaka National Hospital, Osaka, Japan; University of Tsukuba, Tsukuba, Ibaraki, Japan; Chiba Cancer Center, Chiba, Japan; Tokyo Metropolitan Cancer and Infectious Diseases Center Komagome Hospital, Bunkyo, Tokyo, Japan; Toranomon Hospital, Minato, Tokyo, Japan and Kanagawa Cancer Center, Yokohama, Kanagawa, Japan.

Body: Background: In neoadjuvant dual HER2 blockade, over 30% of patients fail to complete treatment as planned because of lapatinib-induced diarrhea, rash, and hepatotoxicity. Lapatinib bioavailability, which affects both efficacy and toxicity, is influenced by prandial conditions.

Methods: To investigate the association between lapatinib dosage timing and toxicity, we reviewed the medical records of patients who were enrolled in the JBCRG-16/Neo-LaTH randomized phase II multicenter trial evaluating the efficacy and safety of neoadjuvant 1000 mg/day lapatinib (La) and trastuzumab (T) therapy for 6 or 12 weeks followed by 750 mg/day La, T and weekly paclitaxel for 12 weeks in Japanese patients with primary HER2 positive breast cancer. Lapatinib dosage timing was divided into three groups: after overnight fasting, between meals, and at bedtime. We also measured serum lapatinib concentrations at steady state and dosage timing on the day prior to pharmacokinetic blood sampling. The primary endpoint was to investigate the association between lapatinib dosage timing and frequency of ≥grade 2 diarrhea. The secondary endpoint was to assess the association between dosage timing and other toxicities, pharmacokinetics, efficacy, and treatment discontinuation. Statistical analyses performed included one-way ANOVA, Welch's test and logistic regression.

Results: Out of 213 patients enrolled in JBCRG-16/Neo LaTH, we obtained dosage timing data from 143 (67%) patients: 16 (11%) after overnight fasting, 53 (37%) between meals, and 74 (52%) at bedtime. Serum lapatinib concentrations were obtained in 34/143 (24%) of patients. Dosage timing was not associated with ≥grade 2 diarrhea (8/16 (50%) after overnight fasting, 18/53 (34%) between meals, and 26/74 (35%) at bedtime; p = 0.48). However, multivariate analysis revealed that the after overnight fasting group is less likely to develop acne-like rash during La + T treatment regardless of age, BMI, or treatment.

BMI cut off is based on Asian criteria for overweight status. La: Lapatinib, T: Trastuzumab, *statistically significant

In addition, serum lapatinib trough concentration and its variability were significantly reduced in the after overnight fasting group (mean ± standard deviation (SD) = 0.35 ± 0.15 µg/ml, coefficient of variation (CV) = 42.7%) as compared to the others (mean ± SD = 0.77 ± 0.44 µg/ml, CV = 57.8%) (p<0.01). The chance of pCR was not associated with dosage timing (8/16 (50%) after overnight fasting, 24/53, (45%) between meals, and 38/74 (51%) at bedtime; p = 0.79).
Conclusions: These data suggest that overnight fasting stabilizes the bioavailability of lapatinib, which may aid in managing lapatinib-induced rash without diminishing its therapeutic efficacy.

**Body: Background**

Stomatitis is the most frequent adverse event reported in trials of mTOR-inhibitors, including EVE. In the pivotal phase 3 BOLERO-2 study, stomatitis incidence in the EVE + exemestane (EXE) arm was 59%. The BOLERO-4 study (NCT01698918) evaluated the efficacy and safety of first-line EVE + LET in postmenopausal pts with HR+, HER2− metastatic or locally advanced breast cancer (ABC). BOLERO-4 also assessed the effectiveness of an alcohol-free dexamethasone (0.5 mg/ 5ml; DEX) oral rinse for treating stomatitis in a subset of pts (USA).

**Methods**

Postmenopausal pts with HR+, HER2− ABC previously untreated for advanced disease received EVE (10 mg/day) + LET (2.5 mg/day). At disease progression, pts were offered EVE (10 mg/day) + EXE (25 mg/day). Pts who had at least one episode of stomatitis received oral stomatitis daily questionnaire (OSDQ), which is a 6 question pt-reported outcome (PRO) survey (Stiff et al, JCO. 2006). A subset of these pts (USA) was randomized (1:1) to receive DEX or standard of care (SOC). The primary objective of investigator-assessed progression-free survival in the first-line setting for ABC was presented previously. A secondary objective was to evaluate the effectiveness of the DEX oral rinse in reducing the severity and duration of stomatitis, using OSDQ data.

**Results**

Of the total 202 pts enrolled in this study, 52 pts were enrolled in USA, of which, 24 (46.2%) were randomized to receive DEX (n=11) or SOC (n=13), upon confirmation of stomatitis. The median duration of first stomatitis episode was longer per OSDQ (DEX, not estimable vs SOC, 13.7 wk) compared with physician-reported duration (DEX, 1.6 wk vs SOC, 1.9 wk). PRO OSDQ results were similar in both arms.

Among the 202 pts enrolled, 89 (44.1%) filled the OSDQ at their first stomatitis episode. The median time from treatment initiation to first stomatitis episode was 1.7 wk; median duration of stomatitis was 13.7 wk (OSDQ) vs 2.1 wk (physician reported). The majority of pts experiencing stomatitis had moderate/little/no soreness, moderate/low/no pain, and stomatitis had low/no effect on daily activities (Table 1).

Conclusions

Overall, patient-reported median duration of stomatitis was longer than that reported by physicians, most likely due to differences in perceptions and the challenges in collecting and cleaning PRO data. Overall good health score was maintained in the majority of pts experiencing stomatitis and stomatitis had low/no effect on daily activities. However, these results, especially in the randomized subset need to be interpreted with caution owing to the small sample size, missing data and lack of commercially available DEX in most countries.
Introduction: Currently, the global rate of breast conserving therapy (BCT) increased steadily. Most patients with BCT are treated with chemotherapy. However, most chemotherapeutical drugs that kill cancer cells also cause undesirable injuries to normal breast tissues. Normal breast tissue damage will further cause destruction of female secondary sex characteristics, and ultimately affect the quality of patients’ lives. Therefore, it is urgent to protect the normal breast tissues for BCT patients during chemotherapy. More and more evidence shows that chemotherapy-induced normal tissue damage is mainly caused by the activation of p53 pathway, which is separate from the tumor suppressor pathway of p53. Previous studies found that use of low-dose arsenic (LDA) could temporarily and reversibly suppresses p53 activation. There are recent studies showing LDA selectively protect bone marrow and gastrointestinal tract during cancer treatment. Therefore, we hypothesize that use of LDA to temporary inhibit p53 activity will be a new strategy to protect the breast normal tissues for breast conserving patients.

Methods: Human breast epithelial cell line, MCF-10A, and three breast cancer cell lines MCF-7 (estrogen receptor and E6 expressed), MDA-MB-231 (triple negative and p53 mutated) and BT-474 (HER2 overexpressed and p53 mutated), were tested in this study. All cells were pretreated with either PBS or 100nM sodium arsenite for 12 hours, followed by 375 µM 5-fluorouracil (5-FU) or DMSO for 24, 48 and 72 hours. Cellular viability was determined by MTT assay and cell morphology was recorded under a light microscope.

Results: Morphology changes after 5-FU treatment include: the cell density decreased, the cells became rounded in shape, the cell membrane atrophied, the cell nuclei underwent pyknosis, and the cells formed a globule with nuclear and cytoplasmic fragments surrounded by the cell membrane. LDA pretreated-MCF10A cells showed significant reduced growth inhibition by 5-FU at all detected time pointes as demonstrated by MTT assay and morphology observation. Interestingly, LDA treatment had negligible effect on survival in breast cancer cells.

Conclusion: Temporary LDA pretreatment selectively protected normal tissue cells, but not tumor cells from toxicity of 5-FU chemotherapy. Our findings indicated that LDA pretreatment is a potential strategy to protect normal breast tissue during chemotherapy for BCT patients.

Title: Effect of supplementation with eicosapentaenoic and docosahexaenoic omega-3 polyunsaturated fatty acid on the chemotoxicity in Mexican patients with locally advanced breast cancer (LABC) treated with neoadjuvant chemotherapy (NeoCT)

Body: The aim of this study was to determine the benefits of supplementation with eicosapentaenoic (EPA) and docosahexaenoic (DHA) polyunsaturated fatty acids (PUFA) in terms of chemotoxicity and inflammatory status, to Mexican women with locally advanced breast cancer (LABC), receiving a standard neoadjuvant chemotherapy (NeoCT AC-taxol regimen). We performed a randomized double-blind, placebo-controlled, clinical trial, in which we studied 44 LABC patients (stages IIA to IIIA) who took 2.4g/d (1.6 g EPA and 0.8 g DHA, ratio 2:1) (N=22) or placebo (N=22) during NeoCT with doxorubicin/cyclophosphamide followed paclitaxel weekly. Edmonton Scale and Common Terminology Criteria for Adverse Events (CTCAE) v4. assessment were performed before each CT, and also blood total leukocytes, and percentage lymphocytes and monocytes by standard lab methods. Serum inflammatory proteins and adipokines, were quantified by multiplexed analysis using a luminometer (MAGPIX) at basal time (0) and after cessation (+6 months) of AC and paclitaxel regimen.

RESULTS: There were no differences in age between the supplemented and the placebo groups (51.6y vs. 49.1y, p=0.4), neither in body mass index (BMI, 28.7 kg/m² and 28.9 kg/m², p=0.8). After 6 months of supplementation, patients who were supplemented with PUFAs had significant changes (time 0 vs 6, respectively) in total leukocytes (from 6.3 to 5.1 x10³/mL, p =0.002) lymphocytes (from 33.5 to 25.2%, p =0.002), leptin (from 60.2 to 36.1 pg/mL, p=0.04) and adiponectin (from 36.8 to 43.3 mg/mL, p=0.05 ). On the other hand, placebo group had significant changes in the number of leukocytes (from 6.8 to 10.0 x10³/mL, p =0.04), monocytes (from 6.7 to 10.1%, p=0.03) and an increase in leptin (from 22.7 to 46.3 pg/mL, p=0.04).

CONCLUSIONS: Supplementation with 2.4g/d of EPA and DHA (ratio 2:1) during 6 months in Mexican LABC patients receiving NeoCT resulted in a less inflammatory status when compared to patients who received none. Our results clearly suggest that this type of supplementation may be beneficial to these type of patients. Currently, we are analyzing if treatment with omega-3 PUFAs are associated with lower incidence of side effects due to chemotherapy.
Comprehensive genomic profiling of 34 cases of breast angiosarcoma

Ravi V, Madison R, Schrock AB B, Cote G, Millis S, Alvarez R, Choy E, Katz D, Chung J, Gay L, Miller VA A, Ross JS S, Stephens PJ J, Ali SM M and Schnitt S. Foundation Medicine, Inc; Massachusetts General Hospital; Dana Farber Cancer Institute; Southeastern Regional Medical Center; Beth Israel Deaconness Medical Center and Hadassah-Hebrew University Medical Center.

Background: Angiosarcoma of the breast (BAS) is a rare but lethal neoplasia, either arising de novo or secondary to radiation therapy, with incidence of the latter disease increasing. We queried a database of more than 70,000 advanced cancer patients assayed with comprehensive genomic profiling (CGP) in the course of clinical care to uncover the frequency, type and associated genomic alterations (GA) in BAS and to highlight possible routes to benefit from targeted therapy.

Methods: CGP was performed for 34 BAS cases using a hybrid-capture, adaptor ligation based next generation sequencing assay of up to 315 genes to a mean coverage depth of >500X. The results were analyzed for base substitutions, short insertions and deletions, selected rearrangements, and copy number changes. RNA sequencing for 265 genes was also performed for 24 cases. Limited clinical histories from submitted pathology reports were reviewed under IRB permission.

Results: Clinical specimens from 34 BAS patients, all females, were assayed. The cases harbored 87 total GA for a mean of 2.59 per case, 25% of which were copy number amplifications. The most commonly altered genes were MYC (41%, 14/34), PIK3CA (26%, 9/34), and KDR (26%, 9/34). All MYC alterations were amplifications with a mean copy number of 39, and alterations in other MYC family members (MYCN and MYCL1) were not observed. KDR was recurrently altered as T771R (7/9) and T771K (1/9) and amplified in one case (1/9).

MYC and KDR alterations were mutually exclusive (p<0.0001). 6/14 MYC amplified cases had prior histories of breast carcinoma, with 3/6 noted as being treated with radiation therapy. For the remainder of MYC amplified cases (8/14), no relevant clinical history was available.

Two cases harboring gene fusions were identified including CIC-MEGF8 and NTRK1-PEAR1. Two rearrangements of potential functional significance including CIC-DED2 and HT-ALK (exon1 HT - exon5-29 ALK including kinase domain) were also observed. The case harboring HT-ALK also had MYC amplification and known prior radiation therapy. Two other MYC amplified cases also harbored targetable kinase alterations, including FLT4 amplification (described as targetable in Ravi et al JNCCN 2016) and FGFR3 S249C, a known activating mutation.

Conclusions: MYC amplification defines over 40% (14/34) of advanced BAS cases. Of MYC amplified cases, 28% (4/14) harbored targetable alterations of tyrosine kinases including a potential novel ALK fusion. FLT4 amplification only co-occurred with MYC amplification, but this result was not statistically significant in this small series. KDR and MYC alteration were mutually exclusive, and 45% of non-MYC altered cases (9/20) harbored KDR alterations, which were predominantly mutations of T771. Further clino-pathologic correlation, particularly history of radiation therapy, will be explored in this series, as well defining BAS that harbor neither MYC nor KDR alterations.
Title: Cochrane review of capecitabine for hormone receptor positive versus hormone receptor negative breast cancer

Redfern A, Lau P, White A, Hoon S, Bulsara M and Long A. University of Western Australia, Perth, Western Australia, Australia; Peter MacCallum Cancer Institute, Melbourne, Victoria, Australia; Saint John of God Hospital - Subiaco, Perth, Western Australia, Australia; Westmead Hospital, Sydney, New South Wales, Australia; University of Notre Dame, Fremantle, Western Australia, Australia and Hollywood Hospital, Perth, Western Australia, Australia.

Body: Capecitabine is an oral fluoropyrimidine prodrug which may have differential efficacy in hormone receptor (HR) positive and HR negative breast cancer. We conducted a systematic review of randomised control trials (RCT) comparing chemotherapy regimens with or without capecitabine in HR positive and HR negative breast cancer.

Methods

This review was conducted by standard Cochrane review procedures. Our protocol has been published previously. We conducted a comprehensive literature search including MEDLINE, EMBASE, CENTRAL databases, clinical trial registries and major oncology conferences for capecitabine RCTs. 1913 references were identified with 209 suitable for detailed review. 62 RCTs (40 metastatic, 13 adjuvant, 9 neoadjuvant) comparing chemotherapy regimens with or without capecitabine were identified. 21 studies (10 metastatic, 7 adjuvant, 4 neoadjuvant) reporting outcome data by HR status proceeded to full data extraction. 2 studies reported comprehensive outcome data by HR status, the remainder reporting by hazard or odds ratios only.

Results

In metastatic trials, capecitabine significantly improved outcomes for HR positive but not HR negative disease for chemotherapy alone (SO14999 trial – odds ratio (OR) for OS 0.65 (95% CI 0.47-0.89) v 0.90 (0.65-1.24) and possibly with additional trastuzumab (CHAT trial – OR for PFS 0.61 v 0.87 (significance not reported)). Significant benefit was seen for adding capecitabine to bevacizumab after taxane completion only in HR positive disease (IMELDA trial – OR for PFS 0.33 (0.22-0.50) v 0.70 (0.39-1.25)). In contrast, adding capecitabine to a taxane with bevacizumab showed the reverse with only HR negative patients benefiting (TABEA trial – OR for PFS 1.49 (0.99-2.24) v 0.51 (0.269-0.959)).

Adjuvant trials investigating the addition of capecitabine to anthracycline-taxane containing regimens or as monotherapy in elderly patients. Preliminary analysis indicates HR negative cancers benefit from the addition of capecitabine compared to non-capecitabine containing regimens. No observed benefit in HR positive disease with the addition of capecitabine was been demonstrated.

Odds ratio for outcomes by the addition of capecitabine to adjuvant chemotherapy

Neoadjuvant trials investigating the utility of capecitabine to anthracycline-taxane containing regimens showed no additional
benefit with respect to pCR. Meta-analysis of response rates for all patients and differentiated by HR status showed no significant difference on inclusion of capecitabine.

Conclusion
In summary, metastatic and neoadjuvant trials did not show clear differential benefit of capecitabine in HR positive versus HR negative breast cancer. HR positive tumours in the metastatic setting might be more responsive to capecitabine. Additional benefit to an anthracycline-taxane containing regimens with capecitabine in the adjuvant setting was confined to HR negative cancers. Final results of our analysis will be presented.
Title: Prospective study of acupuncture in the rehabilitation of women undergoing surgical treatment of breast cancer in relation to the strength and quality of life

Giron PS Santolia, Haddad CA Assad, Rizzi SL Lopes, Pinheiro TL Lucia, Luz RP Pitta, Nazário AP Pinto and Facina G. UNIFESP, São Paulo, Brazil.

Body: Objective: To investigate the benefits of acupuncture in relation to the shoulder muscle strength and quality of life in women undergoing surgical treatment for breast cancer.

Methods: Women with breast cancer, aged 18 years or more, with pain level ≥ 3 in the Visual Analog Scale in shoulder girdle or upper limb three months after surgery, were included in this prospective study. The patients were randomly divided into two groups and received weekly treatment for 10 sessions. Kinesiotherapy group (G1): treated with pre-defined standard kinesiotherapy, lasting 30 minutes. Group Acupuncture + Kinesiotherapy (G2): treated with the same Kinesiotherapy group protocol followed by another 30 minutes of acupuncture using pre-defined points. Acupuncture points used were as follows: CV 3, SP 9, ST 36, KD 7, LV 3, GB 21, LI 15, SJ 14, LU 5, LI 4, ST 38 and BL 60. Patients were evaluated at baseline, after five weeks and at the end of 10 weeks. Parameters studied were: clinical profile and socio-demographic data, muscle strength and quality of life.

Results: 48 patients completed treatment, 24 in each group. Regarding shoulder muscle strength, all movements showed improvement and there was no statistical difference between groups. However, when analyzing intragroup changes, improvement of flexion and internal rotation were observed in G1 and increase of all movements were found in G2. Concerning EORTC, there was statistically significant difference between groups of pain symptom in the 5th session, with better score in patients of G2 in relation to G1. About EORTC intragroups results, G1 showed improvement in physical function, pain and insomnia; and G2 in performance roles, fatigue and pain.

Conclusion: According to this prospective study, kinesiotherapy and acupuncture had a positive effect on the shoulder muscle strength and quality of life of patients.

Keywords: 1. Breast cancer. 2. Rehabilitation. 3. Acupuncture. 4. Muscle Strength. 5. Quality of life.
Impact of institution of young women’s breast cancer clinic on time to treatment and utilization of fertility, genetics and social work consultations in women under age 50 with new diagnosis of early stage breast cancer

Kruse ML L, Raska P, Abraham J, Budd GT, Montero A, Grobmyer S and Moore H. Cleveland Clinic, Cleveland, OH.

Background: Genetic counseling and fertility resources are often underutilized in young women with early stage breast cancer (ESBC) due, in part, to concerns about treatment delays. At our institution, women newly diagnosed with ESBC typically see a breast surgeon, medical oncologist and radiation oncologist in a multidisciplinary clinic with additional cancer related subspecialist referrals occurring at those providers’ discretion. We hypothesized that time to treatment (TTT) and utilization of fertility, genetics and social work consultations would improve after implementing a Young Women’s Breast Cancer Clinic. As of January 1, 2015, all patients under age 50 seen at Cleveland Clinic for new diagnosis of ESBC were automatically offered scheduling of appointments with medical genetics, reproductive endocrinology and social work in addition to the usual multidisciplinary team.

Methods: Women under age 50 diagnosed with ESBC seen at Cleveland Clinic from 1/2014-12/2015 were identified using our tumor registry. Demographics, tumor pathology, clinical and treatment histories were obtained through medical chart review as per IRB approved protocol. Time from initial visit in our system to date of treatment initiation was calculated for all patients and compared between the 2014 (pre-intervention) and 2015 (post-intervention) cohorts as was time from diagnosis (biopsy date) to treatment initiation. Completed reproductive endocrinology, genetic counseling and social work consultations were documented. Welch two sample t-test was used to compare time to treatment between groups. Chi squared test was used to compare frequency of subspecialty consultations between groups.

Results: 207 young women with ESBC were identified over the 2 year period, 99 in 2014 and 108 in 2015. Median age was 45 in 2014 and 44 in 2015. Most were diagnosed outside of our hospital system, 58% in 2014 and 76% in 2015. The most common initial treatment was surgery with reconstruction (S+R) (54% and 50% for 2014 and 2015 respectively) followed by chemotherapy (23% and 27%) then surgery without reconstruction (S) (20% and 24%). Median TTT from first encounter was 30 days in 2014 and 28 days in 2015 (p=0.33) and was 36 days versus 33.5 days (p=0.23) when calculated from biopsy date. TTT in the S and S+R groups was 37 vs 28 days (p=0.84) and 36.5 vs 32 days, (p=0.21), respectively. Genetics, reproductive endocrinology and social work consults in 2014 vs 2015 were documented as 89% vs 94%, 4% vs 9% and 58 vs% 55% (p=0.22, 0.32, 0.77). For patients under age 40, 27% in 2014 and 30% in 2015 completed reproductive endocrinology consultations.

Conclusions: Offering upfront scheduling of breast cancer related subspecialty appointments for young women with newly diagnosed ESBC did not significantly improve overall TTT. There was a trend towards improved TTT in those receiving surgery with or without reconstruction as first treatment and no suggestion of delay in TTT. A modest numeric increase in completed genetic counseling and reproductive endocrinology consultations was not statistically significant, but may have been clinically meaningful for affected individuals.
Title: Predictive value of serum anti-Mullerian hormone (AMH) in the outcome of emergency fertility preservation treatments indicated by breast cancer

Rodriguez-Wallberg KA A and Wikander I. Karolinska Institutet, Stockholm, Sweden and Section of Reproductive Medicine, Karolinska University Hospital, Stockholm, Sweden.

Body: Purpose:
Fertility preservation procedures aim at offering young cancer patients an opportunity to build their future families and have biologically-related children. Optimization of fertility preservation options is needed to maximize the chances to success, as the procedures are usually performed as an emergency and they cannot be repeated in most of the patients. We aimed at investigate the predictive value of serum concentrations of Anti-Mullerian Hormone (AMH) in the outcome of emergency controlled hormonal stimulation (COS) treatments aimed at fertility preservation in women with breast cancer.

Patients and methods:
Prospective cohort study. Patients with breast cancer of reproductive age were included in the study at time of counseling for emergency fertility preservation indicated by planned chemotherapy between January 2012 and May 2016. All fertility preservation treatments were performed at the Reproductive Medicine Clinic of Karolinska University Hospital. The study cohort included 124 women with breast cancer that underwent COS cycles using an antagonist protocol either with or without letrozole supplementation, depending on their tumor estrogen receptor status. Blood draws for estimation of serum AMH concentrations were sampled previously to breast cancer treatment initiation and immediately before performance of fertility preservation.

Main Outcome measures:
The main outcome was the association of baseline serum AMH concentration, crude and age-adjusted, with the number of obtained and cryopreserved oocytes or embryos during the subsequent fertility preservation treatment.

Results
Our preliminary analyses indicate that AMH levels estimated previously to a fertility preservation treatment in women with breast cancer might be a reliable predictor of the outcome of fertility preservation in some age subgroups. The association of AMH levels with fertility preservation outcomes did lack significance in the women that were youngest at time of breast cancer diagnosis, indicating that novel biomarkers are needed in this particular patient group to optimize their fertility preservation treatments. Additionally, women that were on oral contraceptives previously to their breast cancer diagnosis presented with unusually low AMH levels for their age, which also did not correspond to their response to fertility preservation. A logistic regression analysis of the outcome including the chosen variables will follow.

Conclusion
The predictive value of AMH concentration before COS in emergency fertility preservation for women with breast cancer is still debatable. Measurements of AMH concentrations to evaluate ovarian reserve previously to fertility preservation might not correlate with the outcome in all patients with breast cancer and novel biomarkers should be investigated.
Title: Differential protein expression in primary breast cancer tumors spreading to liver or elsewhere

Goldberg H, Fell R and Apel-Sarid L. The Galilee Medical Center, Nahariya, Israel.

Body: Breast cancer (BC) outcome is determined mainly by its ability to spread to distant sites, since this is the lethal phase of the disease. Metastasizing cells have to acquire various molecular aberrations in order to go through the metastatic cascade and gain organ tropism. These are probably reflected at the primary tumor. This study was aimed to identify a set of abnormally expressed proteins in primary human BC tumors, which spread preferentially to the liver or elsewhere. Methods: We collected archival paraffin embedded primary BC samples from 48 patients who were divided into 3 groups: 10 who developed liver metastases (A), 20 with metastases to other sites (B) and 18 with no BC recurrence (C). Tissue microarray (TMA) were constructed, sliced and subjected to immuno-histochemical staining. A pre-defined panel of 11 proteins was selected, based on published data that were available at the time of study initiation. Level of expression (coded by IRS scoring) and the intra/extracellular location of each protein was determined by an expert pathologist and compared between the three groups. The panel included: cell-cell interaction proteins (CDH1, BIGH3, MMP14, CD44s, Galectin-3), transcription factors (FRA-1, c-Jun, GATA-3, TP53), an inflammatory chemokine (CCL5), cell signaling protein (Wnt-5a). Results: Metastatic tropism to the liver was studied by comparing results between A and B. When similar, A and B were combined and compared with C group. CDH1 protein expression was significantly reduced in the cytoplasm in groups A and B in comparison to C (p=0.004)and over-expressed in the membrane (p<0.001) in both. Hence, cytoplasmic CDH1 was higher in group A than B (p=0.03). In group A only, a trend of BIGH3 over-expression was noted, though it did not reach significance. No further differences were found between A versus B. MMP14 was over-expressed both in the membrane and cytoplasm (p=0.001) of A and B, in comparison with C. CD44s was over-expressed in the membrane in A&B versus C (p<0.001). Galectin-3 was over-expressed in the cytoplasm (p=0.005) and down regulated in the nucleus (p=0.015) in both metastatic groups. CCL5 (RANTES) level was significantly reduced in the cytoplasm in A & B (p<0.001) while significantly over-expressed in the nuclei (p=0.005). c-Jun (part of AP1 complex) was over-expressed in both A and B (p=0.021). On the other hand, levels of FRA-1, localized in both cytoplasm and nucleus in C, were reduced in both compartments in A & B (p=0.029). No difference was noted between the 3 groups in level and localization of TP53, GATA-3 and Wnt-5a. Conclusions: Assessment of the expression of proteins in tumor cells should include protein localization besides its level of expression. Both CDH1 and BIGH3 seem to be over-expressed in tumors that spread preferentially to the liver. No significant changes in pattern of expression of the other proteins studied could be correlated with metastatic propensity to the liver. Compartmental translocation of various proteins is correlated with the acquisition of metastatic potential, such as CDH1 and CCL5 which presented a shift from nucleus to cytoplasm, and Galectin-3 and CCL5, where translocation from cytoplasm to membrane were observed in both metastatic groups.
Title: Risk Factors for high risk breast density patterns in Hispanic/Latinas living in the Northeast, US

Jones BA A, Claye E, Philpotts L, Hooley R, Silber A and Epstein L. Yale School of Medicine, New Haven, CT.

Body: Introduction: Breast densities are the non-fat (epithelial and stromal) breast tissue observable on screening mammograms. Known to be associated with a 4 to 6 fold increase in breast cancer risk, dense breast patterns complicate the reading of screening mammograms resulting in lowered sensitivity. Little is currently known about the prevalence and/or predictors of breast density in Hispanic/Latino women living in the Northeast, US. Objective: The goal of this prospective study is to identify risk factors for high risk breast density patterns among a large cohort of Hispanic/Latino women with ancestral ties primarily to the Eastern Caribbean (Puerto Rico and the Dominican Republic) as well as Central and South America. Because the hormonal milieu is somewhat different in Hispanic/Latinas compared with White women, and likely also differs from that of Hispanic/Latinas living in other parts of the US, we explored the role of reproductive and physiological factors in high risk breast density patterns.

Methods: We analyzed breast density predictors in an established cohort of 1,600 Hispanic/Latino women recruited from primary care clinics in 4 cities with the largest enclaves of Hispanic/Latinos in Connecticut. Hour-long telephone interviews provided baseline data on biological, medical care, and sociodemographic factors. We retrieved radiology records on 1570 (98.7%) consenting women. For this analysis, we report predictors of breast density among the 1,040 (65.4%) women who received at least one screening mammogram during 2 to 4 years of follow-up. Breast density classification was based on radiologist assigned BI-RADS classification. Associations between predictors and high risk breast density patterns were examined using chi square tests. Multivariate analyses were conducted using logistic regression; odds ratios (OR) and 95% confidence intervals (CI) are reported.

Results: Of the 1,040 women who received at least one screening mammogram during the follow-up period, 280 (27%) women were identified as having high risk dense breasts (extremely or heterogeneously dense, i.e., greater than 50% of the breast composed of fibroglandular densities), while 760 women (73%) were classified as having nondense breasts (fatty or scattered fibroglandular densities), suggesting a lower prevalence of high risk breast density patterns in this population. In multivariate analysis, breast density predictors were similar to those reported for the general population (mostly White) women, and are similar to known risk factors for breast cancer. However, we found that Hispanic/Latinas with diabetes to be at significantly reduced odds of high risk breast density patterns. There was also evidence that the relationship between age at menarche and density was modified by BMI, with early age at menarche a risk factor among normal and underweight women only.

Conclusion: Our findings suggest that Hispanic/Latino women may differ in breast density prevalence relative to the general population. However, we observed a protective effect of diabetes and a potential interaction between age at menarche and BMI. This investigation enhances our understanding of breast density in a subset of the Hispanic/Latino population and provides the basis for further research.
Body: Background: Information and social support for women at risk for and surviving breast cancer are essential components of comprehensive clinical and public health practice in breast cancer prevention, control, and treatment. Jewish women in the US are a population of special concern due to their increased hereditary breast cancer risk for carrying BRCA1/2 gene mutations, and the dearth of culturally-relevant resources for breast cancer education and counseling. As part of a CDC initiative, Sharsheret (a non-profit breast cancer support and advocacy organization) is scaling-up its programs and services for women of all Jewish backgrounds to better meet these needs, guided by program evaluation data on client engagement practices. This abstract describes these practices and survey results.

Methods: Evaluation surveys were individually-administered via e-mail using a secure online platform. Survey invitations were sent to participants ~30 days following their utilization of Sharsheret program services. Evaluation domains included program engagement and satisfaction, health-related quality of life, and resource needs.

Results: The survey response rate was >65% (N=111), and a majority of respondents reported that they were Jewish (75%), married (76%), either or 35-45 years old (35%) or 46-64 years old (48%), and from the northeast region of the US (56%). Most respondents (88%) reported a previous breast or ovarian cancer diagnosis, and 7% indicated they carried a genetic mutation known to increase breast cancer risk. Based on the CDC’s ‘Health Days’ measures, respondents reported a higher number unhealthy days (M=12 days per month) relative to general population averages for adult women (M=6.9 days). Respondents rated their experience with the organization highly (M=4.7 out of 5) for overall satisfaction with the quality of services utilized. There was also strong agreement among respondents (M=4.6 out of 5) about the availability and utility of patient navigation services, and the survivorship program garnered the highest level of engagement (71%) as it was utilized most often by respondents for its healthy living and nutrition resources.

Conclusion: Nonprofit organizations devoted to cancer support and advocacy fill important roles in educating and counseling women about breast cancer prevention, control, and treatment. In an era of precision medicine and discussion of population-based screening for hereditary breast cancer risk, these organizations must scale-up their information and support services. This is necessary to be available for a greater number of women, and can be expected to perform even more important and essential roles, especially for Jewish women at risk for and surviving breast cancer.
Title: Metastatic trial search: Advocacy groups collaborate to engage metastatic breast cancer patients in clinical trials

Cohen EJ J, Colen SL L, Dahlke DV V, Esser M, Flowers L, Guglielmino JE E, Jenkins M, Knackmuhs G, Lusen R, Mertz SA A and Esserman LJ J. UCSF, San Francisco, CA; TX A&M Health Science Center School of Public Health, College Station, TX; Young Survival Coalition, New York City, NY; Triple Step Toward the Cure, Culver City, CA; Living Beyond Breast Cancer, Bala Cynwyd, PA; Breastcancer.org, Ardmore, PA and Metastatic Breast Cancer Network, New York City, NY.

Body: Background: Less than 5% of adult cancer patients participate in trials, delaying the arrival of new therapies to the clinic. This is concerning for metastatic breast cancer patients, for whom there is no curative treatment. To facilitate metastatic patients' access to trials, BreastCancerTrials.org (BCT) partnered with five breast cancer advocacy groups to design and develop Metastatic Trial Search (MTS), a trial matching service based on BCT technology and embedded on their websites.

Approach: BCT's partners include Breastcancer.org, Living Beyond Breast Cancer, Metastatic Breast Cancer Network, Triple Step Toward the Cure, and Young Survival Coalition. MTS was seamlessly integrated on each partner's website. To find trials, users submit data about their gender, age, location, menopausal status, cancer subtype, and sites with evidence of disease and in return receive a list of matching trials in BCT's patient-friendly format. MTS launched October 1, 2015.

Results: Our evaluation included analysis of web traffic, an online user survey, two user focus groups, and partner interviews. MTS traffic between Oct. 2015 and May 2016 resulted in over 10,000 page views; peaks of activity correlated with social media posts. The user survey, conducted between Oct. 2015 and Jan. 2016, had 102 participants; 88% learned about MTS from our advocacy partners, mostly through email (52%) or social media (21%). Most participants (60%) cited learning about new breast cancer research as an important benefit of MTS. Sixty-three percent of users were looking for treatment trials, 16% contacted a research site and 12% spoke to their doctors about trials that they found on MTS. Among all respondents, 7% enrolled in a trial and 29% were still considering enrollment. Sixty percent of MTS users were satisfied with their experience, 33% were neutral, and 6% were dissatisfied; 65% would recommend MTS to a friend. To improve MTS, users ranked adding filters to narrow search results as the most pressing need. Providing a trial alert service was ranked second. Over 80% agreed with the statement: “MTS met an unmet need.” The focus groups were made up of 14 survey respondents who volunteered to participate. Discussants spoke highly about MTS' ease-of-use and its advocacy group endorsement. They also appreciated how MTS helped them learn about different ways to participate in research and provided information to share with their oncologists. According to many participants, one of the most important benefits of MTS was that it helped them "be prepared" if they needed to change treatment. Our advocacy partners were very satisfied with their involvement and all stated that "collaboration and sharing" were the most important outcomes. In addition, they viewed the consistency of seeing MTS on each of their sites as a benefit for patients looking to advocacy groups for trusted information.

Conclusion: Our experience with MTS shows that advocacy groups working together can create an important channel for engaging patients in learning about metastatic breast cancer trials. Next steps will be to expand our advocacy network, make it easier for users to narrow search results, and offer ways for patients to learn about newly opened clinical trials.

Title: OncoGambit: A revolutionary computer-assisted oncology treatment decision

Bourdeanu L, Martel C and Luu TH H. Excelsior College, Albany, NY; Ocogambit, CA and University of Southern California, Pasadena, CA.

Body: Background: Over 14 million new cases of cancer (1.5 million breast cancer) will be diagnosed worldwide in 2016. It is recommended that cancer treatment should be started as soon as possible, as worse survival has been associated more than 90 day-delay in treatment (1). In the era of digital health, cancer patients resort to accessing the internet for treatment information. However, 41.3% of these patients reported being frustrated with the time consuming effort during this process. (2). Since compliance with breast cancer treatment guidelines showed 60-80% variant among treating physicians, it is imperative for patients to seek evidence-based treatment confirmations or second opinions. (3) OncoGambit was designed by experienced oncologists to provide patients with instant information regarding their treatment options based on current, up-to-date, and evidence-based treatments recommended by national guidelines (ASCO, ASTRO, NCCN, ESMO).

Method: The software was designed to provide patients with an algorithmic personalized treatment recommendations for their individual cancer, based on the patient's tumor stage and tumor molecular bio-markers. For example, the treatment for breast cancer is based on patient's age, menopausal status, cancer stage, ER, PR, and HER2neu status. In addition, much needed information such as follow up care plan and survivor care recommendation were also included. Education regarding the patient's cancer type and how its treatment derived was provided prior to the patients’ inputting their information. The first version of the software was piloted and promoted on social media (Facebook and Twitter) between 10/2015 and 12/2016.

Results: During this testing period, 3792 users accessed the site, with 4870 observation sessions, as some patients reviewed more than one cancer type. Users were from 69 countries, with 69% of them being from the US. The most common cancers searched were breast cancer (30.4%), lung cancer (20.3%), melanoma (13.8%), prostate cancer (7.6%). In addition, the cancer genetics information was accessed by 12.7%. Of these early users, 8.5% proceeded to request the complete cancer treatment report.

Conclusion: The preliminary data from the early release testing for OncoGambit version 1.0 demonstrated the need for an instant access cancer treatment application. Treatment confirmation is becoming a high priority for cancer patients. OncoGambit is the first revolutionary computer-aided individualized cancer treatment confirmation resource designed to confirm treatment instantly, thus reducing the time and effort required to acquiring this information from multiple websites. In addition, the information provided is based on the current cancer treatment guidelines that is updated daily, as the guidelines frequently change. OncoGambit can further facilitate patient-physician partnership by engaging and involving cancer patients to participate in their treatment plans. User feedback from the testing phase is currently used to upgrade this resource to accommodate the user's understanding of this resource and ease of use.
Title: Novel visualization tools to search ongoing clinical trials and track trial results for metastatic breast cancer

Body: Metastatic breast cancer (MBC) remains a terminal illness and is the cause of virtually all breast cancer deaths. The median survival for patients with MBC in the US is approximately 3 years from time of stage IV diagnosis. People living with MBC are in urgent need of new treatment options once current therapies no longer keep the disease under control. Access to new treatments is often through clinical trials. We have developed a novel way to visualize active clinical trials and track trial results.

Methods: Clinical trials were queried from Clinicaltrials.gov and the National Cancer Institute. Trials were categorized by breast cancer subtype, line of therapy, hallmark of cancer, sponsor, phase, sample size and compound. A bubble chart was created to display data triplets (x, y, z) corresponding to three continuous variables: x and y to define the position, and z, the radius of each bubble. In our example, x and y coordinates are optimized according to an algorithm that essentially balances the bubble’s gravity (i.e., action of moving towards the center of the plot), friction (i.e., velocity decay) and charge (or repulsion/attraction force). This layout is frequently used for network visualization. In addition to x, y and z, it is possible to encode other information.

Results: We identified 204 clinical trials actively recruiting patients with MBC. The current webpage (www.mbcalliance.org) displays clinical trial data from 204 clinical trials in six different ways. Trials actively recruiting patients will be updated quarterly. In addition to data triplets (x, y and z) we encoded other information about trials using a color code to add three additional dimensions: phase, breast cancer subtype and sponsor type. When a user hovers over a bubble, key information about the clinical trial extracted from Clinicaltrials.gov is displayed. When a user clicks on the bubble, the user is directed to the corresponding landing page at BreastCancerTrials.org to access detailed trial information. We are employing a similar coding scheme and display characteristics for completed clinical trials results.

Conclusions: We have developed a user-friendly, web tool to quickly sort and visualize ongoing clinical trials and results for completed trials to benefit both MBC patients and research scientists.
Title: Building an experience engine to make cancer treatment decisions using machine learning

Body: Introduction: Experts at tertiary care centers provide solutions to complex cases not addressed by high quality evidence. They intuitively retrieve patterns from years of experience to make treatment decisions. Short of personal consultations, there is no way to access this vast “experience database.” Experience Engine (XE) is a machine learning solution to structure experiential knowledge relevant for decision making, derive a similarity metric for patients who have received similar treatments, and predict treatment decisions that experts are likely to recommend.

Methods: 277 patient histories relating to 743 breast cancer tumor board decisions at two tertiary care centers were abstracted as the training set for machine learning. 161 distinct histories relating to 496 decisions for a separate expert opinion service at one of the centers was the holdout test set. Data was structured into 690 features based on a novel ontology designed specifically for breast cancer decision making.

To uncover nonlinear similarities, (for example, treatments for younger patients with multiple comorbidities and elderly patients may be similar), treatment decisions were grouped by timing and modality into 13 groups, such as primary surgery, 1st line palliative chemotherapy, etc.

Similarity metric was derived using machine learning on the training set. The target for prediction was the specific treatment decision i.e. TAC or another adjuvant regimen. The primary endpoint was percent accuracy of agreement between XE’s predicted decision and experts’ actual decision in the holdout test set. Multiple similarity distance metrics including Bhattacharya, Eskin, Goodall, etc., and multiclass classification algorithms such as Extreme Gradient Boosted Trees, Support Vector Machines, etc., were systematically evaluated to arrive at the algorithms that best fit each treatment group.

Results: The winning XE algorithms were 71% to 89% accurate for the various treatment groups, in predicting the actual treatment decisions recommended by the experts. The most frequent treatments recommended across all groups were standard evidence based therapies, as are often recommended by experts. For instance, when XE recommended standard adjuvant therapies for Her2- patients, it was 88% to 97% accurate. When XE recommended nonstandard therapies for the same treatment group, it was 72% to 90% accurate, related to larger number of nonstandard therapies within each treatment group and smaller samples of patients who underwent each type of nonstandard therapy. XE learned to weigh features relating to comorbidities and toxicities when recommending nonstandard therapies.

Conclusion: Machine learning on a structured database of past treatment decisions made by experts, can yield a predicted treatment decision that an expert is likely to recommend for a new patient. By including complex decisions that consider toxicities and morbidities, a rich source of knowledge can be created. Despite the limited dataset, XE learned features that experts strongly consider when making decisions. XE has the potential to analyze variations in decision making at expert practices, assess when to recommend nonstandard therapies, and serve as a training tool for new oncologists to make expert grade treatment decisions.
Body: Rapid autopsy (RA) refers to the recently developed practice of obtaining research tissue within 2-6 hours following the death of a patient. Such tissue can offer insights into the genomic and proteomic evolution of metastatic disease and possible novel therapeutic targets. Although patients generally have positive attitudes towards RA, RA programs have not been widely established by oncologists at healthcare centers with these capabilities. To identify barriers to our adoption of an RA program, we conducted a 21-item web-based survey of academic and community oncologists in a single institution with regard to knowledge, attitudes and concerns about RA. Twenty-six physicians completed the study out of a possible 98 respondents, with 50% in academic practice and 50% in community practice. 46% were not aware of RA prior to the survey. None of the community physicians had experience with patient tissue donations of any kind. In completing the survey, 85% were willing to ask future patients about participating in RA. 58% of oncologists cited lack of awareness as their primary barrier to participation, while 31% reported discomfort in discussing rapid autopsy with patients or concern about the doctor-patient relationship. A minority of physicians had ethical concerns about the practice. The most popular strategies for increasing awareness of the RA program included distributing informational pamphlets to patients, using a third-party advocate or a discussion with the patient's primary oncologist or NP. 92% of those surveyed stated that being aware of patient interest would make them much more likely to recommend RA to patients. Our study is among the first to clarify barriers among oncologists, particularly community oncologists, to establishing RA programs and suggests that increased information alone with clarification of patient perceptions could provide substantial progress in developing RA programs at tertiary healthcare centers and recruiting patients to these programs.
**Title:** Relationship between overall survival and surrogate measures in patients with metastatic breast cancer treated with chemotherapy

Culakova E, Poniewierski MS S, Crawford J, Dale DC C and Lyman GH H. Hutchinson Institute for Cancer Outcomes Research (HICOR), Fred Hutchinson Cancer Research Center, Seattle, WA; Duke University, Duke Cancer Institute, Durham, NC and University of Washington, Seattle, WA.

**Body:** Background: While metastatic breast cancer (MBC) is considered an incurable disease, nearly one-fifth of patients live longer than five years following diagnosis. In an effort to identify novel agents earlier, surrogate end points of overall survival (OS) such as response or progression are often employed in randomized controlled trials (RCTs). The goal of this analysis is to evaluate patterns of outcome reporting and the relationship of OS with surrogate measures in RCTs of patients with MBC.

Methods: The analysis was based on data from a systematic review of patients with MBC evaluating the clinical impact of chemotherapy intensity on survival. Reports of phase 2-3 RCTs published between 1990-2013 comparing more intense chemotherapy regimens (higher dose intensity or use of additional agents) with less intense were identified. For each RCT, clinical, treatment, demographic and outcome data were extracted. Outcomes evaluated included OS, progression free survival (PFS), and time to progression (TTP) with a focus on median survival and hazard ratios (HRs) as measures of treatment effect. Survival post progression (SPP) was calculated as the difference between median survival and median progression free time. The relations between various outcome measures were estimated utilizing weighted Pearson correlation coefficient (CORR) adjusted by Fisher's transformation. Weights were assigned proportionally to the sample size of individual RCTs.

Results: The review identified 70 eligible RCTs including 15,043 patients with MBC. Average median OS, PFS, and TTP were 19.2, 6.9, and 8.1 months reported in 96%, 60%, and 43% of studies, respectively. Progression could be determined in 66 studies, while 6 RCTs provided both outcomes. TTP was more often utilized in earlier studies (65% in 1990-2000, 35% in 2001-2008, and 33% in 2009-2013) and it was superseded by PFS in later years (20%, 70% and 81%, respectively). Only 37%, 33%, and 11% of RCTs reported HRs for OS, PFS, and TTP, respectively. HRs were more often available in recent publications (20% in 1990-2000, 22% in 2001-2008, 63% in 2009-2013 provided HR for OS). The correlation between reported HR and HR estimated by the ratio of arm-specific median survival times was high for OS (CORR=0.87, 95%CI: 0.73-0.94) and TTP (CORR=0.92, 95%CI: 0.61-0.99) and slightly lower for PFS (CORR=0.72, 95%CI: 0.44-0.87). The relationship between OS and surrogate measures (PFS, TTP) was weaker. The correlation between HR for OS and PFS was 0.49 (95%CI: 0.21-0.69) and for OS and TTP it was 0.26 (95%CI: -0.13-0.58). Survival time following progression was dependent on treatment type and was longer in less intense arms than more intense (mean SPP: 12.4 months vs. 11.4 months, P=0.0155).

Conclusions: In RCTs of patients with MBC treated with chemotherapy, when HR is not reported and if necessary statistical conditions are met, the HR approximated by ratio of median survival times may be a suitable proxy estimate. In agreement with other reports, neither PFS nor TTP are acceptable surrogate outcomes for OS in MBC, as survival following progression may be substantial. In these patients, crossover and post-trial treatments may influence the relationship between OS and surrogate measures.

Title: Automated, low-cost palpable breast lump triage for economically-developing countries

Love SM M, Berg WA A, Podilchuk C, Hovanessian-Larsen LJ J, Dauphine C, Jairaj A, Barinov L, Hulbert W, Cen S, Eshraghi L and Mammone R. Dr. Susan Love Research Foundation, Encino, CA; University of Pittsburgh School of Medicine, Magee-Womens Hospital, Pittsburgh, PA; Clearview Diagnostics Inc., Piscataway, NJ; University of Southern California, Keck School of Medicine, Los Angeles, CA; Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; Keck School of Medicine, Los Angeles, CA and Rutgers University, New Brunswick, NJ.

Body: Background: According to GLOBOCAN, 1.7 million women were diagnosed with breast cancer and 445,000 died from the disease in 2012. Breast cancer is the most common cause of cancer death among women worldwide and the numbers are disproportionately high for women in developing countries. Furthermore, breast cancer is more common in young women (age 44 and under) in these countries than in industrialized countries. Shifts in lifestyle typical of industrialized societies are thought to be causing a rise in breast cancer incidence while technical advances in detection, diagnosis, and treatment are not reaching these areas of the world. In developing countries, breast cancer commonly presents in women as a palpable mass and a low-cost solution for breast cancer triage would be beneficial. Ultrasound has been shown to perform very well on palpable masses, is non-ionizing, and affordable, portable systems are available. In the ACRIN 6666 clinical study of asymptomatic women, adding screening ultrasound to mammography significantly increased breast cancer detection in women with elevated cancer risk and dense breasts, and more invasive cancers were seen by ultrasound alone than by mammography alone.

Method: We propose a novel computer-aided diagnosis (CADx) tool for breast cancer triage using a low-cost ultrasound imaging device that will automatically distinguish among (1) suspicious lesions to be sent for biopsy, (2) benign findings that need no additional follow-up and (3) probably benign findings with recommended 6-month follow-up. A validation study at USC Norris Cancer Center and Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center was performed in order to assess the performance of the triage software compared to the standard-of-care and biopsy-confirmed cancers and false positives. The Study machine was the GE Logiq e ultrasound imaging device, which is FDA-approved for small body parts. Lesions that were assessed as BI-RADS 2 by radiologists were determined to be benign while any lesion assessed as BI-RADS 4a or higher was sent for biopsy. This study cohort included women 61 years of age or younger with a palpable mass. The triage software was compared to the performance by radiologists using conventional standard-of-care for palpable masses.

Results: The original milestone for this study was to achieve a sensitivity of 85% while reducing the number of benign lesions going to biopsy by 40%. The validation study showed an actual sensitivity of 100% while reducing the number of benign lesions going to biopsy by 69%. To date, the images collected during the validation study include 152 lesions in total, 22 biopsy-proven cancers and 130 benign lesions; 63 benign lesions were categorized as BI-RADS 4a or higher by a radiologist and sent for biopsy.

Conclusions: The validation study showed that adding automated breast cancer triage software to a low-cost portable ultrasound imaging device is a realistic approach for regions of the world with limited access to highly trained radiologists and diagnostic equipment.

Title: Intraoperative tumor detection using a ratiometric activatable fluorescent peptide: A first-in-human phase I study allows tumors to be visualized in the operating room

Unkart JT T, Chen SL L, González JE E, Harootunian A and Wallace AM M. University of California San Diego, La Jolla, CA and Avelas Biosciences, Inc, La Jolla, CA.

Body: Background:
A continuing challenge in breast cancer surgery is the difficulty with intraoperative lymph node status determination and achieving negative surgical margins. Current techniques such as frozen section, touch prep and intraoperative radiographic imaging are time consuming and vary in accuracy from institution to institution. Our study is a first-in-human study of a novel ratiometric activatable cell penetrating fluorescent peptide dye conjugate that labels breast cancer tumor tissue in vivo.

Methods:
AVB-620 is a substrate for and activated by proteases in the matrix metalloproteinase family. It has two fluorophores moieties linked by a cleavable peptide. Upon cleavage, there is an increase in fluorescence intensity and a change in the predominant wavelength of fluorescence emission. AVB-620 was given preoperatively via intravenous infusion to stage 0-III breast cancer patients. Patients were monitored for safety and AVB-620 pharmacokinetic parameters determined. After 12-20 hours, patients underwent lumpectomy or mastectomy with either sentinel lymph node biopsy (SLNB) or axillary lymph nodes dissection (ALND). Using a customized near-infrared camera system, fluorescence intensity signals at two wavelengths were measured intraoperatively both in vivo and ex vivo of primary tumors, shave margins and lymph nodes. The intensity ratio of these two wavelengths was utilized to distinguish between malignant and non-malignant tissues. Images were correlated to pathology reports.

Results:
Fifteen patients with average age of 59 years were enrolled across 5 dose cohorts without any significant adverse events. All patients underwent definitive breast surgery (12 lumpectomy, 3 mastectomy) and axillary surgery (12 – SLNB, 3- ALND). Four patients that had tumor-positive lymph nodes confirmed pathologically which correlated with increased fluorescence intensity and ratio on imaging. Primary tumor images also demonstrated fluorescence intensity and ratiometric changes that distinguished cancerous and non-cancerous tissues.

Discussion:
The purpose of this phase 1 dose escalation was to determine safety profile and adequate dosing. This study demonstrated a proof of concept of the use of a protease-activatable ratiometric fluorescent peptide dye conjugate to identify malignant tissue intraoperatively. Increased fluorescent ratio correlated and resulted in fluorescent imaging of known tumor in the operating room, with images that directly correlated with position of tumor in the excised tissue. This approach has the potential to quickly and accurately visualize the pathologic status of tumor margins and lymph node intraoperatively. Further studies to optimize dose, timing of administration, and thresholds for ratiometric imaging are underway.

**Title:** Determining the prognostic role of early and end-of-neoadjuvant chemotherapy 18F-FDG PET/CT in patients with locally advanced breast cancer

Muñoz-Sánchez MdM, Molina-Garrido MJ, García Vicente AM, Soriano Rodríguez MdC, Amo Salas M, Olaverri Hernández A, Chacón Muñiz JI, Álvarez Cabellos R, Espinosa Aunión R, Ortega Ruipérez C, Martín Ordóñez F, Pena Pardo FJ, Jiménez Londoño GA, Val Pérez E, Santiago Crespo JA and Soriano Castrejón A. Hospital General Virgen de la Luz, Cuenca, Spain; Hospital General Universitario de Ciudad Real, Ciudad Real, Spain; University of Castilla-La Mancha, Ciudad Real, Spain; Medical Oncology Service. Hospital Universitario Virgen de la Salud, Toledo, Spain and Medical Oncology Section. Hospital La Mancha Centro, Alcazar de San Juan, Ciudad Real, Spain.

**Body:**

**Aim:** To investigate the use of 18F-FDG PET/CT at diagnosis and after end-of-treatment in the prediction of response to neoadjuvant chemotherapy (NAC) and its role in the prognosis of patients with locally advanced breast cancer (LABC).

**Materials and Methods:** One hundred thirty-two patients underwent a baseline FDG PET/CT (PET-1) after the second course of chemotherapy (PET-2) and after the last course (PET-3). Breast tumors were classified into molecular phenotypes and grouped into risk categories according to the biological prognostic factors obtained by immunohistochemistry. PET/CT scans were semiquantitatively evaluated, obtaining the $\Delta$% SUV1-2 and SUV1-3 in primary tumor and axillary lymph nodes to establish response groups attending to EORTC criteria. Moreover, a binary assessment was obtained classifying the studies as positive or negative.

Pathological response was determined both in breast and axillary lymph node specimens. Overall survival (OS) and disease-free survival (DFS) were obtained during the follow-up. ROC analysis was performed to determine a cutoff value of $\Delta$% SUV1-2 and SUV1-3 for the prediction of response and prognosis.

Relations between molecular phenotypes, metabolic behavior, final pathological response, OS, and DFS were evaluated. This prospective and multicenter study was approved by the local ethics committee of our institution and included 7 hospitals of our region.

**Results:** In binary analysis, only PET-3 was able to predict pathological response in lymph nodes. The cutoff values of $\%\Delta$ SUV1-2 and $\%\Delta$ SUV1-3 with the best sensitivity and specificity in the prediction of response in breast tumor were 62% (Se: 70% and Sp: 69%) and 84% (Se: 70% and Sp: 88%). $A%\Delta$SUV1-3 of 74% in breast tumor was a predictor of DFS (AUC = 0.647; $P = 0.037$, $\chi^2 = 5.78$) and DFS (AUC = 0.003, $\chi^2 = 9.10$).

**Conclusions:** Among the multiple metabolic response variables in breast tumor and lymph nodes, end-of-treatment 18F-FDG PET/CT was a significant predictor of breast and lymph node response and patient prognosis. The molecular phenotypes and pathological lymph node response rate were independent predictors of OS and DFS. This stresses the potential of the biological influence over metabolic variables in the prognosis of patients. Metabolic response variables work better in their predictive and prognostic value in high-risk tumors.
Which measure of the interim changes in breast tumoral volume at breast MRI in response to neoadjuvant chemotherapy best predicts final pathological response?

Thompson AM M, Vinnicombe SJ J, Waugh SA A, Purdie CA A, Evans AJ J, Brunton T and Fuller-Pace FV V. Ninewells Hospital Medical School, Dundee, Angus, United Kingdom; University of Dundee, Dundee, Angus, United Kingdom and MD Anderson Cancer Center, Houston, TX.

BACKGROUND: Interim changes in breast tumour volume at magnetic resonance imaging (MRI) can predict ultimate response to neoadjuvant chemotherapy (NAC), but there is little data on the best measure of volumetric change. PURPOSE: To assess whether changes in measurements of semi-automated enhancing tumour volume (ETV) or fully automated functional tumour volume (FTV) between baseline and interim contrast-enhanced MRI are equivalent in predicting ultimate pathological response to neoadjuvant chemotherapy (NAC) for primary breast cancer, assessed using the residual cancer burden (RCB) score.

MATERIALS & METHODS: 78 patients undergoing treatment with NAC for primary breast cancer underwent contrast-enhanced MRI on a 1.5T or 3.0T MRI scanner using a dedicated bilateral breast coil before and after two or three cycles of NAC. Image analysis was performed using either semi-automated, user-defined thresholding (ITK-Snap; ETV) or fully-automated (Siemens SyngoVia BreVis; FTV) approaches. For ETV, the two-minute post-contrast subtracted volumes were analysed, with enhancing pixels thresholded to define tumour volume. FTV was measured using a manufacturer default setting of 50% enhancement threshold, relative to pre-contrast signal intensity, to define tumour volume. ETV intra-observer reproducibility was assessed by repeat analysis one month after initial analysis and a second observer also repeated the measure. Coefficient of reproducibility (CoR) and intraclass correlation coefficients (ICC) were calculated for intra- and inter-observer repeatability.

ETV and FTV percentage reduction between baseline and interim examinations was compared with final pathological response, as assessed using the residual cancer burden (RCB) score on resected cancer specimens. Correlation of the two volumetric measures was performed using a Pearson Intra-class Correlation Coefficient (ICC) and pair-wise comparisons of ETV and FTV changes between RCB groups carried out using a Mann-Whitney U test. All statistical assessment was performed using SPSS, v21, with p<0.05 considered significant.

RESULTS: There was significant correlation between ETV and FTV (ICC= 0.744, p<0.05). Intra and inter observer reproducibility for ETV was excellent, with ICC 0.940 and 0.861 respectively and corresponding CoRs of 11.6% and 14.8%.

Average percentage reductions in ETV for each pathological response category were: pCR 96.4% (n=12), RCB-I 66.6% (n=10), RCB-II 62.9% (n=39) and RCB-III 27.3% (n=17). Corresponding values for FTV were 88.8%, 70.6%, 54.6% and 20.8%.

Significant differences in percentage ETV changes were found for pCR vs. RCB-I (p<0.008), II (p<0.001) & III (p<0.001) and RCB-II vs. RCB-III (p<0.001). For FTV, significant differences were measured only for pCR vs. RCB-II & III (p<0.001).

CONCLUSION: changes in the semi-automated ETV measurement between baseline and interim MRI may provide more useful predictive information on final pathological response to NAC than FTV, as the changes are better able to discriminate between pCR and minimal residual disease (RCB-I). The ability to confidently predict pCR versus all other residual disease categories could facilitate planning of enhanced approaches to surgical management.

Title: Effect of MR imaging contrast kinetic thresholds for prediction of neoadjuvant chemotherapy response in breast cancer subtypes – Results from ACRIN 6657 / I-SPY 1 trial

Body: Background: Breast MRI has the potential to non-invasively measure response to neoadjuvant chemotherapy (NACT). We studied the effect of varying two analytic parameters used to define MRI-measured tumor volume in the prediction of pathologic complete response (pCR) to NACT and to determine if optimization of these parameter thresholds would improve the prediction of pCR.

Methods: Women with locally advanced breast cancer (tumor size $\geq 3$cm) were enrolled in the ACRIN 6657 / I-SPY 1 TRIAL. Each patient had up to four dynamic contrast-enhanced MRI examinations: before NACT (MR1), after one cycle of NACT (MR2), between the anthracycline-based regimen and taxane (MR3), and after NACT and prior to surgery (MR4). Breast cancer was stratified by subtypes of hormone receptor (HR), and human epidermal growth factor receptor 2 (HER2) status: HR+/HER2-, HER2+, and triple negative ((TN) HR-/HER2-). MRI-measured functional tumor volume (FTV) and change in FTV ($\Delta$FTV) were investigated as predictors of the outcome pCR. FTV is defined as the image volume with enhancement kinetics exceeding both an early percentage enhancement threshold (PEt) and a signal enhancement ratio threshold (SERt). Primary study analysis used empirically determined values. For this study PEt was varied from 30% to 200% in 10% intervals, and SERt was varied from 0.0 to 2.0 in 0.2 unit intervals. FTV was measured at each examination (FTV$_1$, FTV$_2$, FTV$_3$, FTV$_4$). $\Delta$FTV was measured relative to the first examination ($\Delta$FTV$_2$, $\Delta$FTV$_3$, $\Delta$FTV$_4$). For each pair of varied PEt and SERt thresholds, the absolute and relative FTVs were re-measured and analyzed for discrimination of pCR using the area under the curve (AUC) of the receiver operating characteristic curve.

Results: A total of 116 patients were included from the ACRIN 6657 / I-SPY 1 TRIAL who had complete data on all four MRI visits, HR/HER2 status, and pCR outcome. Mean age was 48 years old (range 29-69). The full cohort of 116 patients was divided into subgroups: 45 (39%) HR+/HER2-; 39 (34%) HER2+; and 30 (26%) TN. When stratified by subtypes, lower AUCs with less variation were observed in patients with HER2+ cancer than patients with HR+/HER2- and TN breast cancer. When examining prediction by visit, maximum AUCs were found at later time points in all patient cohorts. Specifically, maximum AUC was observed for the full cohort at $\Delta$FTV$_3$ with AUC of 0.78 (CI: 0.69–0.87) when PEt=130% and SERt=0; for HR+/HER2- subtype at $\Delta$FTV$_3$ with AUC of 0.9 (CI: 0.84–0.97) when PEt=130% and SERt=0 were the same as in the full cohort; for HER2+ subtype at FTV$_3$ with AUC of 0.77 (CI: 0.62–0.92) when PEt=70%/SERt=1.4; for triple negative at FTV$_4$ with AUC of 0.89 (CI: 0.76–1) when PEt=40%/SERt=2.0.

Conclusion: This analysis suggests that the thresholds of MRI quantitative DCE measurements may need to be adjusted by breast cancer subtype to improve the predictive performance. The PEt threshold may need to be set higher in HR+/HER2- than other subtypes, which may be due to higher background parenchymal enhancement among HR+ patients. SERt threshold may need to be set at higher level for triple negative subtype. A validation is underway in I-SPY 2, with a larger patient population.

Title: Abstract Withdrawn
Title: Acupuncture for chemotherapy-induced peripheral neuropathy in breast cancer, preliminary results of a pilot randomized controlled trial

Body: BACKGROUND: Chemotherapy-induced peripheral neuropathy (CIPN) is one of the major dose-limiting side effects in breast cancer patients, with up to 97% of patients receiving an adjuvant taxane experiencing this symptom in the months and years after breast cancer treatment. CIPN often leads to loss of physical function; difficulties in activities of daily living and decreased of quality of life (QOL). Few effective interventions have been developed to alleviate CIPN in this patient population. We conducted a pilot randomized controlled trial to assess the feasibility, safety and preliminary effect of an acupuncture intervention on CIPN in breast cancer survivors.

METHODS: Patients with stage I-III breast cancer who were experiencing CIPN after the completion of a taxane-containing adjuvant chemotherapy regimen were enrolled and randomized 1:1 to immediate participation in an acupuncture intervention or to a delayed intervention control group. Participants randomized to the acupuncture arm received 18 sessions of a standardized acupuncture protocol over 8 weeks while the control group received a lower-dose acupuncture protocol consisting of 9 acupuncture sessions over 8 weeks, after the initial 8-week control period. Measures including the Patient Neurotoxicity Questionnaire (PNQ), Functional Assessment of Cancer Therapy Neurotoxicity subscale (FACT-NTX), and the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Chemotherapy-induced Peripheral Neuropathy 20 (EORTC QLQ-CIPN20) were collected at baseline and at 8 weeks after enrollment.

RESULTS: A total of 40 patients were enrolled; 20 were randomized to the immediate acupuncture group and 20 to control. All enrolled patients were female, median age was 54, median time between enrollment and completion of chemotherapy was 14.3 months, and 72.5% of participants were White. Thirty-two patients (84%) completed at least 80% of the required sessions. No serious acupuncture-related side effects were observed. Participants randomized to the acupuncture arm experienced improvements in the PNQ sensory score (p=0.02), FACT-NTX summary score (p=0.002) and EORTC QLQ-CIPN20 score (p=0.006), respectively equivalent to 40%, 36% and 53% improvement in CIPN symptoms, as compared to controls.

CONCLUSIONS: Women with CIPN after adjuvant taxane therapy for early breast cancer experienced a significant and clinically meaningful improvement in neuropathy symptoms as a result of an 8-week acupuncture protocol. Given the prevalence of taxane-induced neuropathy in women treated for early breast cancer, acupuncture could significantly improve QOL and functional status of thousands of women treated for breast cancer every year. Larger studies are needed to confirm these findings and evaluate the impact of acupuncture on functional measures in women with CIPN.
Body: Introduction
Lymphoedema, a complication of nodal surgery in 30-40% of patients, reduces quality of life for sufferers. This prospective, multi-centre study compared multi-frequency bioimpedance spectroscopy (BIS, ImpediMed) with a validated perometer method to determine which test is more sensitive for detecting lymphoedema after axillary clearance and identify the factors predicting lymphoedema development.

Material and methods
Participants (n = 629) undergoing axillary clearance at 9 UK centres underwent pre-operative and arm volume measurements post-surgery (1, 3, 6, 9 & 12 months, then 6 monthly) by arm perometry, BIS measurements (L-Dex) and recorded self-reported symptoms via questionnaires. Follow-up was a minimum of two years from surgery. Change in arm volume was calculated using relative arm volume change (RAVC) with >10% increase defined as lymphoedema. The predictors of lymphoedema development and optimal method for its detection were assessed using Cox Regression, Log Rank and Kaplan-Meier survival analyses.

Results
In total, 629 women underwent axillary surgery, with a median age of 56 (range 22 to 90) years; 80% were ER positive and received endocrine therapy, 65% received chemotherapy. Lymphoedema was detected by 24 months in 124 (20%) women by perometry. Using the LDex ≥10 cut-off score, bioimpedance sensitivity was 71% and specificity was 89% (PPV 47%) compared to RAVC changes. Women who had an RAVC >5%-<10% at six months developed lymphoedema in 44% of cases by two years, whereas those who had less than 3% RAVC developed lymphoedema in 9% of cases (p >0.000001). Twenty-six per cent of ER negative patients developed lymphoedema compared to 19% ER positive cancer patients.

The type (taxane versus no taxane) and whether chemotherapy was neo-adjuvant or adjuvant did not predict lymphoedema development.

Univariate analysis revealed BMI (p=0.003), ER negativity (p≤0.010), absence of endocrine therapy (p=0.034), number of nodes involved (p=0.001) and an increase in RAVC ≥5%-<10% (p≤0.005) all predicted lymphoedema development by two years. On multivariate analysis, RAVC ≥5%-<10% after six months (HR 5.51 95% CI 3.05 – 9.94) along with number of nodes involved (HR 1.06 95% CI 1.03 – 1.09) and BMI HR 1.04 (1.04 – 1.09) were included in the model for predicting lymphoedema development at two years.

Conclusions
This is the first report; ER negative cancer is associated with an increased risk of lymphoedema after axillary node clearance. Arm measurements should be taken from baseline in all patients undergoing axillary surgery and increases greater than 3% should lead to further surveillance to prevent lymphoedema development. Perometer measurement is the optimal technique for measuring and predicting the development of lymphoedema.

A threshold RAVC of ≥5%–<10% after six months predicts lymphoedema in 44% of patients by two years.

Title: Chemotherapy-related risk factors associated with lymphedema in breast cancer patients: Should repeated ipsilateral arm infusions be avoided?

Asdourian MS S, Rao SR R, Skolny MN N, Salama L, Brunelle C, Seward C and Taghian AG G. Massachusetts General Hospital, Boston, MA; Biostatistics Center, Massachusetts General Hospital, Boston, MA; Boston University Medical Center, Boston, MA and Massachusetts General Hospital, Boston, MA.

Body: Background: Breast Cancer-Related Lymphedema (BCRL) is a chronic, iatrogenic condition that can occur after damage to the lymphatic system during surgery (sx) or radiation, precipitating edema of the arm, breast, or trunk. BCRL risk-reduction education is an essential component of clinical care, and practitioners often advise patients (pts) to avoid needle punctures on the treated arm when possible. There is, however, a lack of substantial scientific evidence to lessen patient distress. Considering the common use of chemotherapy (CT) agents in this population, we assessed whether repeated skin punctures on the ipsilateral arm for CT infusions increased the risk of BCRL compared to CT via central lines in a large, prospective cohort of breast cancer (BC) pts.

Methods: We prospectively screened 630 pts with unilateral (487) or bilateral (143) BC sx receiving neoadjuvant (NAC) and/or adjuvant CT (AdjCT) for arm lymphedema (defined as volume change ≥10%) at our hospital from 2005–16. Pts were measured with a perometer pre-operatively and at 3–7 month follow-up intervals. Clinicopathologic and treatment (tx)-related characteristics, including details on CT regimen and the method of intravenous (IV) CT administration [peripheral IV catheters (PIVCs), central venous access devices (CVADs), peripherally inserted central catheters (PICCs)] were obtained by chart review. Cox proportional hazard analyses were applied to ascertain the risk of BCRL associated with these factors.

Results: The median post-op follow-up was 44 months. Of the 630 pts, 40% underwent axillary lymph node dissection (ALND), 60% underwent sentinel lymph node biopsy (SLNB) or no nodal sx, 16% and 89% received NAC or AdjCT, respectively. CT was administered via PIVCs inserted in the hand/arm for 59%, via CVADs or PICCs for 26%, and via both PIVCs at least once and CVADs/PICCs for 15%. The 2-yr cumulative incidence of BCRL was 12% (95% CI 9.9-15.2%). Multivariable regression results indicated that pts with both peripheral IV infusions on the arm and implanted CVADs did not have a higher risk of BCRL (HR(95% CI)=1.4(0.6-3.6)) than pts who received CT via CVADs only (1.7(0.7-3.8)). The overall number of NAC (p=0.24;0.9(95% CI 0.8-1.1)) or AdjCT cycles (p=0.78;1.0(0.9-1.1)) was not associated with BCRL, nor was the number of peripheral IV infusions (p=0.17;1.0(1.0-1.1)). BMI >30 (p<0.0001;3.4(1.9-6.0)) and number of positive lymph nodes (p=0.02;3.2(1.3-8.1)) were significantly associated with BCRL. Among those with PIVCs, pts with bilateral SLNB/ALND were more likely to develop BCRL than pts with unilateral sx (p<0.01;5.0(1.9-13.4)). Only 38% of the 32 bilateral pts with BCRL received at least one peripheral IV infusion on their ipsilateral arm.

Conclusion: Results suggest that repeated skin punctures on the ipsilateral arm for CT infusions do not significantly increase the risk for BCRL compared to implanted CVADs, nor does the overall number of CT cycles. As survivors may be concerned about the risk of developing BCRL following sx and tx, healthcare practitioners should strive to mitigate pt worry during and well beyond the course of tx, educating pts about the lifestyle risk exposures for BCRL and precautionary guidelines not being definitive.
Title: Effectiveness of myofascial techniques in addition to a standard physical therapy program as postoperative intervention for upper limb pain in breast cancer patients: A randomized controlled trial

Body: Background: In addition to fatigue, pain is the most frequent and persistent symptom following cancer and cancer treatment. Despite the effectiveness of several postoperative physical therapy modalities, many patients after breast cancer still have pain at the upper limb region at short and long term. Several authors already recommended the use of myofascial therapy. Therefore, the aim of this study was to investigate short and long term effects of myofascial therapy, in addition to a standard physical therapy program, as postoperative intervention for upper limb pain after breast cancer surgery.

Methods: Randomized controlled trial with assessor and patient blinding and intention-to-treat analysis. One hundred forty-seven consecutive patients with breast cancer and unilateral axillary surgery were included. All participants received a standard physical therapy program starting immediately after surgery during 4 months. The intervention group received additionally 8 sessions of myofascial therapy on weekly basis from 2 up to 4 months after surgery. The control group received 8 sessions of a placebo intervention in addition to the same standard physical therapy program. Primary outcomes were prevalence rate of pain (i.e. pain at the operated upper limb region during the past week), maximal pain intensity at this region (Visual Analogue Scale (VAS) (0-100)), pressure hypersensitivity (pressure pain thresholds (kg/cm²) (PPT)) and pain quality (McGill Pain Questionnaire). All measurements were performed at 2 (=baseline), 4, 9 and 12 months post-surgery. Analysis of covariance (ANCOVA) were performed to correct for differences at baseline (i.e. 2 months after surgery). Additionally, effect size is given by means of relative risk reduction (RRR) and mean differences and their 95% confidence interval.

Results: Both groups were comparable at baseline. At 4, 9 and 12 months post-surgery, prevalence rates of pain were comparable between the intervention and control group (40%, 53%, 49% versus 41%, 47%, 51%, p=1.000, p=0.508 and p=0.868 and RRR of 3.2% (-0.44 - 0.35), -13% (-0.57 - 0.18) and 2.7% (-0.35 - 0.30), respectively). Pain intensity was comparable between the intervention group and control group as well. PPT of the Upper Trapezius muscle was significantly higher in the intervention group at 4 months (4.86 (2.43) versus 3.69 (2.04) kg/cm², p=0.012; mean difference -1.2 (-1.9 – 0.4) kg/cm²). PPT of the Supraspinatus muscle was significantly higher in the intervention group at 4 months (4.54 (2.1) versus 3.8 (1.85) kg/cm², p=0.021; mean difference -0.7 (-1.4 – 0.1) kg/cm²) and at 9 months (3.92 (1.7) versus 3.39 (1.61) kg/cm², p=0.040; mean difference -0.5 (-1.1 – 0.0) kg/cm²). No significant differences in pain quality were found between groups.

Conclusion: Myofascial therapy, in addition to a standard physical therapy program, has beneficial effect as postoperative intervention for pressure hypersensitivity of upper limb muscles after breast cancer surgery. No beneficial effect on pain prevalence rate, pain intensity and pain quality was found.
Title: Survivorship care planning is associated with breast cancer survivors’ reported quality and coordination of care

Body: Primary goals of cancer survivorship care planning (SCP) include the assessment of ongoing risks for late effects and the coordination of health care. SCP strives to improve communication and coordination between survivors, health-care, and supportive care providers. Results on the effectiveness of SCP have been mixed. We report on the relationship between self-reported indicators of care with two essential elements of SCP: receipt of a written treatment summary and written instructions for routine cancer check-ups.

Methods: The Greater Plains Collaborative Clinical Data Research Network conducted the Share Thoughts on Breast Cancer survey across 8 cancer-care delivery sites across the Midwest. Participants were women age 18 years and older who had completed treatment for noninvasive or invasive (but not metastatic) breast cancer diagnosed from 1/1/2013 to 5/1/2014. Women were excluded if diagnosed with lobular carcinoma in situ, had previously been diagnosed with cancer per tumor registry records, did not report having cancer-directed surgery, or did not respond to questions about survivorship care planning. Logistic regression was used to examine characteristics and outcomes associated with a three-category SCP summary variable: (a) received both a written treatment summary and instructions for follow-up care; (b) received only one of these elements; or (c) received neither element. Adjustment variables included age at diagnosis, race, marital status at diagnosis, education, history of smoking, number of comorbidities, self-report that one health professional coordinated cancer care, type of surgery, and treatment with chemotherapy, radiation or hormones, and practice site.

Results: Of the 1148 survivors meeting study criteria, 485 (42.2%), 420 (36.6%), and 243 (21.2%) reporting receiving both SCP elements, one element, or no element, respectively. Several factors were associated with receiving elements of SCP: Those who reported having a single health professional who coordinated their cancer care were twice as likely to receive both elements of the SCP vs neither element (OR=2.3; 95% CI 1.6-3.2). Of patients who received both SCP elements, 88% reported excellent/very good quality of care compared to 73% who received neither element (p = .001). Respondents who reported always knowing who to ask questions about their cancer were far more likely to have received both elements vs neither element (OR=10.1; 95% CI 5.2-19.4). No association was observed between SCP and cancer care delivery site.

Conclusions: Breast cancer survivors who reported receiving a written summary of treatment and instructions for follow-up care reported better quality of cancer care, and they were also more confident about how to find answers to cancer related questions. Survivors who receive SCP were also more likely to have a single health professional coordinating their cancer care, potentially illustrating how SCP may fit into overall care processes.
Title: Investigation of the recurrence dynamics of breast cancer (BC) according to the body mass index (BMI)

Body: Background:
In cancer follow-up (FU), in addition to the evaluation of disease free and overall survival probabilities, there is a fundamental need of assessing the recurrence dynamics. In BC as well as in other cancers, the hazard function for first recurrence presents multiple peaks, with a first major peak occurring before three years of FU. Although the baseline risk is modulated by known prognostic factors with possible time dependent effects such as the estrogen receptor (ER), so far no other factor proved to disentangle this multi-peak behavior. Here, we postulated that adiposity, which is closely related to a state of hyperinsulinemia and chronic inflammation, and reflected by increased patient's BMI, could influence the recurrence dynamics.

Material and methods:
In this study 777 patients with early node-positive BC from a phase III randomized clinical trial were considered (Piccart et al. JCO 2001). The trial compared intermediate or full doses of epirubicin–cyclophosphamide with cyclophosphamide, methotrexate and 5-fluorouracil. BMI was calculated using the WHO classification and was available for 734 patients, of whom 27(4%) were underweight, 377(51%) normal, 213(29%) overweight and 117(16%) obese. Underweight and normal patients were grouped together. Disease free survival (DFS), loco-regional and distant recurrence endpoints were considered. Median FU-time was 15.4 years. Cox regression analysis was performed, adjusting for standard clinico-pathological variables and treatment. Piecewise exponential models with cubic natural and regularized tensor product splines were carried out to estimate the hazard function according to categorical and continuous BMI, respectively.

Results:
Older age at diagnosis, postmenopausal status, and increased tumor size were significantly associated with increased BMI. Adjusted Cox models supported the association between overweight and disease recurrence (HR=1.39; 95%CI=1.05-1.84) as well as distant metastases (HR=1.41; 95%CI=1.01-1.97). There was no evidence of association for loco-regional recurrences. We observed a multi-peak behavior of distant recurrences for all BMI categories. Although, there was no shift of the first peak of recurrences according to BMI categories, occurring at ~2.5 years of FU, a major increase in peak heights for the overweight and obese patients was evident. Obese patients showed a sharper first peak. When considering the three BMI categories according to the ER-status, we observed the worst prognosis for overweight ER-negative patients, as well as different recurrence patterns (Table).

<table>
<thead>
<tr>
<th></th>
<th>Normal</th>
<th>Overweight</th>
<th>Obese</th>
</tr>
</thead>
<tbody>
<tr>
<td>ER-positive</td>
<td>Main recurrence peak culminating at 2 years, with multiple smaller peaks later</td>
<td>One broad peak around 3 years and one smaller around 10 years</td>
<td>One narrow peak at 2 years and one smaller around 10 years</td>
</tr>
<tr>
<td>ER-negative</td>
<td>Similar pattern to ER-positive BC, with however major increase in height of first peak</td>
<td>One broad peak around 3 years, with a major increase in height compared to ER-positive BC</td>
<td>One peak at 2-3 years</td>
</tr>
</tbody>
</table>

Conclusion:
This is the first study to show that both the ER-status of the tumor and the patient's BMI at diagnosis are influencing the recurrence dynamics related to BC dormancy.
Title: Are aromatase inhibitors associated with higher myocardial infarction risk in breast cancer patients? A Medicare population study

Kamaraju S, Smith E, Shi Y, Laud P and Neuner J. Patient Centered Outcomes Research, Medical College of Wisconsin, Milwaukee, WI and Cancer Center, Froedtert and The Medical College of Wisconsin, Milwaukee, WI.

Body: Purpose: Aromatase Inhibitors (AIs) are the current standard of care for post-menopausal adjuvant endocrine breast cancer therapy either following or in place of tamoxifen. While their short-term side effect profile was favorable in most studies, findings were mixed regarding cardiotoxicity, and cardiac outcome definitions were not consistent across studies. Given the five or more year duration of adjuvant endocrine therapy, risk of cardiotoxicity in older patients with pre-existing comorbidities remains a particular concern. We examined Myocardial Infarction (MI) as the cardiac outcome in subjects who received AIs vs. tamoxifen in a cohort of Medicare-based breast cancer survivors.

Patients and Methods: We identified women age ≥ 67 years diagnosed with breast cancer from 6/30/2006 to 6/01/2008 in the Surveillance, Epidemiology, and End Results-Medicare (SEER) database, with the following eligibility criteria: stage I-III breast cancer, continuous enrollment in Medicare Parts A and B for 24 months prior to the diagnosis and Part D enrollment for one month after the breast cancer diagnosis to the end of follow up (12/31/2012), adjuvant endocrine therapy (tamoxifen or AI fill) within 12 months after diagnosis. The main study outcome was the time to first diagnosis of MI after initiation of AIs or tamoxifen. MI was defined precisely by ICD9 and ICD10 codes relating both to incidence and death from MI. We developed and assigned stabilized inverse proportion weights to balance the groups, and performed a Fine and Gray hazards model for the outcomes of MI and death for the treatment groups of AIs vs tamoxifen.

Results: Of the cohort of 5,648 women, 4,690 were treated with AIs and 958 with tamoxifen; a total of 251 patients developed and/or died of MI during the study period while 476 died of other causes. The Fine and Gray Model results in a hazard ratio (HR) were not significantly different from one for weighted AI vs Tamoxifen groups [HR=1.01, C.I. 0.72-1.42]. Covariates which significantly affected the risk of MI were previous diabetes, prior other heart disease, prior congestive heart failure, prior MI, and prior peripheral vascular disease. Other covariates included in the weighted model, were age, American Joint Committee on Cancer (AJCC) cancer stage, chemo, Estrogen and progesterone receptor status, low income subsidy, marital status, prior hypertension, prior stroke, per capita income, race, radiation, SEER region, and urbanization.

Conclusions: The occurrence of MI is very low in this cohort (4.4%), reassuring the clinicians that the older adults with comorbidities may not be at a higher risk of MI with adjuvant endocrine therapy. However, the confidence interval for the hazard ratio of AIs vs Tamoxifen is very wide, indicating that a larger sample may be needed for the power of the study to be conclusive.
Title: Efficacy of compression therapy using surgical gloves for nanoparticle albumin-bound-paclitaxel-induced peripheral neuropathy: A phase II multicenter study by the Kamigata breast cancer study group

Tsuyuki S, Senda N, Kanng Y, Yamaguchi A, Yoshibayashi H, Kikawa Y, Katakami N, Kato H, Hashimoto T, Okuno T, Yamauchi A, Inamoto T. Osaka Red Cross Hospital, Osaka, Japan; Kyoto University, Graduate School of Medicine, Kyoto, Japan; Japanese Red Cross Society Wakayama Medical Center, Wakayama, Japan; Kobe City Medical Center West Hospital, Kobe, Hyogo, Japan; Institute of Biomedical Research and Innovation Hospital, Kobe, Hyogo, Japan; Kobe City Medical Center Central Hospital, Kobe, Hyogo, Japan; Hashimoto Clinic, Kobe, Hyogo, Japan; Nishi-Kobe Medical Center, Kobe, Hyogo, Japan; Tazuke Kofukai Medical Research Institute, Kitano Hospital, Osaka, Japan; Tenri Health Care University, Tenri, Nara, Japan

Body: PURPOSE: Chemotherapy-induced peripheral neuropathy (CIPN) is an adverse effect of many commonly used chemotherapeutic agents, including taxanes. However, there is currently no established effective prophylactic management for CIPN. Thus, we investigated the efficacy of using surgical glove (SG) compression therapy to prevent nanoparticle albumin-bound-paclitaxel (nab-PTX)-induced peripheral neuropathy.

PATIENTS AND METHODS: Patients with primary and recurrent breast cancer who received 260 mg/m2 of nab-PTX were eligible for this case-control study. The patients wore two SGs of the same size, that is, one size smaller than the size that fit, on their dominant hand for 90 minutes. They did not wear SGs on the non-dominant hand, which served as the control hand. Peripheral neuropathy was evaluated at each treatment cycle using Common Terminology Criteria for Adverse Events (CTCAE) version 4.0 and the Patient Neurotoxicity Questionnaire (PNQ). The temperatures of each fingertip of the compression SG-protected and control hands were measured by using thermography.

RESULTS: Between August 2013 and January 2016, 43 patients were enrolled, and 42 were evaluated. As shown in Table 1, the overall occurrence of [ge]grade 2 sensory and motor peripheral neuropathy according to the CTCAE was significantly lower in the SG-protected hands than in the control hands (76.1% vs. 21.4% and 57.1% vs. 26.2%, respectively, p [lt] 0.0001). The PNQ results showed that the incidence of [ge]grade 4 neuropathy was significantly higher in the control hands than in the SG-protected hands in terms of both sensory and motor neurotoxicity (p [lt] 0.0001, Table 2). As the treatment cycles of nab-PTX increased, the mean CTCAE and PNQ grades of the control hands gradually increased. However, the SG-protected hands maintained significantly lower mean grades than the control hands over time (p [lt] 0.0001).

No patients withdrew from this study because they could not tolerate the compression from the SGs. The mean temperature of each fingertip significantly decreased (1.42[ndash]2.60 [deg]C) in the SG-protected hands compared to the control hands.

CONCLUSIONS: SG compression therapy appears effective for reducing nab-PTX-induced peripheral neuropathy. The nab-PTX exposure to the peripheral nerve may be decreased because the SG decreases microvascular flow to the fingertip.

Table 1: Comparison of the overall occurrences of the different grades of peripheral neuropathy according to CTCAE version 4.0 between the compression surgical glove-protected hands and control hands

IMENEO: International MEta-analysis of circulating tumor cell detection in early breast cancer patients treated by NEOadjuvant chemotherapy

Body: Background
We performed an international meta-analysis of individual patient data to assess the clinical validity of circulating tumor cell (CTC) count in non-metastatic breast cancer (BC) patients (pts) treated by neoadjuvant chemotherapy (NCT).

Methods
A protocol pre-specified the study objectives. We performed a literature & abstracts search up to Dec 2014, then contacted all centers deemed to have eligible data (published or not): early BC pts treated with NCT with CTC count by CellSearch®. The primary endpoint was overall survival (OS); secondary endpoints included distant disease-free survival (DDFS), locoregional relapse-free interval (LRFI) and pathological complete response (pCR). Non-overlapping CTC time points were: baseline (5-0 weeks before NCT), 1-8 weeks after NCT start, 5-0 weeks before surgery and 1-52 weeks after surgery. We used Cox regression models, stratified by study, and the landmark method to establish the prognostic value of CTC count/changes during treatment and survival.

Results
We collected 2,156 individual pt data from 21 studies and 16 centers worldwide. With ≥1≥2≥5 CTC/7.5ml as thresholds, CTC positivity rate was 25/13/6% at baseline, 17/6/3% after NCT start, 15/5/1% before surgery and 11/4/1% after surgery (decrease, p<0.0001). Before NCT, ≥1 CTC was found in 19%, 22%, 24%, 29% and 41% of cT1, T2, T3, T4a-c and T4d BC, respectively (p<0.0001) and was also marginally associated with hormone-receptors negativity (p=0.04). Later CTC detection rates were not associated with any of the baseline characteristics. pCR (assessed in 2,072 pts; ypT0/isN0 used as pCR definition in 92% of pts) was observed in 24% of pts but was not associated with CTC count, at any time point. 301, 418 and 157 events were reported for OS, DDFS and LRFI, respectively. In univariate analyses, ≥1 CTC at baseline was a prognostic factor for OS (HR=2.6 [1.9-3.4], p<0.0001), DDFS (HR=2.4 [1.9-3.1], p<0.0001) and -importantly- for LRFI (HR=1.8 [1.2-2.7], p<0.0001). Similar results were obtained using other thresholds (≥2 & ≥5 CTC) and/or later time points (after NCT start, before surgery). There was no interaction between the prognostic impact of CTC count and tumor subtypes. Although rare, pts with persistently elevated CTC count (≥1CTC) before NCT and before surgery (5% of pts) had a worse OS than patients with persistently null CTC count (HR=6.2 [3.4-11], p<0.0001). Finally, in multivariate analyses, baseline CTC detection (whatever the CTC threshold used : ≥1≥2≥5 CTC) was an independent prognostic factor for OS, DDFS and LRFI, together with pCR, cT, cN and tumor subtype, (e.g. for OS: CTC≥2 HR=4.2 [3.0-5.9] p<0.0001, No pCR HR=6.2 [3.7-11] p<0.0001, cT4d HR=2.6 [1.1-6.6] p=0.02, cN+ HR=1.7 [1.2-2.4] p=0.003, triple negative BC HR=3.2 [2.1-5.1]). Similar results were obtained with later time points (after NCT start, before surgery).
Conclusions
Our study demonstrates with the highest level of evidence that CTCs are a prognostic biomarker in early BC treated by NCT. This impact was independent to that of pCR and was observed on OS, DDFS and also -for the first time- on LRFI. CTC count can usefully complement standard prognostic factors and pCR to improve the prognostication of early BC pts.
Body: Background A significant portion of breast cancer patients treated in the neoadjuvant setting does not achieve a pathological complete response (pCR) and has an increased risk of relapse after surgery. The current lack of reliable predictors of response to guide patient therapy in clinical practice requires the identification of predictive biomarkers that could discriminate between responders and non-responders. The purpose of this study was to investigate the potential of circulating microRNAs (miRNAs) as novel non-invasive predictive biomarkers of response to neoadjuvant treatment in HER2-positive breast cancer patients enrolled in the Neo-ALTTO study.

Methods We performed a longitudinal miRNA monitoring of the well-annotated and high-quality plasma samples of patients treated with neoadjuvant lapatinib, trastuzumab or their combination. Before profiling, the overall plasma samples were randomly splitted in two sets, namely the training set and the testing set, with distribution of timing of plasma collection, arm of treatment, rate of pCR, and tumor characteristics resembling that of the entire Neo-ALTTO patient population. To this end a PCR-based high-throughput approach was firstly employed in the training set. After a proper normalization step, for each treatment arm and time-point, a panel of potential miRNAs associated to pCR was identified by resorting to univariate approaches. Multivariate penalized logistic regression models were implemented thereafter, in order to identify specific signatures for each time-point and treatment arm. Finally, the predictive capability of the aforementioned signatures was evaluated in the testing set.

Results Plasma miRNA profiles were available for 435 of the 455 (96%) patients enrolled in the Neo-ALTTO study. In details, miRNA levels were analyzed in 141, 151 and 143 patients assigned to neoadjuvant trastuzumab, lapatinib, and their combination, respectively, at baseline and after 2 weeks of treatment. A total of 30 miRNAs (including both normalizers and specific miRNAs) were identified and 6 signatures were found predictive of pCR in terms of Area Under the ROC Curve (AUC) in the training population. The predictive capability of 4 of 6 of the identified signatures was confirmed in the testing set, specifically: lapatinib at baseline AUC (95%CI) = 0.86 (0.73-0.98) and after two weeks AUC (95%CI) = 0.71 (0.55-0.86), trastuzumab after two weeks AUC (95%CI) = 0.81 (0.70-0.92), and lapatinib + trastuzumab after two weeks AUC (95%CI) = 0.67 (0.51-0.83). Of note, the predictive value of the signature of trastuzumab after two weeks was confirmed after adjustment for hormonal receptor status - training set AUC (95%CI) = 0.90 (0.80-0.99), testing set, AUC (95%CI) = 0.84 (0.74-0.94).

Conclusion These findings provide the first evidence of the potential of circulating miRNAs to predict treatment response in HER2-positive breast cancer patients treated with neoadjuvant therapy. Results obtained in the trastuzumab arms are of special value as in women with unfavorable miRNA signature it is anticipated an unfavorable response to paclitaxel plus trastuzumab after just 2 weeks of treatment. Data on correlation with elapse free survival will be presented at the meeting.
Title: PAM50 intrinsic subtype as a predictor of pathological complete response following neoadjuvant dual HER2 blockade without chemotherapy in HER2-positive breast cancer: First results of the PAMELA clinical trial

Prat Aparicio A, Cortes Castan J, Pare L, Galvan P, Bermejo B, Martínez N, Vidal M, Pernas S, López R, Muñoz M, Nuciforo P, Fasani R, Morales S, Oliveira M, de La Peña L, Peláez A and Llombart A. Hospital Clinic de Barcelona, Barcelona, Spain; Hospital Ramón y Cajal, Madrid, Spain; Instituto de Investigaciones Biomédicas August Pi i Sunyer (IDIBAPS), Barcelona, Spain; Vall d’Hebron Instituto de Oncología (VHIO), Barcelona, Spain; Hospital Clínico de Valencia, Valencia, Spain; Instituto Catalán de Oncología, Hospitalet, Barcelona, Spain; Complejo Universitario de Santiago de Compostela (CHUS), Santiago de Compostela, Galicia, Spain; Hospital Universitari Arnau de Vilanova de Lleida, Lleida, Spain; Hospital Universitari Vall d’Hebron, Barcelona, Spain; SOLTI, Breast Cancer Research Group, Barcelona, Spain and Hospital Arnau de Vilanova de Valencia, Valencia, Spain.

Body: Background: Prior neoadjuvant studies in HER2+ breast cancer have shown that dual HER2 blockade without chemotherapy achieves pathological complete responses (pCR) rates of 6-36% (TBCRC006/TBCRC023/NeoSphere). However, a major challenge today is how to select prospectively patients who will derive the maximum benefit from dual anti-HER2 therapies without chemotherapy. In this context, we and others have previously shown that HER2+ disease is biologically heterogeneous and composed of all the intrinsic molecular subtypes (Luminal A, Luminal B, HER2-enriched [HER2-E] and Basal-like). Among them, the HER2-E subtype shows the highest activation of the EGFR/HER2 pathway.

Methods: PAMELA (NCT01973660) is a non-randomized, open-label, multicentric, prospective translational research study in stage I-IIIA HER2+ breast cancer designed to evaluate the ability of the PAM50 intrinsic subtypes to predict pCR in the breast (pCRB; in situ allowed) following 18 weeks of neoadjuvant lapatinib and trastuzumab. Patients with HR+ disease received letrozole (if postmenopausal) or tamoxifen (if pre-menopausal). The primary objective was to compare the pCRB rates of the HER2-E versus the non-HER2-E subtypes in the intent-to-treat population. The study was planned with a power of 95% at a significance level of 0.05 to detect an absolute relative difference in pCRB rates between the two groups of 27% (i.e. 35% in HER2E and 8% in non-HER2-E). Day-15 formalin-fixed, paraffin-embedded tissue samples were prospectively collected and gene expression profiled using the nCounter platform. The intrinsic subtypes were identified using the research-based PAM50 predictor (Parker JCO 2009).

Results: A total of 151 patients were recruited (n=77 HR+ and n=74 HR-). Patient characteristics were: mean age (55 years), mean tumor size (2.84 cm), negative axilla (63.5%) and postmenopausal (60.2%). At baseline, intrinsic subtype distribution was: HER2-E (n=101, 66.9%), Luminal A (n=22; 14.6%), Luminal B (n=16; 10.6%), Basal-like (n=9; 6%) and Normal-Like (n=3; 2%). The overall pCRB was 30.5% (46/151), 18.2% in HR+ disease and 43.2% in HR- disease. Five patients (3.3%) presented progressive disease. Rates of pCRB in HER2-E and non-HER2-E subtypes were 40.6% and 10.0% (p<0.0001), respectively. HER2-E subtype predicted pCRB independently of HR status. Within HR+ disease, pCRB rates were 31.6% in HER2-E subtype and 5.3% in non-HER2-E subtype (p=0.006). Within HR- disease, pCRB rates were 46.0% in HER2-E subtype and 27.3% in non-HER2-E subtypes (p=0.331). At Day-15, the majority of tumors became Normal-like (48.9%) or Luminal A (27.5%). Rates of pCRB were 46.9% in Normal-like tumors and 11.9% in non-Normal-like tumors when evaluated at day-15 (p<0.0001).

Conclusions: The PAMELA trial met its primary endpoint. PAM50 HER2-E subtype identifies patients with HER2+ disease likely to derive a large benefit from dual anti-HER2 therapies +/- endocrine therapy, especially in HER2+/HR+ disease. In addition, early changes in gene expression indicative of a reduction of tumor cellularity are predictive of pathological complete response at surgery.
**Title:** Primary analysis of PERTAIN: A randomized, two-arm, open-label, multicenter phase II trial assessing the efficacy and safety of pertuzumab given in combination with trastuzumab plus an aromatase inhibitor in first-line patients with HER2-positive and hormone receptor-positive metastatic or locally advanced breast cancer

Arpino G, Ferrero J-M, de la Haba-Rodriguez J, Easton V, Schuhmacher C, Restuccia E and Rimawi M. Università degli Studi di Napoli Federico II, Naples, Italy; Département d’Oncologie Médicale, Centre Antoine Lacassagne, Nice, France; Maimonides Institute of Biomedical Research, Reina Sofía Hospital, University of Córdoba, Córdoba, Spain; F. Hoffmann-La Roche Ltd, Basel, Switzerland and Dan L. Duncan Comprehensive Cancer Center, Baylor College of Medicine, Houston, TX.

**Body:**

**Background:**
Preclinical and clinical evidence suggest that cross-talk between HER2 and estrogen receptor signaling pathways in breast cancer (BC) contributes to treatment resistance (Kaufman et al. *J Clin Oncol* 2009; Arpino et al. *J Natl Cancer Inst* 2007). First-line pertuzumab (P), in addition to trastuzumab (H) + docetaxel (T), significantly improved progression-free survival (PFS) and overall survival (OS) compared with H + T in patients (pts) with HER2-positive metastatic BC (MBC) (Swain et al. *N Engl J Med* 2015; Baselga et al. *N Engl J Med* 2012). PERTAIN (NCT01491737) is the first study to assess first-line P + H + an aromatase inhibitor (AI) ± induction taxane therapy in postmenopausal women with hormone receptor-positive, HER2-positive locally advanced (LA)/MBC.

**Methods:**
Pts with HER2-positive, hormone receptor-positive LA/MBC who had not received prior systemic therapy (except endocrine therapy) were randomized 1:1 to Arm A: P + H + AI or Arm B: H + AI. Study medication: P 840 mg loading dose followed by 420 mg every 3 weeks (q3w); H 8 mg/kg followed by 6 mg/kg q3w; anastrozole 1 mg daily (qd) or letrozole 2.5 mg qd. Induction T q3w or paclitaxel (PAC) weekly could be given for 18–24 weeks at the investigator’s discretion before the start of endocrine therapy. Treatment was continued until disease progression or unacceptable toxicity. The primary endpoint was PFS, stratified by induction chemotherapy (yes/no) and time since adjuvant hormone therapy (<12 months, ≥12 months, no prior hormone therapy) and estimated using Kaplan–Meier methodology. Secondary endpoints included OS, objective response rate (ORR), duration of response (DoR), and safety and tolerability.

**Results:**
From February 2012 to October 2014, 129 pts were randomized to Arm A and 129 to Arm B (intent-to-treat populations; safety populations: 127 and 124, respectively) across 80 sites and 8 countries. Baseline demographics and disease characteristics were generally balanced between arms. Induction T and PAC were received by 42 (32.6%) and 32 (24.8%) pts in Arm A, respectively, and 37 (28.7%) and 31 (24.0%) pts in Arm B. Median PFS was 18.9 months in Arm A and 15.8 months in Arm B (HR 0.65; 95% CI 0.48–0.89; p=0.007). Median OS was not reached in either arm. ORR was 63.3% (95% CI 53.5–72.3) in Arm A and 55.7% in Arm B (95% CI 45.7–65.3; p=0.25). Median DoR was 27.1 months in Arm A and 15.1 months in Arm B (HR 0.57; 95% CI 0.36–0.91; p=0.02). All grade adverse events (AEs) occurred in 122 pts in each arm (96.1% in Arm A and 98.4% in Arm B); grade ≥3 AEs in 64 (50.4%) and 48 (38.7%) pts. The most common grade ≥3 AEs (≥5%; Arm A vs. Arm B) were hypertension (10.2% vs. 11.3%), diarrhea (7.1% vs. 2.4%), and neutropenia (3.1% vs. 6.5%).

**Conclusions:**
PERTAIN met its primary endpoint: P + H + AI is effective and well tolerated, and may offer a novel treatment option for pts with HER2-positive/hormone receptor-positive LA/MBC.
Title: Integrated analysis of multidimensional genomic data on CALGB 40601 (Alliance), a randomized neoadjuvant phase III trial of weekly paclitaxel (T) and trastuzumab (H) with or without lapatinib (L) for HER2-positive breast cancer

Tanioka M, Fan C, Carey LA A, Hyslop T, Pitcher BN N, Parker JA A, Hoadley KA A, Henry NL L, Tolaney S, Dang C, Krop IE E, Harris L, Berry DA A, Mardis E, Perou CM M, Winer EP P and Hudis CA A. University of North Carolina, Chapel Hill, NC; Alliance Statistics and Data Center, Duke University, Durham, NC; University of Michigan, Ann Arbor, MI; Dana Farber Cancer Institute, Boston, MA; Memorial Sloan Kettering Cancer Center, New York, NY; National Cancer Institute, Bethesda, MD; Alliance Statistics and Data Center, M.D. Anderson, Houston, TX and Washington University, St. Louis, MO.

Background: RNA profiling and mutational analyses in CALGB 40601 (NCT00770809) found significant impact on pathologic complete response (pCR) rates from tumor (intrinsic subtype, p53 mutation) and microenvironmental (immune cell) features. Integrated analysis across platforms is needed to better understand the roles of these different factors with respect to response to HER2-targeted therapies.

Methods: We performed a comprehensive genomic analyses on pCR, defined as no invasive tumor in the breast, by integrating clinicopathological information with somatic mutation status, 422 segment-level DNA Copy Number Alterations (CNAs), and 510 gene expression signatures using mRNAseq and DNA exome sequencing from 213 pre-treatment tumors. Excluding 48 samples in the TL arm that was closed early due to futility, and 4 Normal-like tumors, the dataset consisted of 161 patients from TH and THL arms including 47 HER2-enriched (HER2E), 8 Basal-like, 54 Luminal A, and 52 Luminal B, all of whom received H. The main analysis was performed using the Elastic Net on multivariate logistic regression models for predicting pCR. The samples were divided into a training and a test set, then models were built to predict pCR by 10-fold cross-validation in the training set, then applying the best model onto the test set to construct ROC curves and evaluate prediction accuracy by calculating area under ROC (AUC). We also used the DawnRank, a network-based bioinformatics tool that integrates DNA and RNA data to identify driver genes, to find predictors of resistance to H-containing therapies.

Results: Among clinicopathological factors, clinical estrogen/progesterone receptor (ER/PgR) status and intrinsic subtype by PAM50 were statistically associated with pCR, but treatment arm (TH vs THL) and stage were not. In the Elastic Net analysis, the models incorporating either gene signatures (AUC: 0.724) or CNAs (AUC: 0.777) were more predictive of response than mutation status model (AUC: 0.635). Gene signatures and CNAs were further combined with either mutation status (AUC: 0.773), clinical ER/PgR status (AUC: 0.787) or ER/PgR status plus intrinsic subtype (AUC: 0.784). The combination with the highest AUC comprised gene signatures, CNAs, and ER/PgR status, and demonstrated that CNAs at Chromosome (Chr.) 6p, 10q22, or 11q23, the signature of Correlation to HER2E, and a T-cell signature, positively predicted pCR and that Luminal and PgR gene signatures were negative predictors. The CN gain of Chr.6p, which contains the HLA genes, predicted for pCR and was associated with higher expression of HLA genes and B cell / IgG signatures. The CN loss of Chr.11q23 including CD3D, CD3E, and CD3G was also identified by DawnRank as a region associated with resistance.

Conclusions: Tumor genetics (CNAs), tumor RNA subtype (HER2E, Luminal), and the microenvironment (immune cells) were independently predictive of response to H-containing therapies and biologically and clinically important for HER2-positive breast cancer, supporting integrated RNA- and DNA-based tumor assessments to clarify response to HER2-targeting. Support: U10CA031946/033601/180821/180882/180888.
Title: A phase III trial evaluating pCR in patients with HR+, HER2-positive breast cancer treated with neoadjuvant docetaxel, carboplatin, trastuzumab, and pertuzumab (TCHP) +/- estrogen deprivation: NRG Oncology/NSABP B-52

Rimawi MF F, Cecchini RS S, Rastogi P, Geyer, Jr CE E, Fehrenbacher L, Stella PJ J, Dayao Z, Rabinovitch R, Dyar SH H, Flynn PJ J, Baez-Diaz L, Paik S, Swain SM M, Mamounas EP P, Osborne CK K and Wolmark N. NRG Oncology/NSABP (NRG Oncology/NSABP Legacy Trials Are Now Part of the NRG Oncology Portfolio); Baylor College of Medicine/Dan L Duncan Comprehensive Cancer Center, Houston; The University of Pittsburgh; The University of Pittsburgh Cancer Institute; Massey Cancer Center, Virginia Commonwealth University; Kaiser Permanente Oncology Clinical Trials Northern California, Vallejo; Michigan Cancer Research Consortium NCORP; New Mexico Minority Underserved NCORP/University of New Mexico Cancer Center; University of Colorado Cancer Center LAPS; Southeast Clinical Oncology Research (SCOR) Cancer Control Consortium NCORP; Metro Minnesota Community Oncology Research Consortium; Puerto Rico Minority Underserved NCORP, San Juan; Severance Biomedical Science Institute and Yonsei University College of Medicine; Lombardi Comprehensive Cancer Center, Georgetown University; UF Cancer Center at Orlando Health; Baylor College of Medicine/UT Health Science Center, San Antonio and Allegheny Health Network Cancer Institute.

Body: Background:

Preclinical evidence has shown that in xenograft models with estrogen receptor (ER)+/HER2+ breast cancer, signaling through the ER pathway can be enhanced in the presence of anti-HER2 treatment and lead to treatment resistance. Concurrent targeting of ER and HER2 has led to enhanced treatment efficacy and complete tumor disappearance. We hypothesized that targeting ER with endocrine therapy concurrently with chemotherapy plus dual HER2 inhibition will not be antagonistic and can overcome ER-mediated resistance and result in higher pCR as neoadjuvant treatment of ER+/HER2+ breast cancer. NRG Oncology/NSABP B-52 is a phase III, multicenter, randomized neoadjuvant therapy trial designed to determine whether the addition of estrogen deprivation to neoadjuvant therapy consisting of docetaxel, carboplatin, trastuzumab, and pertuzumab (TCHP+Est-Dep) yields a greater rate of pCR (breast and nodes) than TCHP alone.

Methods:

A total of 315 patients (pts) were randomly assigned between January 15, 2014 and March 17, 2016 to receive neoadjuvant therapy consisting of TCHP with or without estrogen deprivation therapy. Pts with locally advanced, hormone receptor-positive, HER2+ invasive breast cancer with no evidence of metastatic disease were eligible. Premenopausal women randomized to estrogen deprivation therapy received ovarian function suppression with goserelin (LHRH agonist) or equivalent plus an aromatase inhibitor (AI). Postmenopausal women received an AI. The determination of pCR (breast and nodes) was defined as the absence of any invasive component in the resected breast specimen and all resected lymph nodes following completion of neoadjuvant therapy. Following the intent-to-treat principle, the difference between the rates of pCR (breast and nodes) was tested using the binomial test for the difference between two proportions. The study was designed to have a statistical power of 80% to detect an increase in the pCR rate from 45% in the TCHP alone group to 60% in the TCHP+Est-Dep group.

Results:

The groups were balanced, with 57% clinically node positive and 50% premenopausal. Assessments for pCR were available from 308 of 315 randomized patients. The pCR (breast and nodes) for TCHP alone and TCHP+Est-Dep were 40.9% and 46.1%, respectively (p=0.36). The pCR (breast) were 44.2% and 47.4%, respectively (p=0.57). Grade 3/4 toxicities included diarrhea (23%, <1% vs 21%,0%) vomiting (8%, <1% vs 5%, 0%), and febrile neutropenia (5%, <1% vs 7%,1%) for TCHP vs TCHP plus estrogen deprivation.

Conclusion:

The addition of estrogen deprivation to neoadjuvant chemotherapy is not antagonistic. It improved pCR rates numerically, but the improvement was not statistically significant. The combination did not increase toxicity and may be a reasonable approach since all patients will receive endocrine therapy after neoadjuvant therapy. Correlative science studies including evaluation of residual cancer burden (RCB) and long-term outcomes will help define the role of estrogen deprivation in the treatment of HER2+ early breast cancer.

Title: Impact of radiotherapy on complications and patient-reported satisfaction with breast reconstruction: Findings from the prospective multicenter MROC study

Jagsi R, Momoh AO, Qi J, Hamill JB, Billig J, Kim HM, Pusic AL and Wilkins EG. University of Michigan, Ann Arbor, MI and Memorial Sloan Kettering Cancer Center, New York, NY.

Body: Background: Patients considering both post-mastectomy radiation (RT) and reconstruction require robust information regarding the expected outcomes of different combinations of approaches in order to make preference-concordant decisions.

Methods: In a prospective multicenter cohort study (the Mastectomy Reconstruction Outcomes Consortium, MROC, funded by NCI 1RO1CA152192) of women diagnosed with breast cancer at 11 institutions between 2012-15, we compared responses of 553 radiated and 1461 non-radiated pts who received different approaches to reconstruction. The primary dependent variables of interest were development of any breast complications (e.g. hematoma, wound infection) by one year post-reconstruction, along with satisfaction measured with the validated BREAST-Q instrument. Mixed-effects regression models assessed impact of reconstruction type and RT on the outcomes of interest. Covariate adjustment included reconstruction timing, age, extent of disease, bilateral vs unilateral treatment, chemotherapy receipt, nodal management, BMI, smoking, diabetes, race, ethnicity, education, employment, income, marital status, and hospital site.

Results: Median age was 49. Bilateral mastectomy was received by 45.6% of radiated and 53.3% of non-radiated pts (p=0.002). Autologous reconstruction was more commonly received by radiated pts (38.3% vs 25.1%, p<0.001). Immediate reconstruction was less common in radiated pts (82.6% vs 95.6%, p<0.001). By one year, at least one complication occurred in 28.8% of radiated pts (30.8% of implant pts and 25.5% of autologous pts) and 22.3% of non-radiated pts (20.4% of implant pts and 28.1% of autologous pts). Among pts with ≥2 years of follow up, a complication had occurred by 2 years in 34.1% of 331 radiated pts vs 22.5% of 946 non-radiated pts. Multivariable analysis showed immediate reconstruction, bilateral treatment, & higher BMI to be predictive of developing a complication by one year. RT effect differed by reconstruction type; RT was associated with 2.1 (95% CI = 1.45, 3.10) times higher odds of complication in implant pts, while showing no difference in autologous pts (OR=1.3, 95% CI = 0.76, 2.09). RT effect on patient outcomes also differed by reconstruction types. In implant pts, adjusted mean BREAST-Q satisfaction with breast scores were significantly lower in radiated pts than in non-radiated pts (51.5 vs. 58.0 at 1 year, p<.001; 48.9 vs. 59.8 at 2 years, p<.001), while satisfaction in autologous pts did not differ by radiation (61.3 in radiated vs. 63.5 in non-radiated at 1 year; 62.8 vs. 65.8 at 2 years). Similarly, in implant pts, satisfaction with outcomes was significantly lower in radiated versus non-radiated pts (66.5 vs. 70.8 at 1 year; p=0.03; 64.4 vs. 70.6 at 2 years, p =0.03), while there were no significant differences in autologous pts (72.7 vs. 75.2 in radiated vs. non-radiated at 1 year; 71.3 and 75.3 at year 2).

Conclusions: In the largest prospective multicenter study of outcomes of breast reconstruction to date, autologous reconstruction appears to yield superior patient-reported outcomes and lower risk of complications than implant-based approaches among patients receiving PMRT.

Title: Radioactive seed localization versus wire guided localization of nonpalpable invasive and in situ breast cancer: A Danish multicenter randomized controlled trial

Langhans L, Tvedskov TF Filtenborg, Klausen TL Levin, Jensen M-B, Talman M-L, Vejborg I, Benian C, Roslind A, Hermansen J, Oturai PS Sandor, Bentzon N and Kroman N. Rigshospitalet, University of Copenhagen, Copenhagen, Denmark; Rigshospitalet, University of Copenhagen, Copenhagen, Denmark; Danish Breast Cancer Cooperative Group, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark; Rigshospitalet, University of Copenhagen, Copenhagen, Denmark; Rigshospitalet, University of Copenhagen, Copenhagen, Denmark; Herlev Hospital, University of Copenhagen, Copenhagen, Denmark; Herlev Hospital, University of Copenhagen, Copenhagen, Denmark; Rigshospitalet, University of Copenhagen, Copenhagen, Denmark; Herlev Hospital, University of Copenhagen, Copenhagen, Denmark; Herlev Hospital, University of Copenhagen, Copenhagen, Denmark.

Body: Background:
The current standard method for locating nonpalpable breast lesions is wire guided localization (WGL) despite several methodological difficulties. Radioactive Seed Localization (RSL) has been developed to reduce these difficulties. The aim of this randomized trial was to compare the rate of positive resection margins between RSL and WGL in patients with nonpalpable invasive breast cancer (IBC) or ductal carcinoma in situ (DCIS).

Material and Methods:
Patients with nonpalpable IBC or DCIS visible on ultrasound were randomized to either of the two localization methods. Primary outcome was margin status at the final pathological evaluation. According to Danish standard in the study period margins were defined positive if cancer cells were found < 2mm from the inked margin. Secondary outcomes were duration of the surgical procedure, weight of the excised specimen and patient's pain perception. χ²-test, Fisher's exact test and Wilcoxon rank-sum test, respectively, were used to test differences between groups. Level of statistical significance was set to 5%. The average activity of seeds used in the trial was 1.70 MBq (range 0.7-3.27).

Results:
413 cases representing 409 patients were randomized; 207 were allocated to RSL and 206 to WGL. 23 cases, who did not meet inclusion criteria, chose to withdraw, or had a change in surgical management, were excluded. The remaining 390 were included in the analysis. Patient, surgical and pathological characteristics between the two groups were alike, except for significantly more patients with DCIS in the WGL group (5.1% vs 0.5%). Significantly more cases in the WGL group (9.7%) needed additional localization compared to the RSL group (2.1%) (p=0.0014). In all cases but one in the RSL group, the index lesion was removed. Margins were positive in 23 cases (11.8%) in the RSL group compared to 26 cases (13.3%) in the WGL group. We were not able to detect a difference in margin status between the two groups (p=0.65). For IBC only, the number of positive margins was 22 (11.3%) in the RSL group and 21 (11.4%) in the WGL group (p=0.997). There was no difference between the two groups in the amount of tissue removed whether the analysis was done on the primary excision (p=0.18) or the total weight including intraoperative re-excisions (p=0.33). There was no difference in pain perception between the two groups whether patients who received local anesthesia were kept in the analysis (p=0.28) or excluded (p=0.91). Local anesthesia was used more frequently in the RSL group. Finally, there was no difference in the duration of the surgical procedure (p=0.12), the complication rate (p=0.89) or the identification rate for SN (p=1.0).

Conclusions:
We were not able to detect any differences considering positive margins, patient's pain perception or duration of the surgical procedure between the two localization methods. However, RSL offers a major logistic advantage, as the seed localization can be done several days before surgery without any risk or discomfort for the patient, with a low proportion of patients needing additional localization. So the RSL procedure has now been found preferable at our institutions.
Title: A novel BRD4 inhibitor enhances endocrine therapy efficacy and circumvents endocrine-resistance in estrogen receptor-positive breast cancer models

De Angelis C, Nardone A, Cataldo ML, Fu X, Trivedi M, Yi S, Breckenridge D, Chamnsess GC C, Vitorino P, Osborne CK Kent and Schiff R.  Lester & Sue Smith Breast Center, Baylor College of Medicine, Houston, TX;  Dan L. Duncan Comprehensive Cancer Center, Baylor College of Medicine, Houston, TX;  Baylor College of Medicine, Houston, TX;  University of Houston College of Pharmacy, Houston, TX and  Gilead Science, Foster City, CA.

Body: Background: The selective estrogen receptor (ER) down-regulator (SERD) fulvestrant (Ful) antagonizes ER activity and degrades ER protein in a dose-dependent manner in the preclinical and clinical settings, though its efficacy is limited by an incomplete abolition of ER protein levels. Therefore additional strategies are needed to achieve a more complete suppression of ER level and activity. The bromodomain-containing protein 4 (BRD4), a member of the BET family that is required both for ESR1 gene expression and for ER-mediated gene transcription, represents an attractive therapeutic target for ER+ breast cancer (BC). Here, we investigated the efficacy of the novel BRD4 inhibitor GS-626510 (GS-6510) in a panel of ER+ BC parental and endocrine-resistant (EndoR) cell lines and in a patient-derived xenograft (PDX) model.

Materials and Methods: The effects of GS-6510 (25nM – 290nM) alone or in combination with endocrine therapies were tested in ER+ MCF7, T47D, and ZR75-1 cell lines, as well as in their derivatives made resistant to estrogen (E2) deprivation (EDR), tamoxifen (TamR), or Ful (FulR). Cell growth (by methylene blue) after 6 days of GS-6510 and protein levels (by Western blot) after 2 days of GS-6510 were assessed. The in vivo efficacy of GS-6510, Ful, and the combination was tested in the ER+ HCBx34 PDX model. The mRNA levels of genes associated with cell cycle, ER signaling, and endocrine-resistance were assessed using the NanoString platform.

Results: A dose-dependent inhibitory effect of GS-6510 was observed in all of the experimental settings. At a clinically relevant dose, GS-6510 reduced E2-stimulated cell growth and enhanced the efficacy of endocrine therapies in all parental cell lines. In the endocrine-sensitive HCBx34 PDX model, GS-6510 reduced tumor growth and, in combination with Ful, induced tumor regression and inhibited the expression of ER-dependent and cell cycle related genes including CCND1, MYC, and BCL2. Notably, the addition of GS-6510 to EndoR cell models that continue to rely on and express ER (MCF7 EDR and TamR) led to a substantial inhibition in cell growth (85%; 98%, respectively). Though the combination of GS-6510 and Ful was not associated with a significantly greater cell growth inhibition compared to GS-6510 alone in these models, a better suppression of ER levels was observed. Interestingly, GS-6510 also remained effective in EndoR models that exhibited an ER-independent growth, including all FulR lines, though its efficacy varied among the different cell lines and resistant derivatives.

Conclusion: Our findings suggest that the epigenetic regulator BRD4 is a suitable target for therapeutic intervention in ER+ BC. The anti-tumor efficacy of GS-6510 in endocrine sensitive and especially in ER-dependent EndoR models is worthy of further clinical investigation. The growth inhibitory effects observed in some of the ER-independent EndoR models suggests that additional genes/pathways involved in endocrine resistance could be affected by GS-6510. Identifying these pathways and determining their predictive role are needed to guide patient selection for future clinical trials.
Title: The Y537S ESR1 mutation is a dominant driver of distant ER-positive breast cancer metastasis

Fuqua SAW AW, Gu G, Rechoum Y, Gelsomino L, Dustin DJ J, Corona-Rodriguez A, Beyer AR R, Pejerrey SM M, Gao M, Tsimelzon A, Tian L, Zhang X, Nagi C and Ando’ S. Baylor College of Medicine, Houston, TX; University of Calabria, Cosenza, Calabria, Italy and MD Anderson Cancer Center, Houston, TX.

Body: Background: Estrogen receptor (ESR1) mutations occur at a high frequency in metastatic breast tumors in patients treated with hormonal therapy in the metastatic setting. We do not know if these mutations are involved in metastasis.

Experimental design and methods: We generated ESR1 Y537S homozygous mutations using CRISPR Casp-9 technology. Treatment synergy was evaluated using Compusyn. Athymic mice were used in tumor xenograft studies. ChIP-Seq and transcriptome analyses were performed.

Results: We generated CRISPR ESR1 Y537S mutation homozygous knock-in clones and lentiviral stable pools in MCF-7 cells. Transcriptome profiling revealed elevated expression of Hallmark pathways, including EMT and estrogen-regulated gene expression. The EMT in mutant cells was associated with a switch from E-cadherin to vimentin, and increased expression of SNAIL and TWIST. Mutant cell growth was resistant to tamoxifen, but responsive to fulvestrant treatment. Synergistic treatment effects were observed with fulvestrant and everolimus or palbociclib. CRISPR Y537S mutant knock-in cells grown in the mammary fat-pad of athymic mice spontaneously metastasized to distant organs including the lung, intestine, and kidneys. In the presence of estrogen, there was no difference in the frequency of distant macrometastases between parental wild-type ER and CRISPR Y537S mutant ER mice. However, in the absence of estrogen, 80% of CRISPR Y537S mutant ER mice displayed overt distant macrometastases, but none were observed in parental wild-type ER mice (p=0.04). Interestingly, although CRISPR Y537S mutant ER tumors grown in the mammary fat-pad were unresponsive to tamoxifen treatment, tamoxifen significantly inhibited the growth of mutant tumors at the distant microenvironment (8-fold). Distant tumors retained ER expression and hormone sensitivity. Comparison of residual tamoxifen-treated metastatic tumors with tumors grown at the primary mammary fat-pad site using immunoblot analysis demonstrated significant reduction in estrogen-regulated gene expression, but no effect on the expression of biomarkers associated with EMT, suggesting a disconnect between EMT and distant metastasis in mutant cells. EMT genes were also identified as direct binding site targets in Y537S mutant cells compared with wide-type ER using ChIPSeq. We discovered that expression of the Y537S mutant was dominant, driving the growth of distant metastatic tumors when co-expressed with wild-type ER cells. A Y537S ER mutant-specific gene expression signature predicted poor disease-free survival of ER-positive patients using the METABRIC database, and lung-specific metastasis-free survival in a Memorial Sloan Kettering dataset.

Conclusion: The Y537S ER mutation is a driver of distant metastasis in ER-positive breast cancer cells. Although tamoxifen treatment was ineffective at reducing the growth of mutant cells grown at the primary site, it was effective at reducing distant metastasis. A Y537S ER mutant-specific gene expression signature predicted poor disease-free, and distant lung metastasis in ER-positive patients. Mutation status is a potential new predictive factor for hormone therapy of metastatic breast cancer patients on maintenance hormonal therapy.
Targeted and selective degradation of estrogen receptor (ER) alpha by PROTACs

Body: ERα-positive breast cancers comprise approximately 80% of all newly diagnosed cases. Current treatment approaches targeting ER signaling include antagonizing and/or downregulating ER or reducing estrogen levels. Faslodex (fulvestrant) is the only clinically-approved agent that is both a potent ER antagonist and downregulator but has limitations given its pharmacokinetics and route of administration. Over the past several years, targeted ER therapies have focused on developing selective estrogen receptor downregulators (SERDs, i.e, GDC-0810, GDC-0927, AZD9496, RAD1901). The mechanisms involved in ER downregulation by SERD binding are not completely understood, but evidence suggests that conformational changes in the receptor upon ligand binding combined with specific co-regulator interactions destabilize the receptor making it a target for passive proteasomal degradation. We hypothesized that the complex ER pharmacology required for SERD-based passive degradation might be different across various ER-positive cell lines and that targeted degradation of the receptor by actively recruiting the ubiquitin-proteasome machinery would provide a better approach for reducing ER levels. To test this hypothesis, we developed potent molecules directed against ER using our pioneering technology proteolysis targeting chimeras (PROTACs). PROTACs are heterobifunctional molecules that actively recruit specific E3 ligases resulting in ubiquitylation and degradation of target proteins. When testing for ER degradation using several SERDs and ER PROTACs, we discovered that both fulvestrant and ER PROTACs provided robust degradation in all ER-positive lines (<1 nM 50% degradation; >90% reduction) whereas other SERDs did not degrade or only modestly degraded the receptor. Importantly, MCF-7 cells were uniquely sensitive to SERD-based degradation of ER compared to other cell lines. Subcutaneous administration of fulvestrant (1mpk) or ER PROTACs (10 mpk) reduced uterine ER alpha levels in immature rats (>65% reduction). PROTAC-mediated degradation of ER was also achieved in breast cancer xenografts. To further validate the PROTAC mechanism, incubation of ER-positive cells with ER PROTACs resulted in increased levels of poly-ubiquitylated ERα when compared to SERDs. Lastly, to demonstrate the specificity of PROTAC-mediated ERα degradation, we utilized a cellular expression proteomics-based approach to examine over 7,000 proteins. In this experiment, only ERα and several known proteins whose genes are regulated by ERα, were significantly reduced by PROTACs. It remains to be seen how the current class of investigational downregulators will perform in the clinic. More importantly, a better understanding of the therapeutic potential and benefit of degrading the receptor instead of inhibiting the receptor needs to be explored. To that end, we continue to develop and characterize novel ER PROTACs with the anticipation that targeted ERα degradation will provide a greater clinical benefit than receptor antagonism.
Title: Tumor microenvironment of metastasis (TMEM) score is associated with early distant recurrence in hormone receptor (HR) positive, HER2-negative early stage breast cancer (ESBC)

Sparano JA A, Gray R, Oktay MH H, Entenberg D, Rohan T, Xue X, Donovan M, Peterson M, Shuber A, Hamilton D, D’Alfonso T, Goldstein LJ J, Gerlter F, Davidson N, Condeelis J and Jones J. Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; ECOG-ACRIN Research Group, Boston, MA; Albert Einstein College of Medicine, Bronx, NY; Mt. Sinai School of Medicine, New York, NY; MetaStat, Inc, Boston, MA; Weill Cornell Medical College, New York, NY; Fox Chase Cancer Center, Philadelphia, PA; Massachusetts Institute of Technology, Boston, MA and University of Pittsburgh Cancer Institute, Pittsburgh, PA.

Body: Background: Metastasis is the primary cause of death in ESBC. We have shown in mouse models that a subpopulation of tumor cells expressing invasive Mena isoforms stream, form microanatomic structures (“TMEM”) with endothelial cells and macrophages, intravasate into the circulation at TMEM sites, and metastasize (Harney et al. Cancer Discovery, 2015). Further, TMEM sites (“MetaSites”) are identifiable in human ESBC, and “MetaSite score” [MS] is positively associated with distant recurrence in HR+/HER2- ESBC independent of clinicopathologic features, including IHC4 (Rohan et al. JNCI 2014). Here we determined the association between MS and recurrence in an independent ESBC cohort (E2197; NCT00003519).

Methods: We evaluated primary tumors from 600 patients (median followup 14.8 years) with ESBC (weighted % = 50% T1, 54% N0, 46% N1) treated with surgery and 4 cycles of adjuvant chemotherapy (AC or AT) and endocrine therapy. Grade, ER, PR, and HER2, and Oncotype DX Recurrence Score (RS) were evaluated in central labs (Badve et al. JCO 2008), and MS was determined in a CLIA-certified lab using an analytically validated, fully automated digital pathology/image analysis method that identifies Mena expressing tumor cells in direct contact with CD68+ macrophages and CD31+ endothelial cells (ie, “TMEMs”, or “MetaSites”). The objectives were to determine the association between MS and distant relapse free interval (DRFI) and relapse free interval (RFI). Kaplan-Meier survival curves were used to estimate time-to-event distributions. Cox proportional hazards models were used to assess hazard ratio associated with MS while controlling for covariates, and allowing time-varying association with MS. Both Kaplan-Meier and Cox regression methods addressed stratified sampling by incorporating proper weights. All analyses were performed in R 3.2.3.

Results: MS ranged from 0-199; the weighted mean MS was lower in HR+/HER2- than TN (16.1 vs. 23.8, p=0.001) and HER2+ disease (26.2, p=0.003). MS was not associated with T or N status, and correlated poorly with RS (r=0.29). Proportional hazards models revealed a significant positive association between continuous MS and DRFI (p=0.001) and RFI (p=0.00006) in HR+/HER2- disease in years 0-5 (and by MS tertiles for DRFI [p=0.04] and RFI [p=0.01]), but not after year 5 or in TN or HER2+ disease. Proportional hazards models including clinical covariates (N0 vs. N1; T1 vs. T2; high vs. int. vs. low grade) also revealed significant positive associations for continuous MS with RFI (p=0.04), and borderline association with DRFI (p=0.08). Similar findings for MS (RFI p=0.05;DRFI p=0.10) were noted in a joint model including categorical RS (<18,18-30, >30).

Conclusions: MS, a novel metastasis biomarker reflecting interaction between streaming and metastasizing tumor cells and microenvironment, provides prognostic information complementary to classical clinicopathologic features and RS in HR+/HER2- ESBC. Further evaluation is warranted in order to identify patients at highest risk of recurrence within 5 years most likely to benefit from adjuvant chemotherapy or novel therapies. (Supported by BCRF and NCI CA21115, CA180794, CA23318, CA66636, CA180820).
Expression of the DEK oncogene promotes M2 polarization and iron recycling in tumor associated macrophages

Privette Vinnedge LM M, Pease NA A and Cheek J. Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Body: The chromatin-remodeling DEK oncogene is highly expressed in over 60% of breast cancers, regardless of sub-type. DEK over-expression correlates with poor clinical outcome, including decreased survival and chemotherapy resistance. Previously, using human breast cancer cell lines and the MMTV-Ron mouse breast cancer model, we have demonstrated that DEK expression promotes proliferation and metastasis and supports the breast cancer stem cell population. These functions were due, in part, through upregulated Wnt ligand expression and β-catenin activation, leading to paracrine and autocrine effects promoting tumorigenesis. To investigate additional drivers of DEK-induced tumorigenesis, we performed RNA-Sequencing on control and DEK over-expressing immortalized MCF10A cells. Gene ontology analysis identified several immune signaling processes. This is in alignment with the well-characterized role of DEK expression in the promotion of inflammatory diseases. We investigated the immune cell infiltration of tumors from MMTV-Ron/Dek\(^{+/+}\) and MMTV-Ron/Dek\(^{-/-}\) mice. Interestingly, we discovered that Dek-expressing tumors demonstrated decreased tumor associated macrophage (TAM) infiltration, where TAMs were largely limited to the periphery. Furthermore, these TAMs demonstrated an iron-recycling phenotype (M2 polarization), whereas TAMs from Dek-knockout tumors retained iron (M1 polarization). M1 macrophages are typically associated with inflammatory responses whereas M2 macrophages have been linked to tissue remodeling, angiogenesis, and tumor promotion. To investigate this further, we compared Dek\(^{+/+}\) and Dek\(^{-/-}\) bone marrow-derived macrophages (BMDM) and found no inherent difference in polarization. However, BMDM demonstrated different gene expression profiles when cultured in conditioned media from Dek-expressing murine breast cancer cell lines compared to isogenic Dek\(^{-/-}\) cells. BMDM exposed to conditioned media from Dek-expressing cancer cells demonstrated the same iron recycling phenotype observed \textit{in vivo}, likely caused by increased expression of ferroportin, as well as increased expression of M2 markers CXCR4, VEGF, and an elevated ARG1\(^{hi}\)/NOS\(^{lo}\) population. We thus used a combination of genetic models and small molecule inhibitors to identify the mechanism of M2 polarization of Dek-expressing cancer cells. NRF2 transcription activity was eliminated as a possible mechanism for ferroportin regulation. However, small molecule inhibitors and gene expression analyses implicated secreted Wnt ligands and S100A8/A9 alarmins from the cancer cells, and downstream C/EBP transcriptional activity in the macrophages, as possible mechanisms of Dek-induced M2 polarization. Combined, this suggests that the poor clinical outcome of high DEK expressing breast cancers may be due to not only cell intrinsic factors, but also cell extrinsic factors, such as the tumor-promoting M2 polarization of tumor associated macrophages.
Biological effects of abemaciclib in a phase 2 neoadjuvant study for postmenopausal patients with HR+, HER2- breast cancer

Hurvitz S, Martin M, Fernández Abad M, Chan D, Rostorfer R, Petru E, Barriga S, Costigan TM Michael, Caldwell CW William, Nguyen T, Press M and Slamon D. University of California, Los Angeles, CA; Hospital General Universitario Gregorio Marañón, Madrid, Spain; Hospital Universitario Ramón y Cajal, Madrid, Spain; Cancer Care Associates, Redondo Beach, CA; UF Health Cancer Center at Orlando Health, Orlando, FL; Medical University Graz, Graz, Steiermark, Austria; Eli Lilly and Company, Madrid, Spain; Eli Lilly and Company, Indianapolis, IN and University of Southern California, Los Angeles, CA.

Background: Abemaciclib is a potent oral CDK4 and 6 inhibitor, which demonstrated evidence of clinical activity and an acceptable safety profile on a continuous dosing schedule either as a single agent (MONARCH 1; NCT02102490) or in combination with endocrine therapies in heavily pre-treated women with HR+ metastatic breast cancer (BC).1,2

Methods: neoMONARCH (NCT02441946) is a randomized, multicenter, open-label phase 2 neoadjuvant study comparing the biological effects of abemaciclib plus anastrozole vs abemaciclib monotherapy vs anastrozole monotherapy in women with early-stage HR+, HER2- BC. Patients (pts) were stratified by progesterone receptor status and tumor size and randomized 1:1:1 ([abemaciclib 150mg orally [PO] every 12 hours [Q12H] plus anastrozole 1 mg PO daily [QD]], [abemaciclib 150mg PO Q12H], and [anastrozole 1mg PO QD]). Each regimen was given for 2 weeks; followed by all pts receiving abemaciclib 150mg PO Q12H plus anastrozole 1mg QD for the subsequent 14 weeks. All pts received prophylactic loperamide during the first 28 days of abemaciclib therapy, then at the discretion of the investigator. Eligible pts included postmenopausal women with HR+, HER2- clinical Stage I breast tumor ≥1 cm in diameter, Stage II, Stage IIIA, or IIIB BC. The primary objective: compare biological activity by assessing the percent change from baseline value in Ki67 protein expression after 2 weeks of therapy with the three initial regimens. Clinical activity and safety of the subsequent 14 weeks of therapy of abemaciclib plus anastrozole are evaluated as secondary objectives at surgery. Exploratory objectives included assessment of changes in cell cycle mRNAs by Modaplex (QIAGEN) analyses and PIK3CA and ESR1 mutational analysis in core biopsy samples.

Statistical methods: The design provides 80% power to detect superiority of the combination vs anastrozole monotherapy, and 80% power to detect superiority of abemaciclib monotherapy vs anastrozole monotherapy, at a 1-sided alpha level of 0.1. Secondary and exploratory objectives will be presented as descriptive data.

Results: Enrollment of 223 pts began August 2015 and was completed August 2016. At a 9 month interim analysis, abemaciclib, given either as monotherapy or in combination with anastrozole showed significantly (p<0.001, n=64) greater suppression of Ki67 after 14 days of dosing than anastrozole alone. The safety profile of the combination differed from that previously reported for abemaciclib 200mg BID monotherapy in the MONARCH 1 study1 and the Phase Ib2 with reduced incidence of diarrhea and hematologic events. Change in proliferation gene mRNAs after 2 weeks of treatment (n=38), in both tumor and blood, appeared to correlate with change in Ki67 expression, with a greater reduction in the abemaciclib-containing arms. Updated data will be presented including safety data for all 223 pts, molecular data on approximately 150 pts who are evaluable for change in Ki67 and mRNA expression at 2 weeks and approximately 100 pts evaluable for clinical efficacy, final Ki67 and RNA expression at surgery.

Title: BELLE-3: A phase III study of buparlisib + fulvestrant in postmenopausal women with HR+, HER2−, aromatase inhibitor-treated, locally advanced or metastatic breast cancer, who progressed on or after mTOR inhibitor-based treatment

Di Leo A, Seok Lee K, Ciruelos E, Lønning P, Janni W, O’Regan R, Mouret Reynier M-A, Kalev D, Egle D, Csoszi T, Bordonaro R, Decker T, Tjian-Heijnen VC, Blau S, Schirone A, Weber D, El-Hashimy M, Dharan B, Sellami D and Bachelot T. Ospedale Misericordia e Dolce, Prato, Italy; National Cancer Center, Gyeonggi-do, Republic of Korea; Hospital Universitario 12 de Octubre, Madrid, Spain; Haukeland University Hospital, Bergen, Norway; Universitätssklinikum Ulm, Ulm, Germany; University of Wisconsin, Madison, WI; Centre Jean Perrin, Clermont-Ferrand, France; Medical University of Varna, Varna, Bulgaria; Univ Frauenklinik Innsbruck, Innsbruck, Austria; JNSZ Megyei Hetényi Géza Kórház-Rendelőintézet, Szolnok, Hungary; ARNAS Garibaldi, Catania, Italy; Onkonet – Onkologie Ravensburg, Ravensburg, Germany; Maastricht University Medical Center, Maastricht, Netherlands; Rainier Hematology-Oncology/Northwest Medical Specialties, LLC, Tacoma, WA; Istituto Scientifico Romagnolo per lo Studio e la Cura dei Tumori (IRST), Meldola, Italy; Novartis Pharma AG, Basel, Switzerland; Novartis Pharmaceuticals Corporation, East Hanover, NJ and Centre Léon Bérard, Lyon, France.

Body: Background: Phosphatidylinositol 3-kinase (PI3K)/mammalian target of rapamycin (mTOR) pathway activation is a hallmark of hormone receptor-positive (HR+) breast cancer (BC) resistant to endocrine therapy (ET). Preclinical and clinical data suggest that adding a PI3K inhibitor (PI3Ki) to ET may overcome resistance. In BELLE-2, a Phase III randomized study, buparlisib (BUP; BKM120; pan-PI3Ki) + fulvestrant (FULV) demonstrated clinical activity and manageable safety in patients (pts) with HR+, human epidermal growth factor receptor 2-negative advanced BC, with the greatest treatment effect in pts with PIK3CA mutation in circulating tumor DNA (ctDNA). Here, we report results from the final progression-free survival (PFS) analysis of the BELLE-3 study.

Methods: Pts (N=432) were randomized 2:1 to BUP (100mg/day) or placebo (PBO) + FULV (500mg per standard of care) and stratified by visceral disease status. Key inclusion criteria: prior aromatase inhibitor therapy; disease progression ≤30 days from combination therapy of ET + mTOR inhibitor as last regimen. Key exclusion criteria: >1 chemotherapy regimen for advanced BC; prior PI3Ki, AKT inhibitor, or FULV; history of/active mood disorders. Primary and key secondary endpoints were PFS (local assessment; Response Evaluation Criteria In Solid Tumors v1.1) and overall survival (OS), respectively. Other secondary endpoints included: overall response rate (ORR); clinical benefit rate (CBR); efficacy by PIK3CA status in ctDNA (BEAMing technology); safety.

Results: BELLE-3 met its primary endpoint with a statistically significant improvement in PFS per investigator assessment in favor of BUP + FULV (BUP arm) vs PBO + FULV (PBO arm; hazard ratio [HR] 0.67; 95% confidence interval [CI]: 0.53–0.84; p<0.001). Median PFS (mPFS) in the BUP vs PBO arm was 3.9 vs 1.8 months. The 6-month PFS rate was 30.6% vs 20.1%. PFS per central assessment was consistent with these findings (HR 0.57; 95% CI: 0.44–0.74; p<0.001). PIK3CA status in ctDNA was available for 349 pts; 147 (42.1%) pts had PIK3CA-mutant (mut) status and 202 (57.9%) had PIK3CA-wildtype (wt) status. PFS improvement in the BUP vs PBO arm was greater in the PIK3CA-mut group (mPFS 4.7 vs 1.6 months; HR 0.50; 95% CI: 0.33–0.76) than the PIK3CA-wt group (mPFS 3.7 vs 2.7 months; HR 0.73; 95% CI: 0.52–1.01). A similar treatment effect was seen in 321 pts with PIK3CA status based on PCR in tissue samples (PIK3CA-mut HR 0.39; 95% CI: 0.23–0.65. PIK3CA-wt HR 0.83; 95% CI: 0.60–1.14). ORR was 7.6% (95% CI: 4.8–11.3) vs 2.1% (95% CI: 0.4–6.0) in the BUP vs PBO arm, and CBR at 24 weeks was 24.6% (95% CI: 19.7–29.9) vs 15.4% (95% CI: 9.9–22.4). Most common (>10%; BUP vs PBO arm) Grade 3/4 AEs were increased alanine aminotransferase (21.9% vs 2.9%), increased aspartate aminotransferase (17.7% vs 2.9%), and hyperglycemia (12.2% vs 0).

Conclusions: BELLE-3 met its primary endpoint in the full population. PFS improvement in the BUP vs PBO arm was greater in pts with PIK3CA-mut than PIK3CA-wt tumors, based on ctDNA and PCR. Secondary endpoints showed improved clinical benefit with BUP + FULV vs PBO + FULV. Safety was in line with that previously seen with the combination.

Keywords: Breast cancer; PI3K inhibitor; Fulvestrant; Buparlisib.
**Body: Background:** PIK3CA mutations frequently occur in breast cancer (BC), being present in ~40% of estrogen receptor (ER)-positive, HER2-negative breast tumors. PIK3CA mutations promote growth and proliferation of tumors and mediate resistance to endocrine therapies in BC. Taselisib is a potent and selective PI3-kinase (PI3K) inhibitor that displays greater selectivity for mutant PI3K\(\alpha\) than wild-type PI3K\(\alpha\) through a unique mechanism. In cell studies, taselisib preferentially degraded mutant compared with wild-type PI3K\(\alpha\), which was not seen with alpelisib and pictilisib. Taselisib has enhanced activity against PIK3CA-mutant BC cell lines, and clinical data include confirmed partial responses in patients with PIK3CA-mutant BC treated with taselisib either as a single agent or in combination with fulvestrant.

**Trial design:** SANDPIPER is a double-blinded, placebo-controlled, randomized, phase III study, designed to evaluate efficacy and safety of taselisib plus fulvestrant in patients with ER-positive, HER2-negative locally advanced or metastatic BC. Patients will be randomized 2:1 to receive either taselisib (4 mg daily) or placebo plus fulvestrant (500 mg intramuscular on Days 1 and 15 of Cycle 1, and on Day 1 of each subsequent 28-day cycle). Randomization will be stratified by visceral disease, endocrine sensitivity, and geographic region. The study enriches for patients with PIK3CA-mutant tumors who will be randomized separately from those with non-mutant tumors.

**Eligibility:** Postmenopausal women with ER-positive, HER2-negative, locally advanced or metastatic BC are eligible if they have disease recurrence or progression during or after aromatase inhibitor treatment. A valid cobas® PIK3CA Mutation Test result via central assessment is required prior to enrollment.

**Aims:** The primary efficacy endpoint is investigator-assessed progression-free survival (PFS) in patients with PIK3CA-mutant tumors. Additional endpoints include overall survival (OS), objective response rate (ORR), clinical benefit rate (CBR), duration of objective response, safety, pharmacokinetics, and patient-reported outcomes.

**Statistical methods:** The primary efficacy analysis population will include all randomized patients with PIK3CA-mutant tumors. Patients will be grouped according to randomized treatment arm. Median PFS and OS will be estimated using Kaplan–Meier methodology. Cox proportional-hazards models, stratified by the stratification factors, will be used to estimate the hazard ratio with 95% confidence intervals (CIs). ORR, CBR, and their 95% CIs will be estimated. Duration of objective response will be estimated using Kaplan–Meier methodology. Quality of life will be analyzed and summarized. Safety will be analyzed for all treated patients according to actual treatment received.

**Accrual:** Target enrollment is 600 patients. The study is open for enrollment and, as at April 2016, over 200 patients have been enrolled. Clinicaltrials.gov ID: NCT02340221.

**Contact information:** For more information or to refer a patient, email global.rochegenentechtrials@roche.com or call 1-888-662-6728 (USA only).
Title: COLET: A multistage, phase 2 study evaluating the safety and efficacy of a doublet regimen of cobimetinib (C) in combination with paclitaxel (P) or triplet regimens of C in combination with atezolizumab (atezo) plus either P or nab-paclitaxel (nab-P) in metastatic triple-negative breast cancer (TNBC)

Miles D, Kim S-B, McNally V, Simmons B, Wongchenko M, Xu N and Brufsky A. Mount Vernon Cancer Centre, London, United Kingdom; Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; Roche Products Ltd., Welwyn Garden City, United Kingdom; Genentech, Inc., South San Francisco, CA and University of Pittsburgh, Pittsburgh, PA.

Body: Preclinical data suggest that upregulation of the MAPK pathway confers resistance to taxane chemotherapy. Mutations and gene amplifications in the MAPK pathway are present in many TNBC tumors and may contribute to taxane resistance. Preliminary data from an initial safety run-in stage of the COLET study (ClinicalTrials.gov ID, NCT02322814; EudraCT number, 2014-002230-32) suggest improvement of clinical outcomes when MEK inhibition is combined with taxane chemotherapy. Additionally, in preclinical models, MEK inhibition was shown to enhance anti–PD-L1 activity. The monoclonal antibody PD-L1 inhibitor atezo has shown promising activity in combination with nab-P in metastatic TNBC. Accordingly, the COLET protocol was amended to include the evaluation of triplet regimens combining atezo with MEK inhibition and taxane chemotherapy.

COLET is evaluating the safety and efficacy of various combinations of C as first-line treatment for metastatic or locally advanced TNBC. Key eligibility criteria include measurable disease per Response Evaluation Criteria in Solid Tumors, version 1.1 (RECIST v1.1) and left ventricular ejection fraction > institutional lower limit of normal or >50%. Neoadjuvant or adjuvant therapy is allowed if completed >6 months prior to study entry. COLET has 3 cohorts: I, II, and III. Cohort I has 2 stages: an initial safety run-in stage (n~12) followed by an expansion stage (n~90) of 1:1 randomization to C + P or placebo (PBO) + P. Patients received P 80 mg/m² on days 1, 8, and 15 and C/PBO 60 mg/day on days 3-23 of each 28-day cycle. In the expansion stage of Cohort I, randomization is stratified by prior neoadjuvant/adjuvant taxane therapy and disease-free interval from last chemotherapy dose. Cohorts II and III will evaluate the safety and efficacy of adding atezo to C + P or nab-P, respectively. Each cohort has a safety run-in stage (n~15) and an expansion stage (additional n~15); each will receive atezo 840 mg on days 1 and 15 and C 60 mg/day on days 3-23 of every 28-day cycle. Cohort II will receive P 80 mg/m² and Cohort III will receive intravenous nab-P 100 mg/m² on days 1, 8, and 15. Patients will receive treatment until disease progression or toxicity. The primary efficacy end point is investigator-assessed progression-free survival (PFS) for the expansion stage (Cohort I), and the primary PFS analysis will be performed when 60 PFS events occur across the 2 arms. This provides 77% power to detect a hazard ratio of 0.5 at a two-sided significance level of 0.05. For Cohorts II and III, the primary efficacy end point is overall response rate per RECIST v1.1; secondary end points include duration of response, PFS, and overall survival. Recruitment into the safety run-in stage of Cohort I is complete. Accrual into the randomization stage of Cohort I and the initial safety run-in stage of Cohorts II and III are ongoing. Patients from sites across North America, Europe, and the Asia-Pacific region will be enrolled.
Title: Phase II Trial of the addition of pembrolizumab to letrozole and palbociclib in patients with metastatic estrogen receptor positive breast cancer who have stable disease on letrozole and palbociclib

Background: The combination of palbociclib and letrozole has become the standard of care for patients with newly diagnosed estrogen receptor positive (ER+) metastatic breast cancer (MBC), with promising prolongation of progression free survival (PFS). However, nearly half of all patients achieved stable disease only after the first 6 months of therapy. Check-point inhibitor pembrolizumab was effective in ER+ MBC with a response rate of 13-17%, this study will evaluate the efficacy of adding pembrolizumab for patients with ER+ MBC who have achieved stable disease (SD) on letrozole and palbociclib.

Trial Design: This is an open-label single institutional study. Patient will receive letrozole (2.5 mg) once a day and palbociclib (125 mg, 100 mg, or 75 mg as established tolerated dose) once a day for 3 weeks on and 1 week off. Pembrolizumab will be given at 200 mg IV every 3 weeks.

Eligibility Criteria: Eligible patients must be postmenopausal women with ER+ MBC with measurable disease by RECIST1.1, ECOG performance status 0-1; must have received letrozole and palbociclib for at least 6 months, and have documented SD per RECIST 1.1. Up to 3 lines of previous systemic therapy including endocrine therapy and/or chemotherapy are allowed. Patients are excluded if they had prior treatment with anti--PD1 or anti-PD-L1 therapy, immunodeficiency; currently using systemic steroids active tuberculosis infection; major surgery within 28 days; active or untreated CNS metastases; history of interstitial lung disease; active infection requiring systemic therapy; or active cardiac disease.

Specific Aims: The primary objective is to evaluate the objective response rate (ORR). The secondary objective is to determine the safety and tolerability of pembrolizumab plus the letrozole/palbociclib combination. We will use clinical benefit rate (CBR), duration of response (DOR), PFS, and OS to test the efficacy of this novel drug combination.

Statistical Design: We will employ a three-at-risk design (modified rolling design) for the initial cohort of this Phase II study to insure the triplet is well-tolerated. This design permits only 3 patients to be a risk for DLT at any one time during the “safety lead-in”. When the first 6 patients have completed the observation period and treatment with ≤1 DLT, the safety lead-in for the triplet will be considered successful, and accrual will proceed to a total of 18 patients. Response (CR or PR by RECIST version 1.1) in patients who have demonstrated only SD on letrozole and palbociclib can be reasonably attributed to the addition of pembrolizumab. As a result, we set the probability of a response occurring without the addition of pembrolizumab as 3% or less. With 18 patients, a true response rate of 20% would result in at least 2 responders with 90% power and a type I error of 10%. With 18 patients, the response can be estimated with a 95% CI half-width of 23%.

Target Accrual: 18.
Title: SOLAR-1: A phase III study of alpelisib and fulvestrant in men and postmenopausal women with hormone receptor-positive (HR+), human epidermal growth factor receptor 2-negative (HER2-) advanced breast cancer (BC) progressing on or after aromatase inhibitor (AI) therapy

Body: Background: The phosphatidylinositol 3-kinase (PI3K)/mammalian target of rapamycin (mTOR) pathway is often dysregulated in HR+ BC and is associated with resistance to endocrine therapy (ET). Alpelisib (BYL719; PI3Kα-specific inhibitor) and fulvestrant showed signs of antitumor activity in patients (pts) with estrogen receptor-positive (ER+), HER2– advanced BC (phase I), especially in \( \text{PIK3CA} \)-altered tumors (Janku et al. SABCS 2014, PD5-5).

Methods: SOLAR-1 (NCT02437318) is a phase III, randomized, double-blind study in men and postmenopausal women with HR+, HER2– advanced BC. Pts are assigned to 1 of 2 cohorts based on \( \text{PIK3CA} \) tumor status (mutant vs non-mutant), and randomized 1:1 to oral alpelisib/placebo (300 mg once daily) and intramuscular fulvestrant (500 mg on Day 1 and 15 of Cycle 1; Day 1 of Cycles \( \geq 2 \) [28-day cycles]) until disease progression or discontinuation. Randomization is stratified by presence of liver and/or lung metastases and prior CDK4/6 inhibitor therapy. Key inclusion criteria: recurrence or progression on or after AI therapy, \( \geq 1 \) measurable lesion (RECIST v1.1) or predominantly lytic bone lesion, and ECOG performance status \( \leq 1 \). Key exclusion criteria: symptomatic visceral disease or disease burden precluding ET, acute pancreatitis \( \leq 1 \) year prior to screening or history of chronic pancreatitis, and prior therapy with fulvestrant, chemotherapy (except [neo]adjuvant), or PI3K/AKT/mTOR inhibitors.

The primary and key secondary endpoints are progression-free survival (PFS; RECIST v1.1; local assessment) and overall survival (OS), respectively, in the \( \text{PIK3CA} \)-mutant cohort. Other secondary endpoints include PFS and OS in the \( \text{PIK3CA} \) non-mutant cohort, PFS (Blinded Independent Central Review; RECIST v1.1), the association between PFS and baseline \( \text{PIK3CA} \) status in circulating tumor DNA, overall response rate, clinical benefit rate, safety, and pharmacokinetics. The primary endpoint will be analyzed by a stratified log-rank test at one-sided 2% level of significance. Recruitment of the planned 560 pts is ongoing.
TRINITI-1: Ribociclib + everolimus (EVE) + exemestane (EXE) triplet combination in men or postmenopausal women with HR+, HER2– advanced breast cancer (ABC) following progression on a cyclin-dependent kinase (CDK) 4/6 inhibitor

Bardia A, Hurvitz S, Yardley DA A, Zelnak A, DeMichele A, Clark AS S, Warsi G, Small T, Tucci C and Moulder S. Massachusetts General Hospital Cancer Center, Harvard Medical School, Boston, MA; University of California, Los Angeles, Santa Monica, CA; Sarah Cannon Research Institute and Tennessee Oncology PLLC, Nashville, TN; Northside Hospital, Atlanta, GA; University of Pennsylvania Abramson Cancer Center, Philadelphia, PA; Novartis Pharmaceuticals Corporation, East Hanover, NJ and The University of Texas MD Anderson Cancer Center, Houston, TX.

Body: Background: There is extensive crosstalk between the cyclin D–CDK4/6–inhibitor of CDK4–retinoblastoma and phosphatidylinositol 3-kinase (PI3K)/mammalian target of rapamycin (mTOR) pathways at the G1/S cell-cycle checkpoint. Both pathways are frequently dysregulated in hormone receptor-positive (HR+) breast cancer and have been associated with endocrine therapy (ET) resistance. CDK4/6 and PI3K/mTOR inhibitors have demonstrated clinical activity in combination with ET. Although CDK4/6 inhibitors combined with ET significantly improve progression-free survival (PFS) in ABC, disease progression eventually occurs, highlighting the need for effective treatment options following doublet therapy. Ribociclib (LEE011; CDK4/6 inhibitor; 3-weeks-on/1-week-off) + EVE (mTOR inhibitor) + EXE triplet therapy has shown preliminary clinical activity in heavily pretreated HR+, human epidermal growth factor receptor 2-negative (HER2–) ABC including patients (pts) with prior exposure to CDK4/6 inhibitors, suggesting this combination may restore sensitivity to CDK4/6 inhibitor-based therapy.

Trial design and objectives: TRINITI-1 (NCT02732119) is a US-based, phase I/II, single arm, open-label study of ribociclib (continuous daily dosing) + EVE (2.5 mg/day) + EXE (25 mg/day) in men and postmenopausal women with HR+, HER2– ABC refractory to ≥1 line of ET. Phase I dose escalation consists of 2 ribociclib dose-level cohorts (250 and 300 mg/day), followed by a Simon Two-Stage phase II trial in pts with disease progression on prior CDK4/6 inhibitor-based therapy. No more than 3 lines of therapy for ABC, including ≤1 prior chemotherapy regimen, are permitted. Previous EXE treatment of >28 days for metastatic disease, prior mTOR inhibitors, and progression on >1 CDK4/6 inhibitor are prohibited. All pts in phase II must have progressed on a CDK4/6 inhibitor as the last regimen before study entry. Additional eligibility criteria include measurable disease or lytic/mixed bone lesions and Eastern Cooperative Oncology Group performance status of ≤1. Exclusion criteria include visceral crisis, unstable CNS metastases, and clinically significant heart disease. Phase I primary objective: maximum tolerated dose and/or recommended phase II dose of the triplet combination. Phase II primary objective: clinical benefit rate (CBR) at 24 weeks (0.1 significance level, 80% power to test CBR ≤15% against CBR ≥30%) with centrally-assessed PFS as a key secondary objective. Other secondary objectives include preliminary antitumor activity (phase I), safety and pharmacokinetics (phase I/II), and overall response rate, overall survival, and duration of overall response (phase II). Tumor assessments (RECIST v1.1) will be performed every 8 weeks for the first 12 months, and every 12 weeks thereafter until disease progression. Exploratory analyses include biomarkers potentially predictive of response and mechanisms of resistance.

Target accrual: Approximately 52 pts at ~30 sites; 3–6 pts per cohort in phase I, an initial 19 in phase II with another 20 enrolled upon demonstration of clinical benefit in ≥4 pts.
Title: Phase III study of palbociclib (PD-0332991) in combination with endocrine therapy (exemestane or fulvestrant) versus chemotherapy (capecitabine) in hormonal receptor (HR) positive/HER2 negative metastatic breast cancer (MBC) patients with resistance to aromatase inhibitors. “The PEARL study” (GEICAM/2013-02)

Body: Background: Endocrine therapy (ET) is the cornerstone treatment for HR–positive, HER2-negative breast cancer patients. However, endocrine resistance is a major clinical challenge. Treatment options at recurrence/progression to AIs include sequential endocrine-based therapies in monotherapy or in combination with a targeted agent or chemotherapy. Preclinical data suggest that ER+/HER2- BC is dependent on cyclin-dependent kinases 4/6 (CDK4/6) function; the inhibition of this target may be effective in overcome endocrine resistance. Palbociclib (P) is an oral novel CDK4/6 inhibitor that is synergistic with ET in preclinical and clinical studies. Initially this study was designed to demonstrate the clinical benefit of P plus exemestane (E) vs capecitabine (C) (cohort1). Recent studies revealed that the acquisition of \( \text{ESR1} \) mutations is a major mechanism of resistance to the treatment of AIs in the metastatic setting. Retrospective analyses show that patients with \( \text{ESR1} \) mutation derived no benefit from sequential AI monotherapy. In contrast, preclinical and clinical data indicated that SERD, fulvestrant (F), is active in \( \text{ESR1} \) mutant tumors. Hence the choice of endocrine partner with P is particularly important to create optimal synergy in endocrine resistance setting. The current design added cohort 2 of P plus F vs C. The overall study goal is to prospectively answer the question of optimal endocrine partner with P and its efficacy/safety over chemotherapy in endocrine resistant setting.

Trial Design: This is an international (5 countries) randomized phase III study with 2 cohorts, patients will be randomized 1:1 to ET (cohort 1: E 25 mg daily, cohort 2: F 500mg days 1 and 15 cycle 1 and then day 1 every 4 weeks) plus P (125 mg daily x3 weeks every 4 weeks) vs. C (1,250 mg/m² twice daily x2 weeks every 3 weeks). Postmenopausal patients with HR+/HER2- MBC are eligible if resistant to previous AI (letrozole or anastrozole in cohort 1 or any AI in cohort 2) defined as: recurrence while on or within 12 months after the end of adjuvant treatment or progression while on or within 1 month after the end of treatment for MBC. Previous chemotherapy is permitted either in the (neo)adjuvant setting and/or as first line for MBC. Patients must have measurable disease according to RECIST 1.1 or bone lesions, lytic or mixed, in the absence of measurable disease. The primary objectives are to demonstrate that P plus F is superior to C and that P plus ET is superior to C inwomen whose tumor had estrogen receptor ESR1 wild type in terms of Progression-Free Survival (PFS); secondary objectives are PFS regardless the ESR1 mutational status, overall survival, response rate, clinical benefit rate, response duration, safety, quality of life and biomarkers. The study will recruit approximately 302 patients in cohort 1 and 300 patients in cohort 2. The study started recruitment in March 2014; 290 patients have been included so far (289 cohort1 + 1 cohort 2). Analysis of primary endpoint is planned in Sep2019 (ClinTrials.gov reference NCT02028507).
Title: A phase 2 study of abemaciclib plus pembrolizumab for patients with hormone receptor positive (HR+), HER2 negative (HER2-) metastatic breast cancer (MBC)

Rugo H, Tolaney S, Dickler M, Kabos P, Ho C-L, Wildiers H, Jerusalem G, Alés-Martínez JE, Hossain A, Johnston E and Gianni L. University of California San Francisco Helen Diller Family Comprehensive Cancer Center, San Francisco, CA; Dana-Farber Cancer Institute, Boston, MA; Memorial Sloan-Kettering Cancer Center, New York, NY; University of Colorado Anschutz Medical Campus, Aurora, CO; Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan; Universitair Ziekenhuis Leuven (Gasthuisbert), Leuven, Belgium; Centre Hospitalier Universitaire du Sart Tilman, Liège, Belgium; Hospital Nuestra Señora de Sonsoles, Complejo Hospitalario de Ávila – Oncology, Ávila, Spain; Eli Lilly and Company, Indianapolis, IN and IRCCS Ospedale, Milano, Italy.

Body: Background:
Abemaciclib is a small molecule inhibitor of both cyclin-dependent kinase (CDK) 4 and CDK6 administered orally twice daily on a continuous schedule. In I3Y-MC-JPBA, a phase I study, abemaciclib demonstrated acceptable safety, tolerability, and single-agent activity as monotherapy in different tumor types, including HR+ MBC (Patnaik A, et al. Cancer Discov 2016;6:1–14).

In MONARCH 1, a phase 2 study, abemaciclib demonstrated a 19.7% objective response rate (ORR) with a median duration of response (DoR) of 8.6 months, median progression-free survival (PFS) of 6.0 months, and clinical benefit rate (CBR) of 42.4% in patients with HR+, HER2- MBC whose disease progressed on or after endocrine therapy and chemotherapy (Dickler, M. et al. American Society of Clinical Oncology (ASCO), abstract #510 (2016)). Pembrolizumab is a humanized monoclonal antibody against the programmed death receptor-1 (PD-1) protein that has shown preliminary efficacy in single-arm monotherapy trials in ER+/HER2- advanced breast cancer.

Trial design:
This open-label, phase 2 study will evaluate the safety and preliminary efficacy of abemaciclib 150 mg given orally every 12 hours on days 1-21 of a 21-day cycle in combination with intravenous pembrolizumab 200 mg on day 1 of a 21-day cycle in approximately 75 patients with stage IV non-small cell lung cancer or HR+, HER2- MBC (ClinicalTrials.gov NCT02779751). The study will include 3 disease-specific cohorts, each with approximately 25 patients. Only the HR+, HER2- MBC cohort will be presented here.

Eligibility criteria:
Eligible patients for the MBC cohort include women with confirmed HR+, HER2- MBC who have completed at least 1 but no more than 2 prior chemotherapy regimens in the metastatic setting; will provide tumor tissue prior to and after treatment (cycle 3, day 1); have measurable disease (RECIST v.1.1), adequate organ function, an ECOG performance status ≤1, and a life expectancy ≥12 weeks; are ≥18 yrs of age and able to swallow oral medications; and have not received treatment with any CDK 4 and 6 inhibitors or PD-1 or PD-L1 inhibitors.

Specific aims:
The primary objective is to characterize the safety profile of the combination of abemaciclib and pembrolizumab. Key secondary objectives include ORR, DoR, disease control rate (DCR), PFS, overall survival (OS), and characterization of pharmacokinetics.

Statistical methods:
The safety population includes patients who received at least one dose of study drug. ORR, DoR, DCR, and PFS analyses will be evaluated according to RECIST v.1.1 and irRECIST for disease progression. Time-to-event variables, such as DoR, PFS, and OS, will be estimated by Kaplan-Meier methodology. An interim analysis of safety and preliminary efficacy may occur for each cohort after all patients have completed (or discontinued from) approximately 24 weeks of treatment. The final analysis of OS will occur based on data collected for approximately 12 months after the last patient receives treatment.

Target accrual:
Approximately 75 patients are planned for the trial; 25 patients will comprise the MBC cohort.

Title: Phase 2 study of abemaciclib plus tamoxifen or abemaciclib alone in women with previously treated hormone receptor-positive (HR+), HER2- metastatic breast cancer

Diéras V, Hamilton E, Johnston EL L, Forrester T and Martín M. Institut Curie Paris, Paris, France; Sarah Cannon Research Institute, Nashville, TN; Eli Lilly and Company, Indianapolis, IN and Hospital General Universitario Gregorio Marañón, Madrid, Spain.

Body: Background:
Abemaciclib, an oral drug administered twice daily on a continuous schedule, is a specific inhibitor of both CDK4 and CDK6. In MONARCH 1, abemaciclib demonstrated evidence of single-agent activity and an acceptable safety profile in patients with heavily pretreated HR+, HER2- metastatic breast cancer (MBC) whose disease progressed on or after endocrine therapy and chemotherapy; with a confirmed objective response rate of 19.7% and a median duration of response of 8.6 months (Dickler, M. et al. American Society of Clinical Oncology (ASCO), abstr #510 (2016)). This Phase 2 study I3Y-MC-JPCG will evaluate the potential to enhance the risk/benefit profile of abemaciclib in women with previously treated HR+, HER2- MBC, either administered in combination with endocrine therapy or as monotherapy (at the maximum recommended single-agent dose with primary prophylactic antidiarrheal medication or at a lower dose of abemaciclib monotherapy). Such intervention with prophylactic loperamide may increase dose intensity and further optimize the clinical benefit for patients.

Trial design:
Study JPCG (NCT02747004) is a Phase 2 multicenter, randomized, open-label trial with 3 separate treatment arms in patients with HR+, HER2- MBC who have progressed on or after prior endocrine therapy and have received prior treatment with chemotherapy. Patients will be stratified based on presence of liver metastases and prior use of tamoxifen in the advanced/metastatic setting and will be randomized in a 1:1:1 ratio to receive abemaciclib 150 mg Q12H plus tamoxifen 20 mg every day (Arm A) or abemaciclib 150 mg Q12H monotherapy (Arm B); or abemaciclib 200 mg Q12H monotherapy plus primary prophylactic loperamide (Arm C).

Eligibility criteria:
Eligible patients include women with HR+, HER2- MBC with evidence of relapse or disease progression following endocrine therapy who have received prior treatment with at least 2 chemotherapy regimens, of which at least 1 but not more than 2 regimens have been administered in the metastatic setting. Patients are required to have measurable disease, adequate organ function, an ECOG PS of ≤1, and no prior treatment with any CDK4 and CDK6 inhibitor.

Specific aims:
The primary objective of JPCG is to evaluate the progression-free survival per RECIST v1.1, of abemaciclib 150 mg Q12H plus tamoxifen 20 mg QD, abemaciclib 150 mg Q12H monotherapy, and abemaciclib 200 mg Q12H plus prophylactic loperamide in women with HR+, HER2- MBC who have progressed on or after prior endocrine therapy and received prior chemotherapy. Secondary objectives are to evaluate response rates, overall survival, safety, pharmacokinetics, and quality of life. Exploratory objectives include evaluation of the associations between biomarkers relevant to abemaciclib and clinical outcomes.

Statistical methods:
Assuming a hazard ratio of 0.667, the study yields approximately 80% statistical power to detect superiority of Arm A over Arm C at a 1-sided alpha level of 0.10 using a log-rank test. Arms B and C will be compared using an informal non-inferiority rule.

Target accrual:
Approximately 225 patients.

Contact information:
For further information, please contact 1-877-CTLILLY (1-877-285-4559).
Title: PALINA: A phase II safety study of palbociclib in combination with letrozole in African American women with hormone receptor positive HER2 negative advanced breast cancer

Lynce F, Shajahan-Haq A, Cai L, Graham D, Gallagher C, Mohebtash M, Kamugisha L, Novielli N, Castle J, Forero A and Isaacs C. Lombardi Comprehensive Cancer Center, MedStar Georgetown University Hospital, Washington, DC; Lombardi Comprehensive Cancer Center, Georgetown University, Washington, DC; Hackensack University Medical Center, New Jersey, NJ; MedStar Washington Hospital Center, Washington, DC; MedStar Union Memorial Hospital, Baltimore; MedStar Good Samaritan Hospital, Baltimore and University of Alabama, Birmingham, Al.

Body: Background: Insufficient data exist to describe the hematological safety of palbociclib in African American women (AAW) who are known to have a high incidence of benign ethnic neutropenia (BEN). The studies that led to the FDA approval of palbociclib (PALOMA 1 and 3) only included participants with baseline absolute neutrophil count (ANC) of ≥1500/mm³. The standard lower limit of ANC of 1500/mm³ for initiation of treatment in those with BEN has been previously challenged. In this current study, we propose to lower the ANC cutoff for enrollment to 1000/mm³.

Trial design: PALINA is a phase II study evaluating the hematological safety of palbociclib with letrozole in 35 AAW with hormone receptor (HR) positive HER2 negative advanced breast cancer and ANC ≥1000/mm³. Patients enrolled will receive palbociclib 125mg daily for 21 days followed by 7 days off and letrozole 2.5mg daily. For patients enrolled with baseline ANC between 1000-1499/mm³, initial dose of palbociclib will be 100mg daily for 21 days followed by 7 days off. Presence of Duffy Null Polymorphism (SNP rs2814778) as a predictive marker for neutrophil count will be assessed at baseline. Metabolite and exosomal signature (proteins and RNA) of drug resistance will be evaluated at different time points.

Main eligibility criteria: Self-identified Black, African or AAW of ≥18 years of age with proven diagnosis of advanced HR-positive, HER2-negative breast cancer; ECOG performance status 0-2; ANC ≥ 1,000/mm³ and no prior receipt of CDK4/6 inhibitors.

Specific aims: The primary endpoint is the proportion of patients who complete planned oncologic therapy without the development of a hematological event defined as episodes of febrile neutropenia and treatment discontinuation due to neutropenia. Additional endpoints include: number of patients who required dose delays or dose reductions in palbociclib attributed to neutropenia; rate of grade 3/4 neutropenia; clinical benefit rate at 24 weeks; correlations between metabolite and exosomal signature with disease response; correlations between baseline ANC prior to cancer diagnosis and the Duffy Null polymorphism with hematological safety.

Statistical methods: The study is designed to assess the rate of completion of planned therapy in the absence of a hematological event defined as episodes of febrile neutropenia and treatment discontinuation due to neutropenia. Simon’s two-stage design with a maximum of 35 patients is used. The null hypothesis that the true completion rate is 60% will be tested against a one-sided alternative. This design yields a type I error rate of 0.05 and power of 80% when the true completion rate is 80%.

Present accrual and target accrual: The Institutional Review Board at Georgetown University Medical Center (GUMC) has approved the study. Enrollment of the first patient is expected in July 2016 with a total of 35 patients planned to be recruited. The recruitment sites are MedStar Georgetown University Hospital and other hospitals of the Georgetown MedStar Cancer Network, Hackensack University Medical Center and University of Alabama at Birmingham. This trial is funded by an ASPIRE Breast Cancer Research Award from Pfizer.
Pilot study of carboplatin, nab-paclitaxel and pembrolizumab for metastatic triple-negative breast cancer (ongoing clinical trial)

Baar J, Abraham J, Silverman P, Budd GT, Vinayak S, Varadan V, Moore H, Montero A and Fu P. Seidman Cancer Center, Cleveland, OH; Taussig Cancer Center, Cleveland, OH and Case Comprehensive Cancer Center, Cleveland, OH.

BACKGROUND. Triple-negative breast cancer (TNBC) is associated with an aggressive phenotype and decreased survival. TNBC is characterized by tumor-infiltrating lymphocytes (TIL) which predict for a better prognosis and likely reflect immune recognition of tumor-associated antigens by TIL. However, potent immune suppressive signals exist in the tumor microenvironment such as those mediated by PD-1 with its ligand, PD-L1. Therefore, to test the validity of decreasing PD-1/PD-L1-mediated immune suppression, a Phase Ib study of single-agent pembrolizumab in 32 patients with advanced TNBC showed a partial response of 16.1% and stable disease of 9.7%, thereby attesting to the effectiveness of single-agent pembrolizumab in these patients. Other studies have demonstrated that cytotoxic chemotherapy favorably modulates immunity against cancer and there is therefore a strong rationale to combine chemotherapy with an immune modulator such as pembrolizumab for the treatment of mTNBC.

TRIAL DESIGN. This is an investigator-initiated, industry-sponsored (Merck) pilot study of carboplatin (C), nab-paclitaxel (N) and pembrolizumab (P) in 30 patients with metastatic (m) TNBC. Eligible patients will receive 3 cycles of CNP, with each cycle consisting of C (AUC 6 on days 1 of a 21-day cycle), N (100 mg/m2 IV on days 1, 8 and 15 of a 21-day cycle), and P (200 mg IV on day 15 of each cycle). After completion of 3 cycles CNP, patients with responding or stable disease by RECIST 1.1 criteria will be eligible for additional cycle(s) of CNP.

ELIGIBILITY CRITERIA. Patients must have radiologically measurable mTNBC, an ECOG performance status of 0-1, must not have received more than 2 prior therapies for this disease, and must be willing to undergo a preliminary biopsy of a metastatic focus for research purposes. A second post-treatment biopsy will be encouraged but will not be mandated.

SPECIFIC AIMS. The primary objective is to determine overall response rate (ORR) in patients treated with CNP. The secondary objectives are to determine progression-free survival (PFS) and safety/tolerability of CNP. Correlative objectives include the identification of pathologic and genomic correlates of response to CNP.

STATISTICAL METHODS. Clinical response will be scored using RECIST 1.1 criteria. Under the proposed treatment, the expected clinical response is about 35%. With the precision of the 2-sided 95% confidence interval for the response rate set to 0.17 (the distance to the expected response rate of 35%), the sample size required for the study is 30 patients. The true response rate of therapy will be estimated based on the number of responses using a binomial distribution and its confidence intervals will be estimated using Wilson's method. The Kaplan-Meier method will be used to estimate PFS. Factors including pathologic and genomic correlates that predict survival outcomes will be identified by Cox model or extensions of the Cox model.

TARGET ACCRUAL. We plan to enroll 30 patients over 2 years, with the first patient expected to be enrolled in September 2016.

CONTACT INFORMATION. Joseph Baar, MD, PhD. Seidman Cancer Center of University Hospitals Case Medical Center. E-mail: joseph.baar@uhhospitals.org.
**Body:** Background: The combination of PI3K-AKT-mTOR pathway inhibitors with endocrine therapy can improve clinical outcomes of hormone receptor positive (HR+) metastatic breast cancer (MBC) patients. Taselisib is a potent and selective PI3K inhibitor, with greater selectivity against mutant (MUT) PI3Kα isoforms than wild-type (WT) via a unique mechanism. Phase Ib data of POSEIDON with Taselisib + tamoxifen (TAM) demonstrated encouraging activity in patients with heavily pre-treated MBC, with an acceptable toxicity profile (Baird et al, ASCO 2016). The recommended phase II dose (RP2D) was Taselisib 4mg plus TAM 20mg, both administered on a daily continuous schedule. ctDNA monitoring may have value in drug development by (1) assessing predictive biomarkers to therapy, (2) providing an early indication of treatment response, and (3) shedding light on potential mechanisms of acquired drug resistance. In some patients included in phase Ib of POSEIDON, tumor response was preceded by a corresponding early change in plasma PIK3CA ctDNA levels. Methods: The phase II portion of the POSEIDON trial is a two-arm, randomized, double blind study of Taselisib plus TAM versus placebo (PLA) plus TAM in pre- and postmenopausal women with HR+/HER2- MBC. In the first part of the Phase II, 180 patients will be randomized (1:1) to receive continuous TAM with either Taselisib at the RP2D or PLA until disease progression, unacceptable toxicity or patient / physician decision. Crossover is allowed upon progressive disease in those patients receiving PLA plus TAM, after collection of tumor and blood samples for exploratory biomarker analysis. Stratification is based on menopausal status, histology [lobular breast cancer (LBC) vs. ductal/others], PIK3CA mutation (WT vs. exon 9 vs. exon 20), prior everolimus, timing of recurrence/progression after prior endocrine therapy, number of prior chemotherapy (CT) lines, and treatment center. After recruiting the initial 180 patients, trial will focus in LBC, until a total number of 110 patients with LBC are enrolled. Other key eligibility criteria include presence of measurable or evaluable disease (RECIST 1.1), prior progression to endocrine treatment, maximum of 5 prior CT lines in the metastatic setting, absence of diabetes under medical treatment, and absence of chronic inflammatory bowel disease. Primary endpoint is investigator-assessed PFS. Key secondary endpoints are PFS in LBC, objective response rate, clinical benefit rate, safety, and exploratory biomarker analysis (including ctDNA). The study has a 90% power at a two-sided log-rank test significance level of 0.2 to detect an HR of 0.64, which corresponds to an increase in median PFS from 4.5 months in the PLA plus TAM arm to 7 months in the Taselisib plus TAM arm. Enrollment to POSEIDON Phase II started in June 2016 (Clinicaltrials.gov NCT02285179).
Title: ENCORE 602: A randomized, placebo-controlled, double-blind, multicenter phase 2 study (with a phase 1b lead-in) of atezolizumab with or without entinostat in patients with advanced triple negative breast cancer (aTNBC)

Forero A, Stroyakovskiy D, Cha E, Cruickshank S, Hasapidis J, Meyers ML L and Slamon DJ J. University of Alabama at Birmingham, Birmingham, AL; Moscow City Oncology Hospital N62, Moscow, Russian Federation; Genentech, Inc., South San Francisco, CA; Syndax Pharmaceuticals, Inc., Waltham, MA and University of California Los Angeles, Los Angeles, CA.

Body: Background: Atezolizumab, a humanized anti-PDL1 antibody, has shown encouraging single agent activity in triple negative breast cancer. Entinostat is an oral, class I selective histone deacetylase (HDAC) inhibitor. In animal models, entinostat has been shown to selectively reduce immunosuppressive myeloid derived suppressor cells (MDSCs) and regulatory T cells (Tregs), enhancing response to immune checkpoint blockade. It is hypothesized that entinostat in combination with atezolizumab will show improved efficacy compared to atezolizumab alone.

Trial Design: ENCORE 602 is a Phase 1b/2 study evaluating the combination of entinostat plus atezolizumab in patients with aTNBC. The study has 2 phases: an open-label Dose Determination Phase (Phase 1b) followed by Phase 2. The objective of the Dose Determination Phase is to establish the recommended Phase 2 dose (RP2D) of weekly entinostat when given in combination with atezolizumab 1200 mg every 3 weeks. Phase 2 will evaluate the efficacy and safety of entinostat at the RP2D with atezolizumab in patients with aTNBC in a randomized (1:1), double-blind, placebo-controlled setting. The randomization will be stratified by geographic location (US vs ex-US).

Key Eligibility Criteria: Eligible patients will have 1) histologically- or cytologically-confirmed triple negative breast carcinoma that is either metastatic (stage IV of the TNM classification) or locally recurrent and not amenable to local curative treatment, 2) measurable disease based on imaging studies within 28 days before the first dose of study drug, and 3) received 1-2 prior lines of systemic therapy for locally recurrent and/or metastatic disease. Previous treatment with a PD-1/PD-L1-blocking antibody or a HDAC inhibitor is not permitted.

Specific Aims: In Phase 2, the primary endpoint is progression free survival (PFS), as assessed by the investigators using RECIST 1.1. Secondary endpoints include PFS by immune response RECIST (irRECIST), overall response rate, clinical benefit rate, overall survival, safety, and duration and time to response for those patients achieving a complete or partial response. Exploratory endpoints include PK, protein lysine acetylation, and immune correlates.

Statistical Methods: The primary analysis of PFS will be performed using a stratified log-rank test. Estimation of the hazard ratio for treatment effect will be determined using a stratified Cox proportional hazards model. 60 PFS events are estimated to provide 80% power to detect the targeted improvement in PFS with one-sided significance level of 0.1. An independent data safety monitoring board will meet at regular intervals to oversee trial conduct and patient safety.

Accrual: Up to 88 evaluable patients are anticipated if the study completes all phases of evaluation (6-18 patients in Phase 1b, 70 patients in Phase 2). The study was activated in May 2016 (NCT02708680).

Title: A phase 3, open-label, randomized, 2-arm international study of the oral dual PARP inhibitor talazoparib in germline BRCA mutation subjects with locally advanced and/or metastatic breast cancer (EMBRACA)

Litton J, Ettl J, Hurvitz SA A, Mina LA A, Rugo HS S, Lee K-H, Yerushalmi R, Woodward N, Goncalves A, Moreno F, Roche H, Im Y-H, Martin M, Bhattacharya S, Peterson A, Hannah A, Eiermann W and Blum J. MD Anderson Cancer Center, Houston, TX; Technische Universität München, Munich, Germany; University of California, Los Angeles, Los Angeles, CA; Indiana University School of Medicine, Indianapolis, IN; UCSF Helen Diller Family Comprehensive Cancer Center, San Francisco, CA; Seoul National University Hospital, Seoul, Korea; Rabin Medical Center, Beilinson Hospital, Petah Tikva, Israel; Mater Cancer Care Centre-Mater Health Services, South Brisbane, Australia; Institut Paoli-Calmettes, Marseille, France; Hospital Clínico San Carlos, Madrid, Spain; Institut Universitaire du Cancer Toulouse, Toulouse, France; Samsung Medical Center, Seoul, Korea; Hospital General Universitario Gregorio Marañón, Madrid, Spain; Medivation, Inc., San Francisco, CA; Interdisziplinären Onkologisches Zentrum Muenchen, Munich, Germany and Texas Oncology-Baylor Charles A. Sammons Cancer Center, Dallas, TX.

Body: Background: Cancer cells with deleterious mutations in breast cancer susceptibility genes 1 and 2 (BRCA1/2) are deficient in the DNA double-strand break repair mechanism, rendering them highly dependent on the single-strand break repair pathway, regulated by poly(ADP-ribose) polymerase (PARP). Inhibition of PARP results in synthetic lethality in cells with a BRCA1/2 mutation because of accumulation of irreparable DNA damage; PARP inhibitors have the potential to be selectively toxic for BRCA-mutated cells. In addition to catalytic inhibition, it has been shown that some PARP inhibitors induce PARP trapping at sites of DNA damage. The capacity to trap PARP-DNA complexes varies widely across different PARP inhibitors and is not correlated with PARP catalytic inhibition. Preclinical models have shown trapping PARP on DNA is more potent at inducing cancer cell death than enzymatic inhibition of PARP alone. Talazoparib is a dual-mechanism PARP inhibitor that both inhibits the PARP enzyme and effectively traps PARP on DNA, preventing DNA damage repair and resulting in cell death in BRCA1/2-mutated cells. In preclinical studies, talazoparib at nanomolar concentrations showed the highest efficiency at trapping PARP-DNA complexes relative to other PARP inhibitors. In a previous phase 1/2 clinical study, talazoparib as monotherapy (1 mg once daily) resulted in a 50% response rate and an 86% clinical benefit rate at 24 weeks in 14 patients with a germline BRCA1/2 mutation and advanced breast cancer (aBC).

Methods: This open-label, randomized, 2-arm, international phase 3 trial (EMBRACA) compares the efficacy and safety of talazoparib with protocol-specific physician's choice (capecitabine, eribulin, gemcitabine or vinorelbine) in patients with aBC. The primary objective is progression-free survival by central imaging. Secondary objectives are objective response rate, overall survival, safety and pharmacokinetics of talazoparib. Exploratory objectives include health-related quality of life measurements and biomarker research in blood and tumor samples that may permit characterization of mechanisms involved in tumor sensitivity and resistance to talazoparib. Key patient eligibility criteria include aged ≥18 years with histologically/cytologically confirmed breast cancer; locally advanced and/or metastatic disease appropriate for systemic single-agent cytotoxic chemotherapy; deleterious or pathogenic germline BRCA1/2 mutations by central laboratory; ≤3 prior cytotoxic chemotherapy regimens for advanced disease (prior platinum is allowed provided patients did not relapse within 6 months in the adjuvant setting or did not progress on platinum therapy); prior treatment with a taxane and/or anthracycline unless medically contraindicated; and ECOG performance status ≤2. Patients (N=429) will be randomized 2:1 to receive either talazoparib capsules (1 mg/day, 21-day cycles) or physician's choice treatment. This trial is currently enrolling patients from the USA, Europe, Israel, Ukraine, Russia, Korea, Australia, Taiwan and Brazil (NCT01945775). This study is funded by Medivation, Inc.
2016 San Antonio Breast Cancer Symposium

Publication Number: OT2-01-14

Title: Triple-negative first-line study: Neoadjuvant trial of nab-paclitaxel and atezolizumab, a PD-L1 inhibitor, in patients with triple negative breast cancer (TNBC) (NCT02530489)

Body: BACKGROUND: TNBC has an especially poor prognosis in patients (pts) whose tumor does not respond to anthracycline and taxane-based chemotherapy. Approximately 50% will have chemoresistant disease (CID) resulting in extensive residual disease at the time of surgery. 40-80% of these pts will recur < 3 years. Recently developed molecular profiling techniques to identify TNBC subsets detect distinct molecular hallmarks. We designed a clinical trial to identify and characterize CID (ARTEMIS: A Randomized, TNBC Enrolling trial to confirm Molecular profiling Improves Survival). Treatment naïve pts with localized TNBC undergo a pretreatment biopsy followed by anthracycline-based chemotherapy (AC). During AC the molecular profile is determined; these results along with the response assessment (clinical exam/diagnostic imaging) will identify CID and guide the second phase of neoadjuvant chemotherapy. Tumor-infiltrating lymphocytes (TIL) have been identified as having prognostic and predictive significance in TNBC pts leading to higher pCR rates post NACT. However, the tumor microenvironment also contains regulatory T cells and myeloid-derived suppressor cells that are immunosuppressive. Programmed death ligand 1 (PD-L1) is expressed in 20% TNBC. Targeting this may lead to a more durable response as compared to chemotherapy alone.

PRIMARY OBJECTIVE: Evaluate the rate of pathologic complete response (pCR)/RCB-0 + residual cancer burden (RCB)-I responses in TNBC pts, determined to have CID after anthracycline-based chemotherapy, then treat with atezolizumab + nab-paclitaxel preoperatively.

TRIAL DESIGN AND STATISTICAL METHODS: Pts deemed to have CID on the ARTEMIS trial can enter this non-randomized phase II study. Pts without response to their initial chemotherapy cycles have a low likelihood (5%) of achieving pCR with additional cycles of chemotherapy. It would be clinically meaningful for pCR to improve to 20%. Counting pCR (RCB-0) or RCB-I as response given similar survival outcomes, a two-stage Gehan-type design will be employed with 14 pts in the first stage. If at least one pt responds, 23 more will be added. This design has a 49% chance of terminating after the first stage if the true response rate is 0.05, 23% chance if the true rate is 0.10, 10% if the true rate is 0.15 and 4% if the true rate is 0.20. If accrual continues to the second stage, the 95% confidence interval for a 0.20 response rate will extend from 0.10 to 0.35.

BRIEF ELIGIBILITY CRITERIA: Inclusion: localized TNBC enrolled onto ARTEMIS and determined to have CID at the time of response assessment after anthracycline chemotherapy, adequate organ, bone marrow and cardiac parameters. Exclusion: prior immunotherapy, IBC, history of autoimmune disease, HIV, Hep-B, Hep-C, active tuberculosis, pregnant.

CORRELATIVE SCIENCE: Evaluate the presence and phenotype of TIL and other immune cell populations in tumor tissue pre/post treatment; determine changes in expression of co-stimulatory and co-inhibitory molecules on tumor cells and immune cells in the microenvironment; evaluate the immune repertoire and cytokine responses in serially collected peripheral blood mononuclear cells and serum respectively.
Body: Background: Triple Negative Breast Cancers (TNBC) are a biologically diverse and aggressive sub-group. Early effective treatment can lead to cure. Current standard treatment is systemic chemotherapy either pre-/post-definitive surgery. No specific targeted therapies are available for TNBC. There are phenotypic and molecular similarities between germline BRCA (gBRCA) breast cancer and TNBC. In TNBC 10%-20% harbour gBRCA mutations. In gBRCA patients, and potentially other homologous recombination deficiencies, these already compromised pathways allow drugs called PARP inhibitors (olaparib) to work particularly effectively.

Aims: To establish if the addition of olaparib to neoadjuvant platinum-based chemotherapy for TNBC and/or gBRCA breast cancer is safe and improves efficacy.

Trial design: 3-stage open label randomised phase II/III trial of neoadjuvant olaparib +/- platinum containing chemotherapy followed by clinicians’ choice of anthracycline regimen. Stage 1 and 2, patients are randomised (1:1:1) to either control (3 weekly carboplatin AUC5/weekly paclitaxel 80mg/m² chemotherapy - 4 cycles) or one of two research arms which uses the same chemotherapy regimen but with two different schedules of olaparib 150mg BD). Stage 3: patients are randomised (1:1) to either control arm or to the research arm selected in stage 2.

Primary outcome measures:
Stage 1: safety of the addition of olaparib to chemotherapy. Prophylactic G-CSF is mandatory.
Stage 2: pathological complete response (pCR) in each of the two research arms. At the end of stage 2, one of the research arms will be dropped.
Stage 3: pCR at surgery after neoadjuvant treatment. pCR - defined as no residual invasive carcinoma within the breast (ductal carcinoma in situ permitted) AND no evidence of metastatic disease within the lymph nodes.

Eligibility:
• Aged 16 to 70.
• Written informed consent.
• Histologically confirmed invasive breast cancer.
• Clinical stage T1-4 N0-2 (tumour or metastatic node diameter>10mm)
• Confirmed ER-negative and HER2-negative or gBRCA mutation positive, irrespective of hormone status.
• Performance Status 0-1

Statistical Methods: Stage 1, Safety: both research arms combined. Stage 2, Schedule selection criteria: pCR rate and completion rate of olaparib protocol treatment. It is a “pick-the winner” design with 53 patients in each research arm. This allows a 90% power, 5% one-sided significance level to test null hypothesis of pCR ≤35% versus an alternative hypothesis of pCR ≥55% in each of the research arms.
Stage 3, Efficacy: anticipated pCR ~45-55% for all trial patients and ~50-60% for gBRCA patients. The trial is powered to detect an absolute improvement of 15% (all patients) and 20% (gBRCA patients) by adding olaparib to chemotherapy (enriched design). TNBC patient recruitment will be capped, to ensure the required number of gBRCA patients are enrolled. Enrichment design is applied with the overall significance level 0.05(α)=0.025(αall)+ 0.025(αgBRCA) and 80% power.

Present accrual: 1 [Trial opened: 23rd May 2016]
Target accrual: 527 (TNBC 307; gBRCA 220)
Contact information: Dr. Jean Abraham; Email: ja344@medschl.cam.ac.uk.
Body: Background: Breast cancer therapy exerts strong selection pressure that shapes the evolution of the cancer. Despite the importance of these treatment-induced changes for the success of subsequent therapy, tumors have been rarely resampled and reanalyzed, with the exception of hematopoietic malignancies. The availability of next generation sequencing (NGS) has made it possible to get highly accurate sequencing that allows detection of mutations and other genetic alterations not only from tumor biopsies but also from circulating DNA fragments.

Objectives: To demonstrate the evolution of the molecular genotype of breast cancer as patients are diagnosed, treated, and upon relapse. This will be accomplished by NGS of the tumor at key time points during the natural history of the disease. The molecular profile at diagnosis will be compared to the profile at recurrence/metastasis and after treatment for metastasis. Correlation with treatment response and adverse clinical outcomes will be determined.

Study Design and Eligibility: We have initiated a prospective observational study in patients with a new diagnosis of Stage I, II and III breast cancer and an ECOG performance status of 0, 1 or 2. Patients should be medically suitable to give informed consent for a biopsy or surgical procedure. Enrollment will occur at community-based cancer centers with inclusion of under-served populations.

Methodology: Tumor samples and blood samples are collected at - initial diagnosis/definitive surgery, first local relapse, diagnosis of metastasis and at first progression after treatment for metastatic disease. Molecular genotype will be analyzed from the tumor samples and from the circulating tumor DNA (ctDNA) in blood samples at each of the time points. ctDNA will also be assessed on blood samples collected annually till the diagnosis of metastasis and then more frequently at 3-6 month intervals in patients with high risk breast cancer.

Statistical Design/Size of study sample: Formal sample size calculations are not required for this study as by design, it is based on participation. There is no discrete endpoint that can be powered by sample size calculation for this study. We are screening all patients who are diagnosed with breast cancer at our facility. The proposed enrollment is 300 patients per year. The study launched in December 2015 at 4 of our community-based cancer centers. Current enrollments is 46 patients.
Title: A Phase II randomized trial of pembrolizumab with carboplatin and gemcitabine for treatment of patients with metastatic triple-negative breast cancer (mTNBC)

Obeid E, Miller KD D, Sparano JA A, Blackwell K and Goldstein LJ J. Fox Chase Cancer Center, Philadelphia, PA; Indiana University, Indianapolis, IN; Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY and Duke University, Durham, NC.

Body: Background: Treatment for mTNBC is limited, and significant challenges persist in treating this disease, as outcomes remain largely dependent on chemotherapy without any effective targeted treatment. Pembrolizumab (MK-3475) is a highly selective, humanized monoclonal antibody against PD-1, blocking the negative immune regulatory signaling of the PD-1 receptor that is usually expressed by T-cells. Recent data showed that some patients with mTNBC may benefit from immune-based therapies (PD-1 or PD-L1 antibodies). Cumulative evidence suggest that stromal tumor infiltrating lymphocytes (sTILs) have a prognostic and predictive role in response to treatment in subsets of TNBC, particularly in response to carboplatin use. Preclinical data revealed that blocking PD-1/PD-L1 pathway in combination with platinum containing cytotoxic therapy improved response rates and survival. High levels of sTILs and an increased PD-L1 expression make mTNBC a candidate for PD-1–targeted therapy. As studies showed that the subset of TNBC with better response rates to carboplatin are heavily infiltrated with sTILs, pembrolizumab, becomes a very attractive drug to be tested in combination with carboplatin, with the goal of improving outcomes in mTNBC. A Phase II multicenter, randomized, trial has been initiated to evaluate the efficacy and safety of combining pembrolizumab with carboplatin and gemcitabine in patients with mTNBC.

Methods: A safety run-in will assess the safety and tolerability of combining pembrolizumab with carboplatin and gemcitabine in patients with mTNBC. Following the completion of the safety run-in, patients will be randomized 2:1 to receive pembrolizumab (200 mg IV) on day 1 along with carboplatin (AUC 2, day 1 and day 8, IV) plus gemcitabine (800 mg/m^2, day 1 and day 8, IV) of a 21-day cycle, or carboplatin plus gemcitabine (same aforementioned dose) alone. Patients will have histologically documented unresectable mTNBC. Prior systemic therapy for mTNBC, for up to 2 lines is allowed, and patients will have ECOG PS 0–2 and measurable disease (RECIST v1.1). Prior carboplatin/gemcitabine or cisplatin therapy is allowed in the adjuvant or neoadjuvant setting, as long as it occurred more than 12 months from the beginning of their enrollment. Subjects whose tumors progressed while on treatment with carboplatin or cisplatin are excluded. Known CNS disease (except asymptomatic treated metastases), autoimmune disease or prior immune checkpoint blockade therapy is allowed in the adjuvant or neoadjuvant setting, as long as it occurred more than 12 months from the beginning of their enrollment. Primary endpoint is assessing the objective response rate according to RECIST v1.1. Other endpoints include clinical benefit rate (CBR), progression-free survival (PFS), overall survival (OS), duration of response (DOR), and safety. Tumor biopsies will be obtained at baseline and just prior to initiation of cycle 3 to assess biomarkers of response and immune escape. PD-L1 expression will be evaluated in exploratory analysis with a planned assessment of response based on PD-L1 status. This trial will enroll 6-12 patients in the safety run-in portion, and 75 patients in the randomized part, at 7 sites in the United States. Clinical trial information: NCT02755272 www.clinicaltrials.gov.
Introduction:
The double blind, placebo-controlled MONALEESA-2 trial met its primary endpoint of clinically meaningful improvement in PFS at the pre-planned interim analysis for the combinatorial treatment of the cyclin-dependent kinase (CDK) 4/6-Inhibitor ribociclib and letrozole vs. letrozole monotherapy for postmenopausal, estrogen receptor positive (ER+), human epidermal growth factor receptor 2-negative (HER2-) women who were naive to treatment for advanced disease. Here we present the national, multi-center, open-label, single-arm phase IIIb trial RIBECCA assessing the efficacy and safety of the combination of ribociclib and letrozole in an additional population, accompanied by a set of exploratory objectives.

Methods:
Main inclusion criteria allow enrollment of women with metastatic or locally advanced breast cancer not amenable to curative treatment by surgery or radiotherapy, and histological or cytological confirmation of ER+, HER2- breast cancer, irrespective of their menopausal status.

The primary objective is to assess the Clinical Benefit Rate (CBR) after 6 months, the secondary objectives include progression free survival (PFS), overall survival (OS), safety and change in quality of life.

The exploratory objectives include the assessment of biomarkers (e.g. ctDNA, CTCs, miRNA) predictive for response and the occurrence of adverse events of special interest. The influence of CDK4/6-inhibition on the immune system will be another exploratory endpoint of this study.

Conclusion:
With a planned recruitment of 500 patients in about 100 trial sites the RIBECCA trial will contribute to a better understanding of the safety, efficacy and possibly mechanisms related to CDK4/6-inhibition through ribociclib.
Title: A randomized phase II trial of fulvestrant with or without ribociclib after progression on aromatase inhibition plus cyclin-dependent kinase 4/6 inhibition in patients with unresectable or metastatic hormone receptor positive, HER2 negative breast cancer

Mundi PS S, Codruta C, Accordino MK K, Sparano J, Andreopoulou E, Vadhat LT T, Tiersten A, Esteva F, O'Regan R, Jain S, Mayer I, Forero A, Crew KD D, Hershman DL L and Kalinsky KM M. Columbia University Medical Center, New York, NY; Albert Einstein College of Medicine, New York, NY; Weill Cornell Medical Center, New York, NY; Mount Sinai School of Medicine, New York, NY; NYU Medical Center, New York, NY; University of Wisconsin School of Medicine, Madison, WI; Northwestern, Chicago, IL; Vanderbilt-Ingram Cancer Center, Nashville, TN and University of Alabama-Birmingham, Birmingham, AL.

Body: Background

Cyclin dependent kinase 4 and 6 inhibitors (CDK4/6i), including palbociclib and ribociclib (R), have demonstrated remarkable benefit in progression free survival (PFS) in patients (pts) with hormone receptor positive (HR+), HER2- metastatic breast cancer (MBC) when combined with anti-estrogen therapy. Switching between anti-estrogen therapies at disease progression is standard of care in the treatment of HR+ MBC. We evaluate the strategy of switching anti-estrogen therapy to fulvestrant (F) and maintaining CDK4/6 inhibition with R in pts with HR+, HER2- MBC who have progressed on an aromatase inhibitor (AI) + CDK4/6i.

Trial Design

Phase II, multi-center, randomized, double-blind, placebo-controlled trial to evaluate F +/- R in pts with HR+, HER2- MBC who have previously progressed on any AI + CDK4/6i. Pts can be screened and registered at two different time points:

Scenario 1: Before receiving any CDK4/6i
In scenario 1, the study will provide pts with letrozole + R, but pts will not be randomized until they demonstrate POD. At randomization, pts will be assigned 1:1 to either a) F + R or b) F + placebo, with treatment given in 4-week cycles. F will be given as a 500 mg dose intramuscularly every 2 weeks for 3 times and then every 4 weeks, as per standard of care. R or placebo will be given orally at 600 mg daily, 3 weeks on/1 week off. CT scans and bone scan are to be performed prior to every third cycle. Serum and whole blood samples and optional tissue biopsies for biomarker assessment will be performed prior to study treatment (scenario 1), prior to randomization to R +/- F, and when the patient goes off study.

Main Eligibility Criteria:

1. Age ≥ 18 years with unresectable or metastatic BC
2. Estrogen and/or progesterone receptor positive, HER2 negative, as per ASCO-CAP
3. Postmenopausal status or receiving ovarian suppression
4. Measurable or unmeasurable disease; stable CNS disease allowed
5. No clinically significant cardiac disease
6. No concomitant CYP3A4/5 inducer or inhibitor

Specific Aims

Primary: Progression free survival (PFS), defined as the time from randomization to POD or death.
Secondary: Objective response rate (ORR), clinical benefit rate (CBR = ORR + stable disease rate), overall survival (OS), and duration of response. Pts in scenario 1 will also be assessed for PFS, OS, CBR, and safety while receiving AI + R (pre-randomization).

Biomarker assessment will include amplification of cyclin D1 and cyclin E, phosphoRb and TK1 expression, Rb1 and p16 loss, and ctDNA for ESR1 and PIK3CA mutations.

Target Accrual

132 pts accrued from 11 academic medical centers in the U.S, with a goal of completing accrual in two years (~60 to 72 pts in each scenario).

Statistical Methods

Assuming a median PFS of 3.8 months with F alone, we predict that F + R will lead to a median PFS of at least 6.5 months. A one-sided log-rank test with a sample size of N=120 and alpha=0.025, achieves 80% power to detect a difference in PFS of 2.7
months. N=132 pts allows for a 10% drop-out rate.
Title: Phase IIB study of neoadjuvant panitumumab combined with carboplatin and paclitaxel (PaCT) for anthracycline-resistant triple-negative breast cancer (TNBC)

BACKGROUND: Approximately 50% of patients with TNBC treated with standard taxane/anthracycline-based neoadjuvant chemotherapy (NACT) have chemo-insensitive disease (CID), i.e., residual disease burden (RCB)-II/III at the time of surgery, and 40-80% of patients develop recurrence within 3 years. Recent developments in molecular profiling have identified subsets of TNBC with distinct, targetable molecular features. We developed a clinical trial to identify and characterize CID (ARTEMIS: A Randomized, TNBC-Enrolling trial to confirm Molecular profiling Improves Survival). In ARTEMIS, patients with localized TNBC will undergo a pretreatment biopsy, then begin anthracycline-based NACT. During NACT, we use molecular profiling and response assessment to identify CID and allocate patients to alternative therapies to overcome CID. Epidermal growth factor receptor (EGFR) is overexpressed in 25-30% of TNBC. In preclinical studies, suppression of EGFR signaling has shown efficacy in controlling cancers through suppression of the stem cell population, enhanced apoptosis via MAPK/PI3K signaling, and modulation of epithelial-mesenchymal transition (EMT). Moreover, in a phase II trial of triple negative inflammatory breast cancer, neoadjuvant PaCT yielded significantly higher pathologic complete response (pCR) rates than historic control. Taken together, we hypothesize that using PaCT to suppress EGFR in TNBC will enhance the pCR rate.

OBJECTIVES: Primary objective: determine pCR and RCB-0/I rates in TNBC patients with CID given PaCT. Secondary objective: determine the benefit of using baseline genomic signatures to develop an alternative second phase of NACT.

TRIAL DESIGN AND STATISTICAL METHODS: Patients with >10% volume reduction for non-CID or <80% for CID will enroll in a biomarker-guided, experimental, nonrandomized phase II study and be given PaCT (panitumumab 2.5 mg/kg, carboplatin AUC 5, paclitaxel 80 mg/m²). Because pCR rates in pts with CID with additional cycles of taxane-based therapy are low (~5%), a 20% response rate (RCB-0 or RCB-I) will be considered clinically meaningful. A two-stage Gehan-type design will be employed. If at least 1 of 14 patients responds, 23 more patients will be added, for a total of 37 patients. This design has a 49% chance of terminating after the first stage if the true response rate is 0.05, 23% if the rate is 0.10, 10% if the rate is 0.15, and 4% if the rate is 0.20. If accrual continues to the second stage and 37 patients are enrolled, the 95% confidence interval for a 0.20 response rate will be 0.10 to 0.35.

BRIEF ELIGIBILITY CRITERIA: Inclusion: localized TNBC; enrolled in ARTEMIS trial; adequate organ, bone marrow, and cardiac parameters; Exclusion: pregnant or lactating, known or suspected metastasis.

CORRELATIVE SCIENCE: Circulating tumor cells (CTCs) and cell free (cf) DNA in baseline and subsequent blood samples, EGFR expression (immunohistochemistry), stem cell/EMT/apoptosis marker changes in tissue and CTCs, PD-L1 glycosylation for EGFR sensitivity.
Title: Phase 2 study of investigational TORC1/2 inhibitor TAK-228 with fulvestrant in women with ER-positive/HER2-negative advanced or metastatic breast cancer that has progressed during or after aromatase inhibitor therapy

García-Sáenz JA, Carrasco E, Kneissl ML L, Zohren F and Martin M. Hospital Clínico Universitario San Carlos, Madrid, Spain; GEICAM (Spanish Breast Cancer Group), San Sebastian de los Reyes, Madrid, Spain; Millennium Pharmaceuticals, Inc., a Wholly Owned Subsidiary of Takeda Pharmaceutical Company Limited, Cambridge, MA and Instituto de Investigación Sanitaria Gregorio Marañón, Madrid, Spain.

Body: Standard therapy for ER-positive tumors in the adjuvant and metastatic settings is antiestrogen therapy, including aromatase inhibitors (AI); however, resistance is common. These tumors may respond to alternative second-line anti-estrogen therapies such as fulvestrant but response durations are often short. Preclinical and clinical studies suggest that simultaneous inhibition of ER and PI3K/mTOR could prevent/delay the emergence of hormone-independent cancer cells thereby improving patient (pt) outcomes. This study will test whether fulvestrant plus TAK-228, a dual TORC1/2 inhibitor, can overcome endocrine therapy resistance in ER-positive breast cancer. This is an open-label, randomized, 3-arm, phase 2 study of continuous once-daily TAK-228 (oral, 4 mg) or once-weekly TAK-228 (oral, 30 mg) plus fulvestrant (500 mg intramuscularly on d1 and d15 of cycle 1 [loading regimen] then d1 of each subsequent 28-d cycle), compared with fulvestrant alone, in pts with advanced or metastatic ER-positive/HER2-negative breast cancer that has progressed during/after AI therapy. Pts will be randomized 1:1:1 to the 3 arms and stratified at randomization via presence or absence of visceral metastasis, prior hormonal therapy sensitivity, and prior exposure to CDK 4/6 inhibitors. Pts will receive study drug(s) until progressive disease (PD), unacceptable toxicity, or consent withdrawal. Postmenopausal women ≥18 yrs old with local histological confirmation of ER-positive/HER2-negative metastatic or advanced breast cancer; with measurable disease; ECOG status 0–1; PD during/after prior AI therapy (defined as progression ≤12 mos after discontinuing adjuvant therapy or ≤1 mo after discontinuation in the metastatic setting) and adequate organ function are eligible. Exclusion criteria include prior therapy with mTOR inhibitors, PI3K inhibitors, dual PI3K-mTOR inhibitors, AKT inhibitors, or fulvestrant; prior treatment with >1 line of chemotherapy for metastatic breast cancer; experienced recurrent or progressive disease on >2 endocrine therapies for metastatic breast cancer; or significant previous/existing cardiac conditions. This study aims to determine the efficacy (primary endpoint: PFS; secondary endpoints: OS, TTP, ORR), safety and tolerability of daily and weekly TAK-228 plus fulvestrant compared with fulvestrant alone. The distribution of PFS will be analyzed via the Kaplan-Meier method. The primary hypothesis (TAK-228 plus fulvestrant can improve median PFS to 8 mos [hazard ratio, HR 0.5] vs fulvestrant-alone median PFS of 4 mos) is to be tested at the 0.10 significance level (2-sided; dropout rate 10%). A total of 72 PFS events are needed for each pair-wise comparison; p-values from a stratified log-rank test and HRs will be presented. The safety profile and clinical laboratory parameters (and/or change from baseline) for all scheduled measurements over time will be summarized by descriptive statistics. Approximately 153 pts (51 pts per arm) will be enrolled from approximately 55 study centers in North America and Spain; to date, no pts have been enrolled. For more information, please contact Michelle Kneissl at michelle.kneissl@takeda.com.

Publication Number: OT2-01-22

Title: NCT02456857: A phase II trial of liposomal doxorubicin, bevacizumab and everolimus (DAE) in patients (pts) with localized triple-negative breast cancer (TNBC) with tumors predicted insensitive to standard neoadjuvant chemotherapy (NACT)

Body: **BACKGROUND:** Approximately 50% of TNBC pts treated with standard taxane/anthracycline-based NACT will have chemo-insensitive disease (CID) manifested as extensive residual disease (RCB-II or III) at the time of surgery. 40-80% of these pts will develop recurrence within 3 years of initial diagnosis. Recent advances in molecular profiling have identified subsets of TNBC with distinct, targetable molecular features. We developed a clinical trial to identify and characterize CID (ARTEMIS: A Randomized, TNBC Enrolling trial to confirm Molecular profiling Improves Survival). In the ARTEMIS trial, treatment naïve pts with localized TNBC undergo a pretreatment biopsy and then immediately start their initial phase of anthracycline-based chemotherapy so that the results of the molecular characterization are used in combination with response assessment (clinical exam/diagnostic imaging) to identify CID and inform the second phase of NACT, thus using a 'second hit' strategy in the middle of NACT to overcome drug resistance. The mesenchymal subtypes of TNBC have a high incidence of PI3K pathway activation. Preclinical models demonstrated response to PI3K inhibitors in this subtype. Metaplastic breast cancers make up ~30% of tumors characterized as 'claudin-low/mesenchymal' by gene signature and are also associated with a high rate of PI3K activating molecular aberrations. A combination regimen of liposomal doxorubicin, bevacizumab and the mTOR inhibitors temsirolimus or everolimus (DAT or DAE) demonstrated response (including durable complete responses) in metastatic metaplastic breast cancer.

**PRIMARY OBJECTIVE:** Determine the rate of pathologic complete response (pCR/RCB-0) or minimal residual disease (RCB-I) after 4 cycles of DAE for treatment of mesenchymal TNBC deemed to be CID through the ARTEMIS trial

**TRIAL DESIGN AND STATISTICAL METHODS:** Only pts deemed to have mesenchymal CID on the ARTEMIS trial can enter this non-randomized phase II study. Realizing that pts without response to their initial cycles of chemotherapy have very low chance (5%) of achieving pCR with additional cycles of chemotherapy, it would be clinically meaningful to see pCR in this pt population improved to 20%. Counting pCR (RCB-0) or RCB-I as response, a two-stage Gehan-type design will be employed with 14 pts in the first stage. If at least one pt responds, 23 more pts will be added for a total of 37 pts. This design has a 49% chance of terminating after the first stage if the true response rate is 0.05, 23% chance if the true rate is 0.10, 10% if the true rate is 0.15 and 4% if the true rate is 0.20. If accrual continues to the second stage and a total of 37 pts are enrolled, the 95% confidence interval for a 0.20 response rate will extend from 0.10 to 0.35.

**BRIEF ELIGIBILITY CRITERIA:**  
*Inclusion:* localized TNBC enrolled onto ARTEMIS trial, adequate organ, bone marrow and cardiac parameters  
*Exclusion:* metastatic disease, pregnant or lactating pts, medical illness that increases chance of moderate to severe toxicity

**CORRELATIVE SCIENCE:** Correlate vimentin expression by IHC, mesenchymal signatures and PI3K pathway aberrations with response.
Photodynamic therapy for the treatment of primary breast cancer: Preliminary results of a phase I/IIa clinical trial

**Body:** Background: Photodynamic therapy (PDT) has been used to treat skin metastases from breast cancer. We investigated the use of PDT for the treatment of primary breast cancer.

**Trial design:** Phase I/IIA, open label, non-randomised, single site, light dose escalation trial in patients with primary breast cancer using verteporfin as the photosensitiser. Verteporfin 0.4mg/kg bodyweight is injected intravenously 60-90 minutes before laser activation through a thin optical fibre inserted percutaneously through a needle positioned under ultrasound guidance under local anaesthesia. The light dose is escalated from 20J to a maximum of 50J in intervals of 10J.

**Eligibility criteria:** Patients aged 30 or over and have opted for mastectomy or wide local excision as primary treatment are included. The tumour should be uni-focal invasive ductal breast carcinoma, or discrete uni-focal site, within a multifocal invasive ductal carcinoma, in a single breast. Participants should not have confirmed distant metastases. The exclusion criteria include: patients who are not undergoing surgery as their primary treatment; patients undergoing surgery for DCIS without invasive breast cancer; lobular cancers and necrotic tumours; patients who have porphyria or are sensitive to verteporfin; patients who have severe cardiovascular disease or severe uncontrolled systemic disease (e.g. hepatic impairment); male breast cancer patients; pregnant or lactating patients; patients taking primary endocrine therapy or taking an experimental medicine as a part of a trial.

**Aims:** We aim to establish the minimum light dose required to induce an area of necrosis with a diameter of at least 12mm perpendicular to the optical fibre; or to achieve a plateau with no increase in diameter of necrosis with increasing light dose. Secondary objectives are to examine the effect of Photodynamic Therapy on the abnormal breast tissue and study if necrosis extends to normal breast tissue. We will be assessing the role of MRI in predicting the response to treatment by measuring the diameter of tumour and the zone of necrosis before and after PDT and confirming it with histological findings. We will be monitoring the number of adverse events arising from the PDT.

**Statistical Methods:** The sample size of the study is based on a standard 3+3 dose-escalation algorithm. Statistical analysis will be descriptive in nature with no formal statistical inference. Summary statistics and analysis will be provided for all patients who receive the study treatment, by dose level for each dosing regimen.

**Accrual Results:** 11 patients have been enrolled and completed the trial up to June 2016 with primary end point achieved and no adverse side-effects to treatment seen.

**Target Accrual:** 21 patients.

**Acknowledgement:** Royal Free Charity.

Title: A randomized, open-label, multicenter, phase 1b/2 study of eribulin mesylate in combination with PEGylated recombinant human hyaluronidase in patients with human epidermal growth factor receptor 2-negative, high-hyaluronan metastatic breast cancer

Alvarez RH H, Savulsky C, Almonte A, Xing D, Lokker N and Chondros D. Cancer Treatment Centers of America, Southeastern Regional Medical Center, Altanta, GA; Eisai Ltd., Hatfield, England, United Kingdom; Eisai Inc., Woodcliff Lake, NJ and Halozyme Inc., San Diego, CA.

Body: Eribulin (ERI), a non-taxane microtubule inhibitor, is approved for treatment in patients (pts) with advanced or metastatic breast cancer (MBC) who have received ≥1 (European Union) or ≥2 (United States) prior chemotherapy regimens for metastatic disease, including an anthracycline and taxane in either the adjuvant or metastatic setting. In a phase 2 study, ERI has demonstrated single-agent activity in first line treatment of pts with human epidermal growth factor receptor 2-negative (HER2−) MBC. Hyaluronan (HA) is a major component of the tumor microenvironment, specifically within the stroma, and high levels of HA are associated with disease progression. In HA-High, triple-negative breast cancer (TNBC) xenografts, the anti-tumor effect of ERI was enhanced by addition of PEGylated recombinant human hyaluronidase (PEGPH20). PEGPH20 is an engineered enzyme under investigation for use in combination with anticancer therapies in pts with tumors that accumulate HA. PEGPH20 acts by temporarily degrading HA to reduce tumor interstitial pressure and decompress blood vessels, thus increasing access of anticancer agents and immune cells to tumor sites. This randomized, open-label, multicenter, study of ERI in combination with PEGPH20 vs ERI alone was designed to evaluate safety and tolerability and efficacy in pts with HER2−, HA-High, MBC previously treated with 0–1 systemic (cytotoxic or targeted) anticancer therapy.

The trial was activated in June 2016 and will enroll approximately 96 pts (aged ≥18 yrs; n=6–18 in phase 1b; n=84 randomized to obtain 80 evaluable pts in phase 2). Pts with measurable disease of ≥1 lesion ≥10 mm in long-axis diameter (nonlymph nodes) or ≥15 mm in short-axis diameter (lymph nodes) with ECOG PS of 0 or 1 will be included. Pts will be excluded for having had adjuvant chemotherapy within the past 6 months, hormonal/biological therapy within the past 3 wks, or radiation or small molecule targeted therapy within the past 2 wks. Pts will also be excluded if they were previously treated with ERI or any hyaluronidase agent.

Phase 1b includes at least 1 initial safety run-in cohort in which 6 pts (any HA level) will receive PEGPH20 3 µg/kg intravenous (IV) on days −1 and 7 of a 21-day cycle, each dose followed approximately 24 (±4) hours later with ERI 1.4 mg/m² IV on days 1 and 8. Dose-limiting toxicity (DLT) will be assessed in the first cycle. The primary endpoint in phase 1b is the recommended phase 2 dose (RP2D) of the ERI and PEGPH20 combination, defined as the maximum dose at which ≤1 pt experiences a DLT. Alternatively, modified dose levels will be evaluated in additional cohorts.

In phase 2, HA-High pts will be stratified by TNBC vs other HER2− status and randomized to receive RP2D combination treatment or ERI alone. Pts with clinical benefit will remain on ERI or both study drugs until unacceptable toxicity or disease progression. The primary endpoint in phase 2 is objective response rate. Secondary endpoints include progression-free survival and overall survival. Exploratory endpoints include clinical benefit rate, disease control rate, and duration of response.
Title: Pilot study of zirconium-89 bevacizumab positron emission tomography for imaging angiogenesis in patients with inflammatory breast carcinoma receiving preoperative chemotherapy

Body: Background: Inflammatory breast cancer (IBC) continues to have a poor prognosis despite standard tri-modality treatment with chemotherapy, mastectomy and radiation. Current methods of assessing primary tumor response (i.e., clinical exam and breast magnetic resonance imaging [MRI]) are limited for distinguishing residual tumor from responsive disease because of persistent morphologic changes in the breast. Therefore, the inability to accurately assess tumor response during treatment often results in the continuation of ineffective systemic chemotherapy until definitive pathologic evaluation at mastectomy. IBC has a highly angiogenic phenotype which is believed to play a role in this tumor’s aggressiveness. The novel radiotracer Zirconium-89 ($^{89}$Zr)-bevacizumab was developed for imaging tumor angiogenesis with PET. We hypothesize that, as an imaging biomarker of angiogenesis, $^{89}$Zr-bevacizumab-PET/CT is a more specific noninvasive functional imaging modality for detecting the presence of tumor angiogenesis compared to current diagnostic methods and will serve as a predictor of response to therapy in patients (pts) with IBC.

Methods: Pts with newly diagnosed HER2neg IBC who will receive preoperative chemotherapy are eligible for this pilot study. $^{89}$Zr-bevacizumab-PET/CT, breast MRI and FDG-PET/CT are performed before, after 2 cycles, and at the completion of preoperative therapy. Biopsies of primary IBC tumors are obtained prior to and after 2 cycles of preoperative therapy. At the completion of preoperative therapy, pts proceed to mastectomy or biopsy if ineligible to proceed to mastectomy based on current standards for assessing primary tumor response, i.e., clinical exam, breast MRI and lack of systemic progression. At the time of mastectomy, standard evaluation of the surgical specimen will determine pathologic response of IBC to preoperative chemotherapy. A research sample will be collected if residual cancer is present at the time of mastectomy for histologic evaluation of tumor angiogenesis.

Objectives/Correlatives: The primary objective is to determine feasibility of $^{89}$Zr-bevacizumab-PET/CT imaging in pts with IBC. The primary endpoint is assessment of radiolabeling of chelated bevacizumab and number of successfully acquired $^{89}$Zr-bevacizumab-PET/CT scans. Correlative studies will be performed on IBC tissue to assess extent of angiogenesis including microvessel density, vessel diameter, vascular pericyte coverage and tumor VEGF levels. Secondary objectives are: 1) To determine if $^{89}$Zr-bevacizumab accumulation in primary IBC tumors correlates with the extent of angiogenesis determined by correlative analysis on IBC tissue; 2) To assess the predictive value of $^{89}$Zr-bevacizumab-PET/CT after 2 cycles and at the end of preoperative therapy for determining pathologic response at mastectomy as given by residual cancer burden.

Statistics: This is an accrual, not statistical based, feasibility justification. Planned sample size is 10 in order to make a preliminary statement about feasibility and ability for $^{89}$Zr-bevacizumab-PET/CT to serve as a surrogate in vivo biomarker of tumor angiogenesis and response to preoperative chemotherapy.

Clinical Trial Information: NCT01894451.
Title: NRG oncology/NSABP B-51/RTOG 1304: A phase III superiority clinical trial designed to determine if chest wall and regional nodal radiotherapy (CWRNRT) post mastectomy (Mx) or the addition of RNRT to breast RT post breast-conserving surgery (BCS) will reduce invasive cancer events in patients (pts) with positive axillary (Ax) nodes and convert to ypN0 after neoadjuvant chemotherapy (NC)

Body: Background:
This phase III post-NC trial evaluates if CWRNRT post Mx or whole breast irradiation (WBI) with RNRT after BCS significantly reduces the invasive breast cancer recurrence-free interval (IBC-RFI) rate in pts presenting with positive Ax nodes that are pathologically negative after NC. Secondary aims are OS, LRRFI, DRFI, DFS-DCIS, and second primary cancer, as well as comparing RT effect on cosmesis in reconstructed Mx pts.

Correlative science studies examine RT effect by tumor subtype, molecular outcome predictors for residual disease pts, and predictors for the degree of reduction in loco-regional recurrence.

Methods:
Clinical T1-3, N1 IBC pts with positive Ax nodes (FNA or core needle biopsy) complete ≥8 wks of NC (anthracycline and/or taxane). HER2-positive pts receive anti-HER2 therapy (tx). After NC, BCS or Mx is performed with a sentinel node biopsy (≥2 nodes) and/or Ax dissection with histologically negative nodes. ER/PR and HER2 neu status before NC is required. Pts receive required systemic tx. Radiation credentialing with a facility questionnaire and a case benchmark is required. Randomization for Mx pts is to no CWRNRT or CWRNRT and for BCS pts to WBI or WBI+RNRT.

Statistics:
1636 pts to be enrolled over 5 yrs with definitive analysis at 7.5 yrs. Study is powered at 80% to test that RT reduces the annual hazard rate of events for IBCR-FI by 35% for an absolute risk reduction in the 5-yr cumulative rate of 4.6%. Intent-to-treat analysis with 3 interim analyses at 43, 86, and 129 events, with a 4th/final analysis at 172 events will occur. Accrual as of 6/13/16 is 356. Pt-reported outcomes focusing on RT effect will be obtained from 736 pts before randomization and at 3, 6, 12, and 24 months.

Title: Feasibility of assessing radiation response with MRI/CT directed preoperative accelerated partial breast irradiation in the prone position for hormone sensitive early stage breast cancer

White J, McElroy S, Seykon A, Wei L, Bazan J, Yang X, DiCostanzo D, Gupta N and Knopp M. The Ohio State University Comprehensive Cancer Center, Columbus, OH; Center for Biostatistics, The Ohio State University Comprehensive Cancer Center, Columbus, OH and Wright Center for Innovation, The Ohio State University, Columbus, OH.

Body: Background: Accelerated partial breast irradiation (APBI) delivers adjuvant radiation (RT) to the 1-2 cm of the breast at highest risk for recurrence surrounding the lumpectomy (L) cavity over 5-8 days and is an alternative to standard whole breast irradiation for hormone sensitive (HS) stage 1 (T1, N0) breast cancer (BC) based on 2 randomized controlled trials. External beam methods for APBI are common but have notable inherent drawbacks that include: inter-fraction inaccuracy due to patient setup based on anatomy, intra fraction error related to patient or respiratory motion, and inaccurate geometric targeting by relying on L cavity position instead of the tumor position. Postoperative RT has other limitations including delivery in the setting of disrupted blood or lymphatic supply that may be suboptimal for radio sensitivity and it eliminates observation of radiation-induced tumor response. MRI is an established tool for measuring BC extent and response from neoadjuvant systemic therapy. It's hypothesized that MRI directed pre-operative APBI using intensity modulated radiotherapy (IMRT) with image guidance (IGRT) will improve RT delivery, and that MRI features can be identified to correlate with pathologic radiation response.

Trial Design: There are 2 cohorts to this single arm prospective trial. The first cohort is for establishing and verifying patient flow and image fusion between MRI, CT and RT planning. In the second cohort eligible patients will receive preoperative APBI 38.5 Gy in 10 fractions BID with IMRT, IGRT in the prone position using MRI defined targets fused to CT treatment planning.

Eligibility: For cohort 1 it is HS Stage 1 BC that has completed CT in prone position for RT planning. Eligibility for cohort 2 requires: age > 60 yo, clinical stage 1 BC, HS, HER2 negative, intending L, clinically negative axilla verified by ultrasound, able to tolerate the prone position, and MRI with contrast.

Specific aims: To determine the reproducibility of MRI directed preoperative APBI based on meeting 3 criteria: ability to define RT targets by MRI, quality of RT plans and completion of treatment (APBI and surgery). Additional aims include assessing toxicity, cosmetic outcome, local regional cancer control and collection of tissue for correlative studies.

Statistical methods: The optimal two-stage design by Simon is used. Sample size for cohort 2 is based on the first endpoint. 19 eligible patients will be required in the first stage; if 3 or more treatments are scored unacceptable, then early stopping will be recommended. Otherwise, accrual will continue to a total accrual of 30. If > 4 of 30 treatments are scored unacceptable, the technique will be considered not reproducible, and a Phase II study will not be pursued. Under the null hypothesis of an 80% reproducibility rate, this two-stage design has an expected sample size of 24.4.

Patient accrual to cohort 1 is 2 and targeted accrual is 3. Patient accrual to Cohort 2 is 0 and targeted accrual is 30.

Title: A randomized trial of 15 fraction vs 25 fraction pencil beam scanning proton radiotherapy after mastectomy in patients requiring regional nodal irradiation

Body: Background: Post-mastectomy radiotherapy improves survival in women with node-positive breast cancer. Pencil beam scanning proton therapy is attractive due to potential to reduce the dose to the heart and lungs compared with traditional photon techniques while improving conformality and limiting skin dose compared with passively scanned proton therapy. The optimal dose and fractionation for pencil-beam scanning proton therapy remains unknown.

Trial Design: This is a multi-center open label phase II randomized controlled trial to determine the safety of 15 fraction vs 25 fraction pencil beam scanning proton radiotherapy after mastectomy in patients requiring regional nodal irradiation.

Eligibility Criteria: Patients $\geq$ 18 years with primary, non-inflammatory invasive breast cancer who have undergone mastectomy with or without immediate reconstruction and chest wall and regional nodal irradiation planned.

Aims: To determine whether the 24 month complication rate (defined as grade 3 or greater late adverse events, and unplanned surgical intervention in patients who undergo mastectomy with reconstruction) of 15 fraction chest wall and regional node pencil beam scanning proton radiotherapy is acceptable relative to 25 fraction chest wall and regional nodal pencil beam scanning proton radiotherapy and worthy of further investigation.

Statistical methods: The study is designed as a non-inferiority/superiority “hybrid” design using the approach of Freidlin et al. It is Using a one-sided type I error rate of 0.05 (corresponding equivalently to constructing a 1-sided 95% confidence limit), 72 evaluable patients will have 80% power to reject the null hypothesis that the 24-month complication rate in the experimental arm is higher than that of the control arm by more than 10% (i.e. rule out inferiority) under the alternative hypothesis that the complication rate in the experimental arm is 5% less than that of the control arm (i.e. superiority). However, the design will have only 41% power when the two treatment arms are equivalent (i.e. the complication rate is 10% for both arms).

Accrual: The study opened in June 2016. Five of a planned eighty-two patients have been accrued to date.
Title: Study on the usefulness of the skin wound therapeutic agent ‘Neo dermal activator’ in breast cancer surgery

Body: Background: Wound infection after breast cancer surgery is considered to be factors that increase the discomfort of the patient and increase of the extension and the use of antibiotics in the treatment time period, in particular breast cancer postoperative wound infection resulting slow the implementation of adjunctive therapy such as radiation therapy or chemotherapy after surgery can cause, it is important to effectively prevent, there has been a development of a variety of skin wound therapeutic agent to reduce them. The purpose of this study was to evaluate the effects of the wound dressing with existing wound dressing Neo dermal activator compared to the patients receiving preoperative chemotherapy.

Methods: A total of 54 breast cancer patients who recieved BCS & mastectomy devided two group(each 27 patients) through the random assignment between Jan, 2016 and June, 2016. Day one weeks after surgery to examine the wound infection rate (surgical site infection, SSI rate). After six months of outpatient surgery visits to check the wounds of patients, using the VAS records the scar of the wound satisfaction. For patients who underwent radiation therapy, check out the time it took to begin radiation therapy after surgery.

All tests were two-sided. All statistical analyses were performed using SPSS version 20.0 (SPSS Inc., Chicago, Illinois, USA).

Eligibility criteria is:
- one side breast cancer
- not inflammatory breast cancer
- received BCS and mastectomy only (without immediate reconstruction surgery)
- stage IV breast cancer.
Title: Comparison of axillary sentinel lymph node biopsy versus no axillary surgery in patients with early-stage invasive breast cancer and breast-conserving surgery: A randomized prospective surgical trial. The Intergroup-Sentinel-Mamma (INSEMA)-trial

Reimer T, von Minckwitz G, Loibl S, Hildebrandt G, Nekljudova V, Schneider-Schranz C and Gerber B. Breast Center University of Rostock; German Breast Group and Radiotherapy University of Rostock.

Body: Background:
Currently, axillary surgery for breast cancer is considered as staging procedure that does not seem to influence breast cancer mortality, since the risk of developing metastasis depends mainly on the biological behaviour of the primary. Based on this, the postsurgical therapy should be considered on the basis of biologic tumor characteristics rather than nodal involvement.

Trial design:
The goal of INSEMA is to show that early-stage breast cancer patients with reduced extent of axillary surgery are not inferior regarding invasive disease-free survival (IDFS) outcome. Patients with planned breast-conserving surgery (BCS) will be first randomized (1:4 ratio) to either no axillary surgery or axillary sentinel lymph node biopsy (SLNB). Patients with SLNB and pN+(sn) status will be secondly randomized (1:1 ratio) to either SLNB alone or completion axillary lymph node dissection (ALND) in cases with less than three involved nodes (one or two macrometastases).

Primary objective:
-IDFS after BCS (non-inferiority question)

Inclusion criteria:
-Written informed consent
-Histologically confirmed unilateral primary invasive carcinoma of the breast (core biopsy)
-Age at least 35 years
-Preoperative imaging techniques with estimated tumor size of maximal 5 cm (iT1/iT2 irrespective of hormone sensitivity or HER2 status)
-Clinically and sonographically tumor-free axilla prior to core biopsy
-In cases with cN0 and iN+, a negative core biopsy or fine needle aspiration biopsy of the suspected lymph node is required
-No clinical evidence for distant metastasis (M0)
-Planned breast-conserving surgery (R0 resection) with postoperative external whole-breast irradiation (conventional fractionation or hypofractionation)

Statistics:
The calculated total case number for per-protocol analyses is 6,740 (5,940 German and 800 Austrian patients), the expected total number of randomized patients is 7,095.

Time lines:
-First patient in: September 2015
-Last patient in: August 2019
-Final analysis: End of 2024

Present accrual: In June 2016, more than 1,000 patients were recruited in Germany and Austria.
Title: Comparative performance of surveillance mammography and breast MRI in women with a history of breast cancer

Wernli KJ J, Ichikawa L, Kerlikowske K, Bush M, Johnson D, Buist DSM S, Brandzel SD D, DeMartini WB B, Henderson L, Nekhlyudov L, Onega T, Sprague B and Miglioretti DL L. Group Health Cooperative, Seattle, WA; University of California, San Francisco, San Francisco, CA; University of Wisconsin School of Medicine, Madison, WI; Brigham and Women's Hospital, Boston, MA; Dartmouth Medical School, Hanover, NH; University of Vermont, Burlington, Burlington, VT and University of California, Davis, Davis, CA.

Body: Introduction: National guidelines recommend annual mammography for surveillance to detect second breast cancer events for all women with a personal history of breast cancer in the absence of new signs or symptoms. Increasingly, women are also receiving surveillance breast magnetic resonance imaging (MRI), despite limited evidence regarding its effectiveness in this population. Our goal was to evaluate performance of surveillance breast MRI and mammography in women with a personal history of breast cancer.

Methods: Study population included 13,038 women aged ≥18 with history of stage 0-III breast cancer diagnosed from 2003–2012 who received 33,601 surveillance mammograms and 2,397 surveillance breast MRI examinations from 2005-2012 in the Breast Cancer Surveillance Consortium. Exams were linked to pathology and cancer registry data to assess second breast cancer events within 12 months of the surveillance exam. Descriptive statistics evaluated patient and tumor characteristics associated with use of breast MRI. Unadjusted performance measures were calculated with 95% confidence intervals.

Results: From 2005 to 2012, 11% of women received a breast MRI, and the proportion of use of breast MRI doubled from 4.6% in 2005-2006 to 9.7% in 2011-2012 of women receiving surveillance breast MRI. Patient characteristics associated with breast MRI receipt included: younger age at diagnosis, primary diagnosis of invasive lobular carcinoma, mammographically occult breast cancer, higher AJCC stage and treatment with radiation or chemotherapy, and having heterogeneously or extremely dense breasts. 427 breast cancers were diagnosed within 1 year of a surveillance exam (301 invasive, 126 DCIS; cancer rate 17.9 for breast MRI vs 11.1 mammography per 1000 exams). Cancer detection rates (95%CI) were higher for MRI (10.8; 9.6-12.1) than mammography (7.1; 6.8-7.4) for all cancers and for invasive only (7.5; 6.5-8.6 and 4.7; 4.4-4.9, respectively). Mammography sensitivity was 64.2% (95%CI 59.3-69.1%) and 60.5% (95%CI 45.9-75.1%) for breast MRI (OR=0.94, 95%CI 0.15-5.9=87). Mammography sensitivity for invasive cancer was 59.3% (95% 53.4-65.3%) and was 62.1% for breast MRI (95% CI 44.4-79.7%). Mammography specificity was 93.2% (95% 92.9-93.5%) and 87.8% for breast MRI (95% CI 86.5-89.1%). Biopsy rates at one year per 1000 exams were 3.9 (3.7-4.2) for mammography and 10.1 (95%CI 8.9-11.3) for breast MRI. Positive predictive value among women with biopsy performed was 32.0% (95% CI 28.4-35.5%) for mammography and 21.2% (95%CI 13.7 -28.8%) for breast MRI.

Conclusions: We found significantly higher cancer detection rates (overall and invasive only) among women who received surveillance MRI compared to surveillance mammography alone. Higher cancer detection rates resulted from higher biopsy rates, lower PPV₃, and lower specificity than mammography in women who received surveillance MRI. Further work is needed to account for differences in women who receive MRI and additional research should evaluate the relative performance accounting for confounding due to patient and tumor characteristics, and benefits of MRI for subgroups of women.
Title: Trends in positive predictive values following transition from screen film to digital mammography

Motiuk DA A, Dahl P, Roy E, Docktor B-J and Burrowes P. University of Calgary, Calgary, AB, Canada and University of British Columbia, Vancouver, BC, Canada.

Body: Purpose
Our health region converted from screen-film mammography (SFM) to digital mammography (DM) in 2005. DM has several advantages over SFM, including superior contrast resolution, less noise, and opportunities for image optimization through post-acquisition processing; although, the spatial resolution of DM is inferior to SFM. We sought to determine what effect this transition may have had on positive predictive values (PPVs) for malignant and premalignant lesions.

Methods
From our institution’s breast biopsy database, we retrospectively reviewed core biopsy results for mammographic calcifications performed in the years 2001-2004 (SFM years) and 2009-2012 (DM years). We subsequently determined the PPV (detection of malignancy after biopsy) for each group of years (SFM and DM). We then performed subgroup analysis to calculate PPVs for each of ductal carcinoma in-situ (DCIS) without invasion, DCIS with invasion, and premalignant lesions. Premalignant lesions included atypical ductal hyperplasia, atypical lobular hyperplasia, and lobular carcinoma in-situ.

Results
A total of 4787 biopsies in 4633 patients were reviewed. The comparative detection of cancer after biopsy performed for mammographic calcification between SFM and DM was not statistically significant (PPV = 23.5% and 24.0%, respectively; P=.71). Upon further analysis, however, PPV for premalignant lesions increased (SFM=6.6% and DM=8.9%; P<.01) and PPV for DCIS without invasion increased (SFM=15.5% and DM=18.2%; P=.015), while PPV for DCIS with invasion decreased (SFM=8.0% and DM=5.8%; P<.01).

Conclusion
We observed no significant impact on PPV for calcifications following the transition from SFM to DM; however, our subgroup analysis suggests that with digital mammography we are now detecting a statistically significantly lower proportion of DCIS with invasion but greater proportions of DCIS without invasion and premalignant lesions. As the natural history of these lower-grade lesions, particularly in the premalignant category, is still not entirely understood, the significance of potentially detecting more of these earlier cancers/precancers is uncertain.

Title: Milky Way sign: A potential predictive sign of breast cancer on digital breast tomosynthesis

Miyake KK K, Lipson JA A, Allison KH H, Xu Y, Liu YI I, Downey JR R and Ikeda DM M. Stanford University School of Medicine, Stanford, CA; Kyoto University Graduate School of Medicine, Kyoto, Japan; Rakuwakai Otowa Hospital, Kyoto, Japan and Stanford University School of Medicine, Stanford, CA.

Body: Purpose: “Milky Way sign (MWS)”, which we recently reported[1], is a new finding on digital breast tomosynthesis (DBT) showing microcalcifications overlying non-calcified band-like density. Our study purpose was to describe frequencies of and imaging findings associated with MWS, and to examine the predictive value of MWS for breast cancer.

Materials and Methods: We reviewed all stereotactic core biopsies of suspicious calcifications at our institution from 1/1/2015 to 12/31/2015, finding 124 lesions with calcifications, including 20 malignancies (2 IDC, 5 IDC+DCIS, 13 DCIS) and 104 non-malignant lesions (23 high-risk [14 ADH, 6 LCIS/ALH, 1 intraductal papilloma, 2 other atypical], 81 benign), in 116 patients undergoing both 2D mammogram and DBT before biopsies. 2 radiologists reviewed images for the presence of MWS, local breast density within 1 cm surrounding the calcifications, classifying BI-RADS calcification morphology and distribution. We assessed the predictive value of MWS for malignancy using Chi square test and multivariate logistic analysis.

Results: MWS was identified more frequently with DBT (27/124, 22%) than with 2D (13/124, 10%), and more in locally less dense tissue than in locally dense tissue. The calcifications in MWS were fine pleomorphic (13/27, 48%), amorphous (8/27, 30%), fine linear/branching (5/27, 19%), or other (1/27, 4%), with distributions of grouped (20/27, 74%), linear (5/27, 19%) or segmental (2/27, 7%) categories. MWS on DBT was observed in 60% (12/20, including 2 IDC, 2 IDC+DCIS, 8 DCIS) of malignant lesions and 14% (15/104) of benign lesions (table1), and was significantly and positively associated with malignant lesions (p < .001). Multivariate analysis demonstrated the MWS on DBT (p < .001) and fine linear/branching calcifications (p < .001) were independent predictors for malignancy.

Conclusions: Although sample size was limited, our results indicate that DBT may contribute in detecting MWS, and that MWS may be a predictive sign for breast cancers, leading to biopsy of suspicious calcifications.

Title: Potential clinical application of mammography conducted immediately after contrast enhanced CT as contrast enhanced subtraction mammography

Ohtani S, Yoshimura Y, Kin T, Fujihara M, Kajiwara Y, Ito M, Okada N and Urashima M. Hiroshima City Hiroshima Citizens Hospital, Hiroshima, Japan and Hiroshima City Hiroshima Citizens Hospital, Hiroshima, Japan.

Body:

Background
Contrast Enhanced Subtraction Mammography (CESM) has gained worldwide popularity. It is said that CESM can not only identify tumors but also delineate high-density lesions of the mammary gland that are difficult to be identified by normal mammography (MMG), as well as intraductal progress, and tumor hemodynamics.

In general, imaging is commenced two minutes after injection of the contrast medium, and is conducted in two directions, i.e., left to right craniocaudal view and mediolateral oblique view in the similar manner to the normal MMG.

Subjects and purpose
The study was performed upon the approval of the institutional review board, and included 70 patients who had undergone CESM during the nine-month period from August 2015 to April 2016 using the method that MMG was performed within 2-8 minutes after injection of the contrast medium during contrast enhanced computed tomography. The scan was performed as postoperative follow-up in 29 patients, and as preoperative testing in 41 patients. This method allowed us to obtain additional data with contrast imaging without placing financial burden on the patient, and we investigated whether this method was effective as CESM in the present study.

Results
Of the 41 patients who had undergone the scan as a preoperative test (bilateral scans in 3 patients, and 44 breasts), it was in 43 breasts (97.7 %) that lesions could be identified by MMG, and in 42 breasts (95.5 %) that lesions could be identified by CESM. Of the 44 breasts, three breasts showed high-density mammary glands, in two of which the mass was lateral to the margin of the mammary gland, and therefore could be identified by normal MMG; however, in one breast the mass was medial to the margin of the mammary gland and difficult to be identified by MMG, and could only be identified by CESM. The lesions in the two breasts that were difficult to be identified by CESM exhibited the histological type of DCIS, and the lesions were able to be identified as calcification with normal MMG.

The tumor diameter was compared using invasion size determined by CESM, contrast-enhanced MRI, and postoperative pathological specimen, respectively. The correlation coefficient for CESM and contrast-enhanced MRI was 0.9668, and the correlation coefficient for CESM and postoperative pathological specimen was 0.984887, with a strong correlation observed (Pearson's correlation coefficient test).

Conclusion
To the best of our knowledge, no reports of CESM in which MMG is performed immediately after contrast-enhanced CT have been published to date, and thus this is the world's first attempt of such method performed at our hospital. CESM ensures diagnosability without being invasive or placing financial burden on the patient. It was suggested that CESM can be clinically useful particularly for those who cannot undergo contrast-enhanced MRI due to hardware problems, financial difficulties, or metal embedded within the body.
Title: Influence of hormone replacement therapy following bilateral salpingo-oophorectomy on mammographic breast density in women newly diagnosed with breast cancer

Pivo S, Schwartz S, Chun J, Guth A, Axelrod D, Shapiro R and Schnabel F. New York University Langone Medical Center, School of Medicine, New York, NY and New York University Langone Medical Center, New York, NY.

Body: Background: Studies have demonstrated that use of hormone replacement therapy (HRT) in post-menopausal women results in increased breast density. This is associated with increased risk of breast cancer and reduced sensitivity of mammography. The purpose of the present study was to compare breast densities of women following surgical menopause with and without use of HRT to women who had natural menopause without use of HRT.

Methods: Our institutional Database was queried for post-menopausal women newly diagnosed with breast cancer from 01/2010 to 01/2016. Patients were divided into following groups: 1) natural menopause with no HRT use, 2) history of a bilateral salpingo-oophorectomy (BSO) with no HRT use, 3) history of a BSO with HRT use prior to diagnosis, or 4) history of BSO and use of HRT at the time of diagnosis. BSO may have occurred with or without concurrent hysterectomy.

Results: 1106 women were eligible for analysis. 976 (88%) had natural menopause with no HRT, 63 (6%) had a BSO with no HRT, 51 (5%) had a BSO with previous history of HRT, and 16 (1%) had a BSO and were using HRT at time of malignancy diagnosis. Though not statistically significant, women who had a prior BSO and were on HRT at the time of diagnosis had more dense breasts (69% heterogeneously or extremely dense) than women who had natural menopause with no HRT (44% heterogeneously or extremely dense). However, women who had a prior BSO and were on HRT in the past had significantly less dense breasts (p=0.007) than women who underwent natural menopause without HRT use (67% vs. 56%).

Breast density

- Entirely fatty: 94 (10%) vs. 5 (8%) (p=0.95)
- Scattered fibroglandular: 448 (46%) vs. 30 (47%) (p=0.34)
- Heterogeneously dense: 393 (40%) vs. 25 (40%) (p=0.11)
- Extremely dense: 41 (4%) vs. 3 (5%) (p=0.17)

Conclusion: In our study cohort, women with history of surgical menopause who were on HRT at the time of breast cancer diagnosis had a trend towards more dense breasts. Surprisingly, women who were prior users had less dense breasts than women who never used HRT. Despite the change observed in breast density, the tumor characteristics do not differ with HRT usage, suggesting that variability in breast density did not correlate with stage of disease at presentation. This may be related to heightened awareness among clinicians regarding risk associated with HRT use that led them to modify screening and surveillance in these patients.
Visualizing the real difference between 2-D and 3-D specimen mammography

Kaufman CS S and Zacharias K. University of Washington; Bellingham Regional Breast Center and Bellingham Ambulatory Surgery Center.

BACKGROUND: Specimen mammography aids in the determination 1) if the target lesion has been removed and 2) whether there is a clear margin at excision. In the past, two orthogonal views using 2-D imaging has been considered to be equivalent to a three dimensional perspective. Yet tomosynthesis for screening mammography has demonstrated the value of thin sliced imaging over two view screening mammography. In March, 2015, we began using true 3-D tomosynthesis of breast specimens at lumpectomy and have compared 2-D and 3-D specimen mammography.

METHODS: We have examined 125 consecutive breast cancer patients with both 2-D and 3-D imaging of the same specimens since March 2015. The circulating nurse would take the specimen and obtain two orthogonal views using both 2-D and 3-D devices with images sent to the radiology department. It was not felt ethical to blind the surgeon from having both images available to make an intraoperative clinical decision regarding immediate re-excision. We compared the data noted from each method and which method best aided the decision to perform immediate re-excision, and time required to obtain the images.

RESULTS: We have studied 125 patients over 11 months since March 2015. Confirmation of complete lesion excision was easier with 3-D tomosynthesis than with 2-D as the 3-D slice did not include overlying skin or dense breast tissue surrounding the lesion in the image, making the target lesion stand out more clearly. Although the 2-D images appear to have higher contrast than the individual 3-D slices, the tomosynthesis 3-D images contained more actionable data than the 2-D. Also decisions to excise more tissue during the procedure were enabled by the additional information included in the 3-D images. In addition, the 3-D images provided the depth of field to enable accurate re-excision using the Z-axis (see figures). Finally, it took about a minute longer to obtain and review the 3D images, although this difference did not delay surgical decisions nor prolong operative time.

CONCLUSIONS: 3-D specimen tomosynthesis facilitates the reduction of post-operative re-excision for lumpectomy patients by providing more information than 2-D orthogonal views, providing easier, more accurate confirmation of the extent of the target excision. Additionally, serial 1mm slices of the specimen allowed the integration of Z-axis targeting, ensuring that any necessary margin excision during surgery was accomplished immediately with maximum tissue conservation. More studies are planned to further validate these findings of these first 125 patients.
Title: BI-RADS classification in daily practice: Keep it simple

Body: Aim
To investigate the risk of malignancy following stereotactic biopsy of calcifications classified as BI-RADS 3, 4 and 5.

Methods
All women with calcifications (not associated with masses or architectural distortions) who underwent stereotactic breast biopsy procedures at the Dutch Cancer Institute between January 2011 and October 2013 were included in the study. Suspicious calcifications (defined as BI-RADS 3, 4 or 5) detected on mammography were biopsied. All lesions were analyzed by dedicated breast radiologists and classified according to the BI-RADS lexicon.

Findings
Overall, 473 patients underwent 497 stereotactic breast biopsy procedures. Sixty-six percent (326/497) of the calcifications were classified as B4, 30% (148/497) were classified as B3 and 4% (23/497) were classified as B5. In total, 226 (45%) lesions were malignant. The malignant lesions consisted of 182 cases of pure DCIS (ductal carcinoma in situ), 22 cases of mixed DCIS and invasive carcinoma (ductal or lobular), 21 cases of pure invasive carcinomas (ductal or lobular) and 1 angiosarcoma. Malignancy was found in 32% (47/148) of the B3, 49% (160/326) of the B4 and 83% (19/23) of the B5 calcifications.

Conclusion
Considering the high incidence of malignancy in B3 calcifications, we believe that these lesions should either be classified as clearly benign (B2) or suspicious (B4 or 5) to avoid missing a malignant lesion. This simplification could improve patient care, avoiding delays in both diagnosis and treatment.

Title: Pre-operative breast MRI would not benefit breast cancer patients’ survival, even in young patients treated with breast-conservative surgery

Huang N, Chen J, Yang B, Quan C, Xue J, Huang X and Wu J. Fudan University Shanghai Cancer Center, Shanghai, China and Shanghai Medical College, Fudan University, Shanghai, China.

Body: Background
Although breast magnetic resonance imaging (MRI) could help to identify occult lesions in breast cancer, its role in patient outcome has always been controversial. The current study aimed to evaluate the role of MRI in Asian breast cancer patients, especially young patients that might have dense breasts.

Methods
Patients with non-metastatic unilateral breast cancer who received surgery in our institute during 2007-2013 were retrospectively reviewed. The differences between groups were compared using Pearson’s \( \chi^2 \) test. Loco-regional recurrence-free survival (LRRFS) and recurrence-free survival (RFS) were estimated using the Kaplan-Meier method.

Results
A total of 13,681 patients were included into analysis, among which 5823 (42.6%) had pre-operative MRI. Of all patients, 39.7% were stage 0-I according to TNM system, 35.5% were stage II, 14.8% were stage III and 10.0% could not be staged. Patients with axillary lymph node metastasis were comparable in MRI and non-MRI groups (35.3% versus 35.6%, \( P=0.695 \)). The percentile of patients receiving MRI increased from 7.3% in 2007 to 67.5% in 2013. Patients in the breast-conservative surgery (BCS) group were more likely to receive MRI compared with the mastectomy group (\( P<0.001 \)).

Age and menopausal status were also related with the choice of pre-operative MRI. When patients were grouped according to age, 56.7%, 48.9%, 43.6%, 37.0% and 27.1% patients in the \( \leq 35, 36-45, 46-55, 56-65 \) and \( >65 \) years old group had MRI, respectively (\( P<0.001 \)). When patients were grouped according to menopausal status, 37.8%, 48.8% and 27.3% patients in the post-menopausal group, pre-menopausal group and unknown menopausal status group had MRI, respectively (\( P<0.001 \)).

In survival analysis, the average follow-up time for the MRI group (\( N=5823 \)) and non MRI group (\( N=7858 \)) were 88.5 and 114.4 months, during which 238 (4.1%) and 464 (5.9%) breast cancer recurrences occurred, while 63 (1.1%) and 159 (2.0%) loco-regional recurrences occurred. The estimated 5-year RFS for MRI group and non-MRI group were 90.1% and 90.0% (\( P=0.510 \)). The 5-year LRR-free survival LRRFS for MRI group and non-MRI group were 96.7% and 97.3% (\( P=0.128 \)).

In subgroup analysis, 2376 patients received BCS, and 11,035 received mastectomy. Patient in the pre-operative MRI group did not have superior RFS or LRRFS compared with the non-MRI group, regardless of surgical management (BCS versus mastectomy). Then we restrained the analysis to patients who were \( \leq 45 \) years old and treated with BCS. A total of 699 patients had pre-operative MRI, and 419 patients did not. The 5-year RFS for MRI group and non-MRI group were 95.8% versus 94.6% (\( P=0.231 \)); the 5-year LRRFS for MRI group and non-MRI group were 99.8% and 97.1% (\( P=0.144 \)).

Conclusions
There was an increasing trend of pre-operative MRI examination during 2007-2013, especially in young patients and patients treated with BCS. However, pre-operative MRI could not benefit breast cancer patients’ survival by detecting occult lesions, even in young patients treated with BCS, who were considered to have dense breasts.
Title: Predictive value of breast MRI in detecting mammographically occult contralateral breast cancer: Can we target women more likely to have contralateral breast cancer based on primary tumor clinicopathologic factors?

Susnik B, Lillemoe TJ J, Swenson KK K, Tsai ML L, Finkelstein MJ J, Schneider L, Braatz CM M, Krueger JL L and Rueth N. Allina Health, Virginia Piper Cancer Institute, Minneapolis, MN and Allina Health, Piper Breast Center, Minneapolis, MN.

Body: Background: Use of preoperative magnetic resonance imaging (MRI) staging in newly diagnosed breast cancer increases detection of synchronous contralateral breast cancer (CBC) over other screening modalities; however, it is associated with a high false positive rate, additional biopsies, extensive surgical procedures, and possibly increased psychological morbidity.

Specific Aims: To determine predictors of synchronous, mammographically-occult but MRI-detected CBC in women newly diagnosed with breast cancer.

Methods: We performed a retrospective review of patients at Allina Health, Abbott Northwestern Hospital who had preoperative breast MRI prior to surgical resection of their breast cancer from 2010–2014. We collected patient demographic and clinicopathologic data. To determine the association between MRI-detected CBC versus benign findings based on clinicopathologic data, we performed univariate analysis (p<0.05). Multivariate Logistic Regression was used to adjust for covariates and factors predictive of CBC. Area under the Receiver Operating Characteristic Curve provided a measure of model accuracy.

Findings: 1894 patients had pre-operative MRI during the study period. Of those, 201 had suspicious findings on contralateral breast MRI requiring biopsy (table 1). Overall 3% (60/1894) had synchronous CBC (invasive carcinoma or DCIS) detected on MRI. The majority of CBCs (n=60) were stage 0 or IA (85%), ER/PgR+ (98%), HER2- (89%), and low/intermediate grade (80%). Women more likely to have mammographically-occult CBC were older (p<0.001), had lobular versus ductal index cancer (p=0.03), and had ER positive (p=0.027) or PgR positive (p=0.002) tumors. On multivariate logistic regression analysis (ROC area=0.75), PgR positive status (p=0.022), and older age (p=0.004) were predictive of CBC. With each year of additional age, odds of CBC increased by 5%. No CBC was identified in women < age 45 with high risk index cancers (ER- or HER2 +). CBC was 11 times more likely when PgR status was positive versus negative. CBCs were diagnosed significantly more frequently in patients with index cancers that were hormone receptor positive and HER2 negative compared to HER2 positive or triple negative invasive index cancers (Fisher's exact test; p=0.041).

Conclusions: Preoperative MRI is effective in detecting mammographically-occult early stage, hormone receptor positive CBC in older women. MRI-detected CBC is more common in patients originally presenting with hormone receptor positive and HER2 negative index cancers. Our results suggest that it may be possible to determine a subset of patients who are less likely to benefit from a preoperative breast MRI, an important implication in an era of increasing healthcare cost utilization awareness.
**Body: Objective** Breast density (BD) is a measure of the distribution of variable tissue types within the breast and higher BD has been shown to positively correlate with breast cancer risk. As such, the accurate measurement of BD has become a priority for risk assessment and for evaluating the effects of prevention strategies aimed at reducing BD. Mammography (MG) is the most common method of BD determination but is limited by the exposure to ionizing radiation, particularly for studies requiring repeated measures. BD derived from fat-water decomposition magnetic resonance imaging (FWMRI-BD) has been proposed as an alternative, safe, and quantitative method for BD. To optimize its use, we developed a new FWMRI-BD that is automated, more accurate and reliable. In this study, we compare our automated method to digital MG and a previous reported algorithm for MRI derived BD.

**Methods** From a completed prevention trial, 42 pre- and post-menopausal patients receiving tamoxifen therapy for early stage breast cancer or as primary chemoprevention were identified. Patients had undergone prior digital MG within 6 months from the date of MRI scan and MG-BD was calculated using a well-established method (Cumulus). MRI scans were performed on a 1.5T GE Signa NV-CV/i scanner using an axial radial IDEAL-GRASE sequence to generate quantitative fat fraction maps of the entire breast. Total acquisition time was < 5 min and automated breast segmentation was applied to all scans. Only the contralateral, unaffected breast was analyzed. Pearson correlation analysis compared BD as measured by MG (range 0-100%) and FWMRI based methods. BD by FWMRI was initially calculated as the ratio of breast voxels with <80% apparent fat fraction (Fra\(_80\)). Fra\(_80\) had been previously shown by our group to correlate with MG-BD (Spearman \(\rho = 0.86, p<0.001\)). Here, BD was calculated using a new algorithm (Fra\(_G+W\)) that accounts for the total amount of fibroglandular tissue and water content in the breast after correction for fat-water signal intensity bias and fat-water signal shine-through. Reliability of FWMRI measurements was tested in 24 repeated scans from 9 patients and evaluated using intra-class correlation (ICC) analysis.

**Results** Table 1 shows the correlation and reliability analysis results between MG-BD and FWMRI-BD. Both FWMRI-BD measures (Fra\(_80\) and Fra\(_G+W\)) were strongly correlated with MG-BD. More importantly, they exhibit superior test-retest reliability (ICC > 0.98) compared to MG-BD values from the literature (reported ICC range 0.91-0.95). Fra\(_G+W\) showed improvement over Fra\(_80\) in all measures tested including correlation to MG-BD, dynamic range, standard errors and ICC.

**Table 1. Accuracy and Reliability of the FWMRI-BD measures**

* All P-values < 1e-10

**Conclusion** The refined and automated FWMRI-BD that quantifies the entire fibroglandular and water content of the breast (Fra\(_G+W\)) strongly correlates with MG-BD and is more accurate and reliable than previous FWMRI-BD method.

Title: Is breast magnetic resonance imaging (MRI) useful for diagnosis of additional sites of disease in patients recently diagnosed with ductal carcinoma in situ (DCIS)?

Ortiz-Perez T, Benveniste AP, Ebuoma LO, Sepulveda KA, Severs FJ, Kapoor M and Sedgwick EL. Baylor College of Medicine, Houston, TX.

Body: Purpose: To determine if breast MRI is useful for detecting additional sites of disease in patients initially diagnosed with pure DCIS.

Materials and Methods: A retrospective review of women diagnosed with pure DCIS who underwent a breast MRI for evaluation of extent of disease was performed at a single institution from January 2013 to April 2015. Data analysis included imaging (mammography, ultrasound and MRI) and pathology characteristics (histology and biomarker status) of the primary DCIS as well as descriptors for the additional sites of disease incidentally found by breast MRI.

Results: A total of 94 patients were diagnosed with pure DCIS during this time period, ages ranging from 38 to 79 years old (median, 58.5 years); sizes ranging from 0.6 to 16 cm (mean, 4.5 cm). A total of 28 patients (30%) had other MRI findings suspicious for additional sites of disease in either breast. From this group of patients, 23 (82%) patients underwent MRI-guided biopsy. The 5 patients who did not have the MRI guided-biopsy either underwent total mastectomies or declined biopsy. Five out of the twenty-three patients (22%) were diagnosed with an additional site of cancer. Three of these patients were Hispanic, one was Asian/Pacific and one was Caucasian. Of the five patients, five had contralateral disease (100%) and none had a second site of disease in the ipsilateral breast. The size of the additional sites of disease ranged from 0.4 to 7.2 cm (mean, 2.1 cm) and the size of the primary lesion in this selected group ranged from 0.4 to 9 cm (mean, 3.4 cm). Ages ranged from 47 to 63 years old (median, 55 years). Four out of five patients (80%) presented with the first site of disease as pure DCIS with estrogen (ER) and progesterone (PR) receptors positive and one case (20%) was pure DCIS ER/PR- negative. The second incidental lesion found on MRI demonstrated 3 cases of contralateral pure DCIS. From this group, all the biomarkers status for the first and second site were concordant. From the 5 cases of second disease, 2 (40%) presented with invasive component in the contralateral side of the initially biopsy-proven pure DCIS and, one of these cases had discordant biomarkers compared with the first site of disease, the first site of pure DCIS was ER/PR-negative and the second site of invasive ductal carcinoma (IDC) presented with ER/PR-positive status.

Conclusion: From a total of 94 patients with recent diagnosis of pure DCIS who underwent breast MRI examination for diagnosis of additional sites of disease, approximately 5% were diagnosed with an additional site of cancer and 2% of the total cases had invasive disease in the additional sites with different biomarker status; changing their management and prognosis. Breast MRI plays a role in the setting of staging patients initially diagnosed with pure DCIS.
Title: Does MRI influence surgical planning more than clinical outcome? A cohort study of breast cancer patients receiving neoadjuvant therapy

Body: Background: While magnetic resonance imaging (MRI) is a powerful diagnostic tool, there is currently no consensus on its role for breast cancer patients prior to the initiation of neoadjuvant therapy (NAT). In the adjuvant setting, there is evidence that the use of MRI is correlated with an increase the rate of mastectomies performed. There is currently no data describing how MRI is influencing treatment decisions or surgical management in the neoadjuvant setting. This study aimed to determine the impact of MRI on patients' surgical plan, and to understand the demographic differences in patients who had an MRI compared to those that did not in the neoadjuvant setting.

Methods: A secure database containing all potential NAT patients seen by medical oncologists at the BC Cancer Agency Vancouver Centre since 2012 was searched. Breast cancer patients who were treated with NAT and had undergone breast surgery before March 30, 2016 were identified. Tumour characteristics, surgical plan and surgical outcome were assessed retrospectively and compared between patients who had an MRI and patients who did not have an MRI.

Results: 270 patients were identified who met the inclusion criteria. Of those, 107 patients had a breast MRI and 163 patients did not. The two groups showed no significant pre-treatment differences with regards to type of breast cancer, receptor status, or clinical stage. The median age was 10 years younger in the MRI group (47 years) compared to the non-MRI group (57 years), p < 0.0001. Patients who had an MRI had a non-significant higher rate of pathological complete response (pCR) than those who did not (30.8% and 21.5%, respectively, p=0.08). The surgical treatment did differ between these two groups; those who had MRI were more likely to have bilateral mastectomy (36.4% vs 23.3%, p=0.019) and less likely to have breast conserving surgery (BCS) (19.6% vs 31.9%, p=0.026). In the cohort that had an MRI, there was no significant difference in percentage of patients whose surgical plan was changed compared to the patients who did not have an MRI (33.6% and 28.8%, respectively). A change in surgical plan from a mastectomy to a BCS was more common in patients who did not have an MRI than those that did (31.9% and 13.9%, respectively). 45% of the surgeons who dictated a follow-up surgery consultation stated that the MRI was used to inform the surgical plan.

Discussions/Conclusions: In this real-world cohort, patients who had an MRI were more likely to undergo a bilateral mastectomy and less likely to have a BCS than the patients who did not have an MRI, despite having a higher rate of pCR. Age was the only baseline demographic difference between the two groups. These findings suggest that the role of MRI in the neoadjuvant setting needs to be refined further in order to avoid over-treatment.
Title: Magnetic resonance imaging (MRI) surveillance for patients with dense breasts and a previous breast cancer (BC) and/or high risk lesion

Nadler M, Al Attar H, Curpen B, Martel AL L, Balasingham S, Zhang L, Eisen A and Warner E. McMaster University, Hamilton, ON, Canada; Sunnybrook Health Sciences Centre, Toronto, ON, Canada; Physical Sciences, Sunnybrook Research Institute, Toronto, ON, Canada and Medical Biophysics, University of Toronto, Toronto, ON, Canada.

Body: BACKGROUND AND PURPOSE
The benefits of breast MRI for screening women at high risk of developing BC is established, but its role in women with a personal history of BC or dense breasts is unknown. We sought to estimate the performance of annual surveillance MRI added to mammography in women at moderately increased BC risk due to a personal history of breast cancer and/or a high-risk breast lesion and dense breasts.

METHOD AND MATERIALS
We performed a retrospective chart review of the clinical, radiological, and pathological parameters of women who received annual, concurrent surveillance breast MRI and mammography between 04/2013 and 12/2015. We included women who met all of the following criteria: age<69; prior diagnosis of high-risk lesion (ADH, ALH, LCIS), DCIS, or invasive BC; heterogeneously (50-75%) or extremely dense (>75%) breasts; and did not qualify for our provincial MRI screening program for high risk women (calculated lifetime BC risk ≥ 25%). Results of each scan were analyzed using descriptive statistics and Chi squared for comparisons between subgroups.

RESULTS
A total of 199 patients (267 MRI exams) were included in this study. The mean age at initial diagnosis was 45 years and at subsequent diagnosis of DCIS or invasive cancer was 53 years. Mean time to new diagnosis was 86 months (range 14-202). All 15 cancers diagnosed during the study period were MRI detected: 11 invasive stage I (66% IDC, 7% ILC) and 4 DCIS (27%). Of these 15, all but 1 were mammographically occult. Five (33%) were found in the breast ipsilateral to the original lesion. The cancer detection rate was 6% (12/199) on the first screening round and 4.7% (3/64) on the second screening round. Specificity and positive predictive value respectively for MRI exams increased from 77% and 22% on the first screening round to 88% and 30% on the second round. Of women who developed BC, 57% had a history of breast or ovarian cancer in a first degree relative. None of the 72 women who were on hormonal therapy at the time of surveillance imaging had a new cancer detected compared to 11% (14/125) of those who were not on hormonal therapy (p=0.0025).

CONCLUSIONS
The incremental early-stage BC detection rate and specificity of MRI in this population are comparable to what is observed in screening women at high risk. The addition of annual MRI to mammography should be considered for surveillance of women with a personal history of BC / premalignant lesion and heterogeneous / extremely dense breasts, particularly if they have a family history of BC and are not on hormonal therapy.
Title: Predictors associated with MRI surveillance screening in women with a personal history of unilateral breast cancer but without a genetic predisposition for future contralateral breast cancer

Body: Purpose
Women with a personal history of breast cancer (BC), in the absence of genetic predisposition or significant family history, are generally categorized as having an intermediate (15-20%) risk of developing future BC. Screening MRI is recommended as a supplement to mammography for women with a ≥20% lifetime risk. However, models available to calculate risk exclude women with a personal history of BC. Thus, there has existed no reliable mechanism to calculate future risk in these women to refine MRI surveillance recommendations. The Manchester score was recently developed and intended to inform contralateral breast cancer (CBC) risk for surgical decision making. We hypothesized that the score could be informative to guide follow-up imaging recommendations among women with a personal history of BC.

Patients & Methods
322 women with newly-diagnosed, non-metastatic, unilateral BC were seen in multidisciplinary breast clinic and underwent unilateral surgery (either breast conserving surgery or mastectomy) at our institution between June 2012 and November 2015. Using life expectancy, family history, genetic mutation status, and endocrine therapy use, we calculated the Manchester score, i.e. CBC risk, for all women. Patients were categorized as low- (<10% CBC lifetime risk), above average- (10-20%), moderate-(20-30%), and high-risk (>30%). We also reviewed the rationale that treating physicians noted for recommending MRI surveillance. Univariate logistic regression analysis (UVA) was used to assess if Manchester score was predictive of MRI surveillance in addition to other known factors.

Results
In the entire cohort, 75.8% (n=244) were low-risk for CBC, 18.6% (n=60) were above average-risk, 4.3% (n=14) were moderate-risk, and 1.2% (n=4) were high-risk. Using a 20% CBC risk as a threshold for MRI justification, 5.6% (n=18) met indications for MRI surveillance. Among the 21.7% (n=70) undergoing MRI surveillance, 57.1% (n=40) were low-risk, 32.9% (n=23) were above average-risk, 7.1% (n=5) were moderate-risk, and 2.9% (n=2) were high-risk. There was a significant trend for higher rates of MRI surveillance as the risk score increased (odds ratio, OR 1.1, p<0.0001). On UVA, the highest odds for MRI surveillance were in women with a mammographically-occult BC history (OR 9.35, p<0.0001), pre-operative breast MRI use (OR 8.41, p<0.0001), and dense breast tissue (OR 4.88, p<0.0001). The top clinician-endorsed reasons for MRI surveillance were dense breast tissue (61.4%), young age at diagnosis (28.6%), and mammographically-occult BC history (25.7%).

Conclusions
Although Manchester score was significantly predictive for MRI surveillance, we identified a large subset of women with <20% calculated CBC risk who underwent MRI surveillance (90.0% of the cohort undergoing MRI) and a small subset with ≥20% CBC risk who continue with mammography alone (4.4%). Overall, concern about poor detection of a future CBC appeared to dominate the selection of surveillance MRI use, even within a largely low-risk population. We believe this calculation could be informative prospectively to select surveillance strategies in women at a high future risk of CBC.

Title: Association of background parenchymal enhancement with breast cancer risk factors and tumor characteristics

Body: Background: Background Parenchymal Enhancement (BPE) in a dynamic contrast enhanced (DCE)MRI refers to change in morphology and temporal degree of enhancement expressing physiology of breast tissue. Improvements in the analysis and interpretation of BPE have been shown to increase diagnostic accuracy of the MRI. We explored associations of BPE with breast cancer (BC) risk factors and tumor characteristics.

Methods: We conducted a retrospective chart review study of 149 women who were treated for BC at the University of Maryland Medical Center (UMMC) between 2003-2015. Institutional Review Board approval was obtained. Subjects had BI-RADS 4,5 or 6 on their mammograms and/or biopsy proven BC. Women with false positive mammograms (n=2), missing BPE grade in their MRI reports (n=6), metastatic BC at diagnosis (n=2), MRIs done outside of a year of diagnosis (n=3), and who followed up outside UMMC (n=1) were excluded. Final analysis included 135 women. We used 1.5T or 3T scanners for DCE MRI. Standard contrast enhanced MRI protocol, T1, T2, and dynamic series were acquired according to American College of Radiology requirements for breast MRI accreditation and interpreted with Maximum Intensity Projection and subtracted imaging. Fellowship-trained breast imagers performed qualitative BPE assessment as per standard BI-RADS classification. BI-RADS classes were grouped as high BPE (BI-RADS moderate and marked) and low BPE (BI-RADS minimal and mild). Multivariable logistic regression was used to assess associations with predictors including individual and tumor characteristics.

Results: Preliminary analyses showed BPE was significantly associated with alcohol intake, with drinkers being more likely to have high BPE compared to non-drinkers [odds ratio (OR) =3.08 (95% confidence interval (CI) = 1.34-7.09; p=0.008]. Women who received adjuvant radiation for their BC were less likely to have high BPE compared to women who did not undergo radiation [OR= 0.37 (95% CI=0.15-0.90); p=0.03] implying higher likelihood of breast conservation surgery in the former group. High BPE was less often observed for invasive ductal carcinoma histology vs. in-situ ductal carcinomas [OR= 0.40 95% CI=0.16-1.00); p=0.05] and in post- vs. premenopausal women [OR=0.47 (95%CI=0.22-1.00); p=0.05]. No association was found between BPE and race, BMI, prior HRT/OCP use, smoking, or ER/PR/HER-2 status.

Conclusion: We observed association between higher BPE and alcohol exposure and lower BPE and, invasive ductal histology, postmenopausal status at diagnosis of BC and adjuvant radiation for BC. Larger studies are needed to corroborate our findings and identify the underlying mechanisms.
Title: Do radiographic features influence the decision to order a breast MRI? A prospective cohort study

Body: Background:
The clinical impact of breast MRI in the neoadjuvant setting is unclear. It is assumed that MRI may help with surgical planning. Factors that may affect whether an MRI is ordered for breast cancer in the neoadjuvant setting may include both imaging and tumour characteristics. Literature suggests MRI can be used in the neoadjuvant therapy (NAT) if there is evidence of high density of breast tissue, multifocal disease, multi-centric disease, lymph node involvement or presence of calcifications. In a non-trial setting, it is unclear when MRI is ordered and if it is indeed ordered based on the above imaging criteria. We sought to determine how MRI is currently implemented in a provincial practice to determine which patients are selected for MRI prior to NAT. Specifically, we aimed to determine if the imaging characteristics determined likelihood of use of MRI in the neoadjuvant setting.

Methods:
Patients who received neoadjuvant therapy between May 2012 and May 2016 were captured in a prospective database at the BC Cancer Agency in Vancouver. Patients were reviewed and identified as those who either received a breast MRI or not. A random sample of 80 cases, 40 who received MRI and 40 who did not, was taken from this database. Charts were reviewed in detail, and detailed review of the radiographic features from mammogram and ultrasound imaging reports was recorded.

Results:
80 patients were reviewed in detail. There were no differences in patient demographics or tumour characteristics. Imaging review demonstrated no statistical significant difference in use of MRI based on reported density, multi-centric disease, calcifications, and nodal involvement. The only radiographic feature that was different was presence of multifocal disease on conventional imaging, where 40.0% of patients who had an MRI had multifocal disease reported whereas only 17.5% of those who did not have an MRI had multifocality reported (p = 0.03).

Discussion/Conclusions:
Despite radiographic guidelines for use of MRI, the decision by the ordering physician regarding who should receive an MRI prior to NAT still appears to be unsystematic. This could be due to incorrect interpretation of radiographic reports by the ordering physicians and lack of availability or access to the interpreting radiologist. Results suggest that the ordering physician is already aware of multifocal disease and is utilizing MRI to verify this presence, rather than using MRI to investigate the possibility of multifocality in dense breast tissue. Based on this strategy of use it is unlikely that MRI will reduce the rate of mastectomy in this patient population.

Title: Selective use of MRI and impact on management in breast cancer

Jafferbhoy S, Tandon M, Kirby R, Narayanan S, Bajwa S, Salehi Bird S, Mohd-Isa Z and Soumian S. Royal Stoke University Hospital, Stoke-on-Trent, Staffordshire, United Kingdom.

Body: Introduction:
Breast cancer can present as a mammographically occult lesion. Lobular carcinoma has the propensity to develop multifocal and multicentric disease. Studies have suggested that invasive carcinoma with lobular features have similar biological characteristics as invasive lobular carcinoma. In our unit, patients with mammographically occult cancer and those with lobular features on core biopsy have a pre-operative MRI scan. The aim of this study is to assess the impact of contrast enhanced MRI on management of these cases.

Methods:
Over a 3 year period from November 2012 to October 2015, all breast MRI scans were reviewed and those patients with mammographically occult cancer and invasive carcinoma with lobular features on biopsy were included. Demographic data, imaging, pathology and treatment details were collected from Clinical Information System. A size difference of +/-10% between the imaging modalities was considered to be concordant

Results:
Out of 389 patients with breast MRI for invasive carcinoma, 104 patients with a median age of 57 years were included. 69 patients (66%) were symptomatic and 35 (34%) were screen-detected cancers. 64 patients had lobular features on core biopsy and 40 patients had mammographically occult cancer.
In patients with lobular features group, MRI findings were concordant with mammograms in 26 patients (40%) while 38 (60%) had additional findings (28% multifocality, 19% non-concordant size, 6% contralateral findings and 7% ipsilateral benign findings).
In patients with non- concordant findings, 58% underwent USS and 24% had biopsy following MRI.
In the mammographically occult group, USS identified the primary lesion in 32 patients (80%) while 8 patients (20%) had occult lesion both on USS and mammograms. MRI findings were concordant in 90% while 10% had non-concordant findings (6% multifocality and 4% non-concordant size). Following MRI, 8% had another USS and 3% had biopsy.
MRI findings changed the treatment plan in 19% cases with lobular features. 14% underwent mastectomy instead of wide local excision, 3% primary chemotherapy and 2% bilateral wide local excision. There was a change in treatment plan in 25% of the mammographically occult cancers of which only 6% had lesion visible on USS. 15% of mammographically occult cancers had mastectomy instead of WLE and 10% had neo-adjuvant chemotherapy.

Conclusion:
This study has demonstrated that pre-operative MRI leads to additional investigations. Its impact on management is low if the lesion is mammographically occult but visible on ultrasound. In cases with ultrasound occult cancer and those with lobular features on core biopsy, it changes management in a significant proportion and should therefore be considered as a part of the diagnostic work-up.
Clinical examination and breast MRI as predictors of pathologic complete response post neoadjuvant therapy in HER2 overexpressed subtypes and triple negative breast cancer

Background: Preoperative identification of pathologic complete response (pCR) is important to decrease surgical morbity. The objective of this study was to determine diagnostic validity of clinical examination and magnetic resonance imaging (MRI) in determining pathologic response in patients with breast cancer subtypes HER 2 overexpressed and triple negative after neoadjuvant therapy.

Methods: This is a cross- sectional study, with a sample comprising 72 patients woman with HER-2 overexpressed or triple negative breast submitted to neoadjuvant treatment at Hospital Sírio Libanês between January 2005 and December 2012. All patients were clinically evaluated by a group of seven breast surgeons. Double reading of breast MRI was performed in three periods: at the beginning of treatment, after the second cycle of chemotherapy and after treatment. Photographic record of the breast was done before and after chemotherapy. HER-2 and hormone receptors were assessed using immunohistochemistry. Sensitivity (Se), specificity (Sp), positive predictive value (PPV), and negative predictive value (VNP) were estimated using pathology as the gold standard. Area under ROC curve and the corresponding 95% confidence intervals (95% CI) were calculated.

Results: Thirty- two patients (44,4%) had triple negative tumors while 40 (55.6%) overexpressed HER-2. Among those with triple negative tumors, clinical examination evidenced a completed response in 31.2% (10/32) of the cases. pCR was observed in 3 patients (9.4%). Diagnostic validity measures for clinical examination were: Se= 100%, Sp=75.9%, PPV=42.9% and NPV=100%. In this group, MRI detected a complete response in 7 cases (21.9%). Therefore, MRI presented a Se=66.8%, Sp=82.8%, PPV 28.6% and NPV= 96%. Area under ROC curve was 0.88 (95% CI 0.80-0.96) and 0.75 (95% ci 0.41-1.00) for clinical examination and MRI, respectively. Among woman with tumors over expressing HER-2, complete response was observed through clinical examination in 45% (18/40) of these cases, showing Se= 100%, Sp=71%, PPV=100% and NPV=70,9%. In this group, complete radiological response was noted in 8 cases (20%). Therefore, MRI had Se=33.3%, Sp=83.9%, PPV 37.5% and NPV=96%. Area under ROC curve was 0.85 (95% CI 0.77-0.94) and 0.59 (95% CI 0.41-0.76) for clinical examination and MRI, respectively.

Conclusions: Our findings demonstrate that clinical examination is superior to MRI to predict pCR for woman wth tumor overexpressing HER-2, while for tumor patients with triple negative tumors the two methods were equivalent. Therefore, clinical examination can be used with MRI to monitor tumor response to neoadjuvant chemotheraphy and also to determine the best course of surgical action. Monitoring and assessment, however, are better when both methods are associates.
**Title:** Impact of magnetic resonance imaging on conversion from wide local excision to mastectomy in patients with ductal carcinoma in situ: First results from the ECOG-ACRIN 4112 prospective study

Lehman CD D, Gatsonis C, Greco E, Khan SA A, Sparano JA A, Solin LJ J, Badve SS S, Corsetti RL L, Rahbar H, Spell DW W, Blankstein KB B, Han LK K, Sabol JL L, Bumberry JR R, Miller KD D and Comstock C. Massachusetts General Hospital, Boston, MA; Brown University, Providence, RI; Northwestern University, Chicago, IL; Montefiore Medical Center, Albert Einstein College of Medicine, Bronx, NY; Albert Einstein Medical Center, Philadelphia, PA; Indiana University, Indianapolis, IN; Ochsner Medical Center Jefferson, New Orleans, LA; University of Washington, Seattle, WA; Gulf South NCORP, New Orleans, LA; Hunterdon Medical Center, Flemington, NJ; Lankenau Medical Center, Wynnewood, PA; Mercy Hospital, Springfield, MO and Memorial Sloan Kettering Cancer Center, New York, NY.

**Body:**

**Purpose:** To estimate the proportion of patients with ductal carcinoma in situ (DCIS) judged to be candidates for wide local excision (WLE) based on mammography (+/- sonography) and clinical exam who: (A) convert from WLE to mastectomy as the first surgical procedure based on magnetic resonance imaging (MRI) findings, and (B) have a mastectomy as the final surgical procedure.

**Patients and Methods:** The study population included women with DCIS diagnosed by core needle biopsy (and no evidence of invasive or micro-invasive disease) judged to be candidates for WLE by their surgeon based on standard imaging (mammogram +/-sonography) and clinical exam without prior breast MRI. After registration bilateral contrast enhanced breast MRI was performed, and a protocol management algorithm was followed. Before and after MRI, the surgeon documented the planned surgical procedure, including reason for conversion from WLE to mastectomy if the surgical plan changed. Prior evidence suggests that about 8-12% of patients initially considered candidates for WLE based on mammography ultimately require mastectomy, and the addition of MRI increases the likelihood of mastectomy by about 1.5-fold. A sample size of 350 (332 evaluable) was planned to ensure a 95% confidence interval (C.I.) of 8% if the actual mastectomy conversion rate was as high as 16%. Two-sided 95% Wilson confidence interval for proportion of patients converting to mastectomy based on MRI was derived.

**Results:** Of 363 patients enrolled, 340 had sufficient information to assess aim A (conversion to mastectomy after MRI), and 322 for aim B (mastectomy as final surgical procedure). At study entry, median age (range) was 59 years (34-87). Features of DCIS lesions included: median longest diameter (range) 11 mm (1-100); ER positivity 76.2%; low, intermediate and high grade 15.9%, 40.9% and 39.4% respectively (3.8% unknown). Based on MRI findings (Aim A), mastectomy rather than WLE was recommended as the first surgical procedure in 25/340 (7.4%, 95% CI: 5.0%, 10.6%). Reasons included large lesion size (N=15), multi-centric disease (N=6), and contralateral disease prompting bilateral mastectomy (N=4). An additional 28/340 (8.2%) converted to mastectomy as the first surgery based on other factors, including patient preference (N=25), interval discovery of genetic mutation (N=2), or inability to receive radiation treatment (N=1). Of the 278 patients for whom initial WLE was performed after MRI, 10/278 (3.7%) converted to mastectomy, all due to positive or close (< 2 mm) surgical margins. Overall (Aim B), 62/322 (19.3%, 95% CI 15.3%, 23.9%) had mastectomy as the final surgical procedure.

**Conclusion:** In women with DCIS judged to be candidates for WLE based on mammography (+/- sonography), conversion to mastectomy is fairly common with nearly 1 in 5 patients ultimately undergoing mastectomy. Breast MRI findings account for less than half of the conversions to mastectomy. For patients who remained candidates for WLE after MRI, 96.3% achieve successful WLE as the final surgical procedure.
Title: A novel high-throughput secreted factor screen and bioinformatics pipeline identifies microenvironment-derived FGF2 as a mechanism of resistance to anti-estrogens, PI3K, and mTOR inhibitors in ER+ breast cancer

Shee K, Hinds JW W, Hampsch RA A, Golub TR R, Straussian R and Miller TW W. Geisel School of Medicine at Dartmouth, Lebanon, NH; The Broad Institute, Cambridge, MA and Weizmann Institute of Science, Rehovot, Israel.

Body: Resistance to anti-estrogen therapy is a serious obstacle to the treatment of patients with ER+ breast cancer. Unlike the majority of preclinical studies that focus on cancer cell-intrinsic mechanisms of resistance, we hypothesized that the tumor microenvironment significantly contributes to drug resistance, and that individual factors present in the microenvironment differentially modulate response to therapy.

To systematically test this hypothesis, high-throughput screens were performed in which 297 unique secreted proteins (cytokines, growth factors, and extracellular matrix) were tested on ER+ breast cancer cell lines (MCF-7 and T47D) treated +/- anti-estrogen fulvestrant or the PI3K inhibitor GDC-0941 (pictilisib). Cytokines that rescued cells (hits) were validated in two additional ER+ breast cancer cell lines (ZR75-1 and HCC-1500), and expanded to include the anti-estrogen tamoxifen and the mTORC1 inhibitor everolimus. Hits were also found to rescue from combinations of fulvestrant/GDC-0941 and fulvestrant/everolimus in models with acquired resistance to fulvestrant. Multiple factors, such as ErbB family ligands and fibroblast growth factors (FGFs), were among the top validated hits.

To parse out which hits are most likely to be relevant in the setting of the ER+ breast tumor microenvironment, a bioinformatics filter was developed to incorporate gene and protein expression data for secreted proteins in non-cancer human tissues relevant to ER+ breast cancer. These tissues include primary breast tissue components (breast mammary, adipose, primary fibroblasts) and common metastatic sites (bone marrow, lung, liver). After filtering, the top hit was fibroblast growth factor 2 (FGF2), which significantly drives resistance to anti-estrogens, PI3K, and mTOR inhibitors, and is highly expressed in non-cancer tissues relevant to ER+ breast cancer.

FGF2-mediated rescue was completely abrogated by the ATP-competitive pan-FGFR inhibitor PD173074, confirming FGFR kinase specificity of the rescue phenotype. Immunoblot data confirmed that FGF2 induced phosphorylation of FGFR and the FGFR effector FRS2, and a consistent pattern of downstream MEK-ERK-Rsk90 activation for rescue to all drugs. Flow cytometry data showed that FGF2-mediated rescue leads to decreases in drug-induced apoptosis and G1 cell cycle arrest, which correspond at the protein level to increased degradation of the pro-apoptotic protein Bim and upregulation of the cell cycle driver cyclin D1, respectively.

Mice bearing MCF-7 xenografts were treated with vehicle, FGF2 (20 ug/kg/d, s.c.), fulvestrant (5 mg/wk, s.c.), or the combination. Vehicle-treated and FGF2-treated mice showed similar rates of tumor growth. Single-agent fulvestrant significantly suppressed tumor growth, while the addition of FGF2 rescued from the growth-inhibitory effect of fulvestrant. Studies in other tumor models are ongoing. These data collectively suggest that stroma-derived FGF2-mediated drug resistance is a novel therapeutic opportunity in ER+ breast cancer.
Title: Inhibition of NOS promotes ER stress response and augments docetaxel-mediated apoptosis in TNBC

Davila-Gonzalez D, Choi DS, Kuhn J, Granados SM M, Rosato RR R, Dave B and Chang JC C. Methodist Cancer Center, Houston Methodist Hospital, Houston, TX; Tecnologico de Monterrey, Campus Monterrey, Monterrey, Nuevo Leon, Mexico; UT College of Pharmacy, UTHSCSA, San Antonio, TX; Hospital Complex of Jaen, Jaen, Spain and GENYO, Centre for Genomics and Oncological Research, Granada, Spain.

Body: Introduction: Chemoresistance in triple negative breast cancer (TNBC) is related to an activation of a survival response orchestrated by endoplasmic reticulum (ER) stress. We hypothesize that attenuation of nitric oxide (NO) signaling pathway can overcome treatment resistance, preventing relapse, ultimately improving survival of TNBC patients. Here, we aimed to investigate the effects of pharmacological iNOS (inducible nitric oxide synthase) inhibition by L-NMMA on docetaxel-meditated ER stress response and to determine whether the therapeutic NOS inhibition may improve chemotherapy-based response.

Methods: BT-549, SUM-149, MDA-MB-436, and MDA-MB-468 TNBC cell lines were treated with docetaxel (D; 5 nm)/ L-NMMA (L; 4mM)/ amlodipine (A; 5 µM) daily for 48 and 72 hours. Cell death and proliferation were assayed by Annexin V and ATP quantification, respectively. Western Blot (WB) was used to measure ER stress markers. In vivo regimen treatment followed three 2-weekcycles of D (20 mg/kg intraperitoneal [IP] on day 1) and L (200 mg/kg oral gavage on day 2-6); A (10 mg/kg IP on day 2-6) A was administered together with L to counteract the well-known effects of L on blood pressure (hypertension). TNBC Patient derived xenograft (PDX) models #2147, #5998, #3107 and #4664 were transplanted into the mammary fat pad of SCID Beige mice. PDX #2147 received either, single drug (vehicle, L, A, D), double (L+A, D+L, D+A), or triple drug combination (L+A+D). Models #4664, #3107 and #5998 received only vehicle, D or D+ L+A. Mice weight and tumor volumes were recorded twice weekly. D concentration was measured by mass spectrometry.

Results: Studies on SUM-159 cell line showed that, when compared to the docetaxel-treated group, D+L+A increased cell death significantly, as indicated by a rise in annexin V/propidium iodide-positive cells. Increase in cell death by D+L+A was further demonstrated by accumulation of mitochondrial cleaved BAX. The enhanced apoptotic effects of D+L+A in MDA MD 468, BT 549 and MDA MD TNBC cell lines were confirmed by a decrease in ATP levels compared to D alone. WB revealed a survival stress response activated by docetaxel. When it was coupled with NOS inhibition, ER stress response showed higher expression of ATF4 and CHOP, triggering a proapoptotic response by pASK1/JNK pathway and cleaved caspases (CC3 and CC9). PDX #2147 showed that L, A and L+A treatment groups had similar tumor volume growth as the untreated group. However, combination therapy, D+L+A, significantly reduced the tumor volume and increased survival proportions compared with vehicle and docetaxel. Combination therapy also dramatically reduced tumor size on TNBC #4664 and #3107, and significantly improved response on #5998 compared with docetaxel alone. Intratumoral docetaxel concentration was 5.3-fold higher in mice receiving D+L+A than in those receiving docetaxel alone (#5998). In both groups, docetaxel was not detected in the plasma one week after injection.

Conclusion: The present data suggest that iNOS may be a critical target for docetaxel resistance in TNBC. iNOS inhibition enhanced chemotherapy response in TNBC PDX models indicating that addition of iNOS inhibitor may improve prognosis and prevent relapse in TNBC patients who have failed conventional chemotherapy.
An acquired HER2 T798I gatekeeper mutation induces resistance to neratinib in a patient with HER2 mutant-driven breast cancer

**Body:** *ERBB2*, the gene encoding HER2, is mutated in 2-4% of breast cancers. The HER2 irreversible tyrosine kinase inhibitor (TKI) neratinib has shown clinical activity against breast cancer cells harboring HER2 activating mutations. Here, we report for the first time an acquired gatekeeper HER2 T798I mutation in a patient with HER2-mutant breast cancer after an initial exceptional response to neratinib.

A patient with ER+/PR+/HER2-negative invasive lobular breast cancer progressing on standard therapy was found to harbor a L869R kinase domain mutation in HER2. HER2 L869R is homologous to the known activating mutation EGFR L861R/Q. MCF10A breast epithelial cells expressing HER2 L869R displayed enhanced HER2-mediated signaling and were resistant to lapatinib and trastuzumab but sensitive to neratinib. The patient was enrolled in the phase II SUMMIT trial (NCT01953926) and treated with neratinib, achieving a partial response lasting 16 months before developing progression. Next gen sequencing of DNA from both a new skin metastasis and plasma cell-free DNA (cfDNA) identified HER2 L869R (8.7% cfDNA), whereas a novel HER2 T798I mutation was detected only in plasma at 1.3%. Deep sequencing of pre-therapy tumor tissue and plasma did not detect HER2 T798I, suggesting that this mutation arose upon resistance. HER2 T798I has not been reported in TCGA, COSMIC, or among plasma samples from 17,345 cancer patients subjected to digital DNA sequencing using the Guardant360 assay. HER2 T798I is homologous to the EGFR T790M, KIT T670I and BCR-ABL T315I gatekeeper mutations known to mediate resistance to erlotinib/gefitinib and imatinib. To examine if HER2 T798I mediates resistance to neratinib, we employed biochemical and biological assays and molecular modeling of wild-type (WT) HER2 and HER2 T798I. Structural modeling showed the increased bulk of the isoleucine at position 798 would result in a steric clash with neratinib, thus reducing drug binding. We stably expressed HER2 WT, HER2 T798I, HER2 L869R and HER2 L869R/T798I in MCF10A cells and NR6 mouse fibroblasts. Neratinib (10-100 nM) blocked HER2-mediated signaling in cells expressing HER2 WT or HER2 L869R but did not in cells expressing HER2 T798I. The EGFR irreversible TKI osimertinib (100 nM), which isselective for mutant EGFR (including EGFR T790M) and approved for treatment of NSCLC expressing EGFR T790M, failed to inhibit HER2 WT, HER2 L869R or HER2 T798I. In contrast, either the EGFR/HER2 irreversible TKI afatinib or AZ5104, a metabolite of osimertinib, strongly blocked signaling induced by HER2 WT, HER2 L869R or HER2 T798I. Cells expressing HER2 T798M displayed a significantly higher IC50 to neratinib than cells expressing HER2 WT, whereas afatinib or AZ5014 were very active against all cells (IC50<10 nM).

**Conclusions:** The acquisition of a T798I gatekeeper mutation in HER2 upon development of clinical resistance to neratinib in a breast cancer with an initial activating mutation in HER2 strongly suggests that HER2 L869R is a driver mutation. We speculate that HER2 T798I may arise as a secondary mutation following response to effective HER2 TKIs in other cancers with HER2 activating mutations. Certain irreversible EGFR inhibitors may be effective in patients with HER2-driven breast cancer resistant to neratinib.
Title: Sensitivity to lapatinib differs between HER2-amplified breast cancer cells harboring kinase and helical domain mutations in PIK3CA and relies on production of PIP₃

Garay JP P, Korkola JE E and Gray JW W. Oregon Health & Science University, Portland, OR.

Body: Introduction: HER2 is amplified in nearly 25% of all primary breast cancers. Lapatinib is a targeted therapy that inhibits overactive HER2 signaling but invariably resistance to this targeted therapy occurs in a substantial number of patients. The PI3K-AKT axis is the major pathway downstream of HER2 signaling. Activated PI3-kinase phosphorylates the membrane lipid PIP₂ resulting in PIP₃. PIP₃ is as a docking site for pleckstrin homology (PH) domain proteins, such as the AKT. AKT influences a variety of pathways inside the cell involving cell growth, regulation of apoptosis, glucose metabolism, and others. Mutations in the gene PIK3CA deregulate this signaling axis. In HER2 amplified cancers, co-occurrence of PIK3CA mutations have been reported in approximately 20% of cases. Hotspot mutations of PIK3CA translate to changes in either the helical domain (E545K) or kinase domain (H1047R) of the protein and these two hotspots comprise over 80% of all reported oncogenic mutations across all tumor types. Crystallographic studies have shown conformational differences between the two hotspot mutations in PIK3CA, yet it is unclear if functional differences exist between the two mutations.

Methods: We generated isogenic knockin mutants of the helical domain (E545K) and kinase domain (H1047R) of PIK3CA in the HER2-amplified breast cancer cell line SK-BR-3. Mutant and parental cell lines were subjected to drug sensitivity assays measured by cell growth during prolonged exposure to drug. We investigated changes of relevant intracellular signaling pathways via western blot analysis. Additionally, we used immunofluorescence of PIP₃ and confocal microscopy to visualize cellular differences in the production of this signaling molecule.

Results: Our results demonstrate a distinction between the helical domain (E545K) and kinase domain (H1047R) mutations of PIK3CA. Mutations in the helical domain do not confer resistance to lapatinib while mutations in the kinase domain do. This is a result of sustained AKT signaling even in the presence of high dose lapatinib in cells with the kinase domain mutation. We also show the PTEN loss phenocopies this phenomenon. Finally, we show that kinase domain mutations allow the protein to generate significantly higher levels of PIP₃ which is the necessary molecule for downstream signaling through AKT but helical domain mutations do not.

Conclusion: This phenotypic disparity between helical and kinase domain mutations of PIK3CA has important clinical implications. It is possible to imagine that in a heterogeneous tumor in which some cells are wildtype and some cells carry this mutation for PIK3CA treatment with lapatinib will select for cells with the mutation conferring a growth advantage. Our results show that only H1047R mutant cells demonstrate lapatinib resistance and this is achieved via sustained AKT signaling through continual production of PIP₃. Altogether, we demonstrate a mechanism of de novo resistance to HER2-targeted therapy in breast cancer.
Title: PI3K/PDK1 mediates resistance to CDK4/6 inhibitors through dysregulation of S-phase cyclins/cyclin dependent kinases (CDKs)

Jansen VM M, Formisano L, Witkiewicz A, Estrada MV V, Sanchez V, Dugger TC C, Knudsen ES S and Arteaga CL L. Vanderbilt University Medical Center, Nashville, TN; UT Southwestern Medical Center, Dallas, TX and University of Arizona, Tucson, AZ.

Body: Background: CDK4/6 inhibitors in combination with antiestrogens are approved for the treatment of ER+ advanced breast cancer. However, not all patients benefit from CDK4/6 inhibitors, underscoring the need to develop therapeutic strategies to circumvent de novo and acquired drug resistance.

Methods: ER+ breast cancer cells (MCF-7, T47D, HCC1428, and HCC1500) were made resistant to increasing doses to the CDK4/6 inhibitor ribociclib (LEE011; Novartis). LEE011-resistant cells were characterized by 2D/3D growth, cell cycle, and immunoblot analyses. GSK2334470 (PDK1 inhibitor) and dinaciclib (CDK2 inhibitor) were used to modify resistance to ribociclib. PDK1 and pS6 immunohistochemistry (IHC) were performed on primary human tumor explants treated ex vivo with palbociclib.

Results: Resistant cell lines (MCF-7/LR, T47D/LR, HCC1428/LR, and HCC1500/LR) exhibited an IC_{50} at least 20-fold higher than that of their parental cells. They displayed cross-resistance to the CDK4/6 inhibitors palbociclib and abemaciclib. Immunoblot analysis of ribociclib-resistant cells showed increased levels of 3-phosphoinositide dependent protein kinase 1 (PDK1), S227 pRSK2 (target of PDK1), T308 pAKT (target of PDK1), and pS6 (downstream effector of the PDK1 target p70S6K), compared to parental drug sensitive cells. PDK1 is a master kinase that functions downstream of phosphoinositide 3-kinase (PI3K) and is crucial for the activation of AKT and many other AGC kinases including PKC, S6K, SGK, and RSK. Primary tumor explants treated ex vivo with palbociclib for 96 h also exhibited upregulation of PDK1 and pS6 by IHC. Cell cycle analysis revealed that CDK4/6 inhibition failed to induce G1 arrest, a reduction in S phase, and senescence in MCF-7/LR and T47D/LR compared to parental cells. Progression into S phase in the presence of ribociclib suggested the PI3K/PDK1 pathway mediates acquired resistance to CDK4/6 inhibitors through dysregulation of the cell cycle.

Conclusions: These data support a critical role for PI3K/PDK1 in acquired resistance to CDK4/6 inhibitors in ER+ breast cancer cells. Co-targeting of PI3K/PDK1 and CDK4/6 may overcome resistance to CDK4/6 inhibitors and is worthy of further translational and clinical investigation in patients with ER+ breast cancer.
Title: Characterization of HER2-positive breast cancer (BC) cells selected for tolerance to trastuzumab-induced antibody-dependent cell-mediated cytotoxicity (ADCC)

Biswas T, Fritzemeier R, Mark A, Meißner T, Young B, Jones BL L and Pegram M. Stanford Cancer Institute, Stanford School of Medicine, Stanford, CA; University of Washington, Seattle, WA; Avera Cancer Institute, La Jolla, CA and Avera Medical Group Precision Oncology, Sioux Falls, SD.

Body: Cellular mechanisms of trastuzumab resistance include alteration(s) in cell signaling pathways (PTEN loss, activation of PI3K/Akt signaling), steric hindrance of antibody binding (by Muc-1/Muc-3), over-activation of alternate receptor kinases (HER3/c-Met/IGF-1R), and proteolysis of HER2 extracellular domain harboring target epitopes for antibody-based therapeutics. Prior studies of trastuzumab resistance have focused largely on cells selected ex vivo with the antibody in absence of human immune effector cells. We developed a selection model, wherein human HER2 positive BC cells (BT474, SKBR3) were subjected to acute ADCC (>90% cell death), trastuzumab concentration 100ug/mL, effector-target ratio 100:1, using human peripheral blood mononuclear cells (PBMCs) as effectors. Surviving cells were allowed to recover to confluence over 8-10 weeks, for 10 total rounds of ADCC selection ex vivo. Mock-treated parent, IgG1 isotype control, trastuzumab, and PBMCs alone were used as controls. ADCC assays based on calcein fluorescent labeling of live target cells, revealed significant reduction (maximum 20%, p<0.005) in cell lysis in immune-selected BT474 cell lines compared to parental controls (immune-selected SKBR3 cells exhibited a non-significant trend towards reduced ADCC). Transcriptome-wide next-generation RNA sequencing (Illumina NextSeq 500, 2 x 75 bp paired-end, median of 46 million paired-end reads/sample), coupled with pathway enrichment analysis (Reactome), followed by q-PCR validation, confirmed significant changes in expression in immune-selected cells (compared to parent control) for genes including: ALDH1, ANK1, TMPRSS3, HINT1, DNM2, TNNC1, COL4A4 in BT474; and ALDH1, ANK1, CAMP1, CPE, IDO1 in SKBR3 cells. Whole-genome sequencing (Illumina HiSeq X, 150 bp paired end, 30x coverage) elucidated 180 genes with single nucleotide variations (SNVs) in immune-selected cells compared to parent in BT474 cells, and 215 genes in SKBR3 cells. Thirty-four SNVs were shared in both cell lines. Further screening and validation confirm genes with SNVs demonstrating significant transcript up-regulation. These include: COL4A3, LEP, SOX-9 in BT474; and HLA-B, TNFRSF10B, HLA-B, PSMA6 in SKBR3. In further phenotypic analysis, ADCC-conditioned BT474 cells exhibit an elongated fibroblast-like morphology with multiple processes, in contrast to control. Immune-selected SKBR3 cells (and not BT474 cells) demonstrate significantly increased motility compared to control in transwell migration assays (p<0.001), and demonstrated increased cell proliferation (MTT assay, 10-15%, 48h; p=0.0242) as compared to parent controls. Our data indicate immune-selection by effector cells contributes to ADCC tolerance in vitro, and is associated with distinct genotypic and phenotypic alterations. Future investigation will determine whether Fc-engineered MAbs (afucosylated), antibody drug conjugates (T-DM1), or potentiation of ADCC by co-stimulatory agonist CD137 antibodies will re-sensitize ADCC-tolerance. This investigation will help to elucidate potentially targetable pathways that emerge from immune-selection with trastuzumab.

Title: High-throughput pharmacogenomic platform to functionally probe breast cancer vulnerabilities in the context of the 3-dimensional tumor microenvironment

Dhimolea E, De Matos Simoes R, Awate P, Tang H, Culhane A and Mitsiades C. Dana Farber Cancer Institute, Boston, MA.

Body: The pharmacological vulnerabilities of malignant cells have been traditionally evaluated by the use of cell lines grown in vitro in 2-dimensional (2D) plastic surfaces. In contrast, malignant tumors in vivo grow as 3-dimensional (3D) cellular masses. We used Estrogen Receptor (ER)-positive (MCF7, ZR75-1 and T47D) and triple-negative (MDA-MB-231) breast cancer (BrCa) cells to assess the differences between the malignant growth in 2D vs. 3D conditions with regards to morphology, molecular characteristics and response to therapeutic agents. The ER-positive BrCa cells formed compact spheroids when grown in collagen type I or matrigel; in contrast the MDA-MB-231 cells assumed an invasive phenotype characterized by infiltrating bundles of cells. Antiestrogens induced acinar differentiation in the compact spheroid morphology of ER-positive BrCa cells. This effect of antiestrogens was blocked in co-cultures of BrCa cells with bone marrow stromal cells, suggesting that the 3-dimensional microenvironment of distant metastatic sites can affect the susceptibility of BrCa cells to anti-tumor agents. We further probed this question through pharmacological screens of ~100 FDA-approved antineoplastic agents and 400 target-annotated kinase inhibitors, to assess the pathophysiological relevance of these in vitro interactions and to identify specific BrCa vulnerabilities in 3D conditions. The 3D spheroid morphology was associated with significant decrease in the efficacy of several classes of conventional DNA-damaging (e.g. anthracyclins) and anti-microtubule (e.g. vinca alkaloids) agents, proteasome inhibitors, as well as recently established targeted therapies, including kinase inhibitors. This differential 3D spheroid-associated drug resistance vs. sensitization was more pronounced for the triple-negative MDA-MB-231 cell line compared to the ER-positive BrCa cells. Interestingly, inhibition of folate metabolism induced reduced viability of ER-positive BrCa spheroids, indicating increased dependency of ER-positive tumor cells on this pathway, under 3D growth conditions. Interestingly, mut-p53 T47D 3D spheroids were resistant to antifolates, suggesting a possible role of functional p53 for the anti-BrCa effect of antifolates in 3D conditions. Gene expression analysis and reverse-phase protein array analyses of BrCa cells in this system indicated that growth of malignant cells as 3D spheroids was associated with switch to glycolysis metabolism and up-regulation of survival signals (e.g. Mcl1, Hsp70 et.c.). We conducted a genome-wide CRISPR screen in MCF7 and MDAMB231 2D cultures and identified several known and previously underappreciated BrCa essential genes; we are currently using the insight obtained by these molecular analysis to conduct focused CRISPR screens in our 3D cultures, to validate the genetic vulnerabilities observed in 2D conditions and to determine the mediators of malignant growth and drug resistance in 3D conditions. This approach can reveal novel and previously underappreciated therapeutic targets for drug-resistant BrCa.
Title: A large-scale functional screen to identify resistance mechanisms to selective estrogen receptor degraders fulvestrant and GDC-810 in ER+ breast cancer

Mao P, Quartey Q, Cohen O, Piccioni F and Wagle N. Dana Farber Cancer Institute, Boston, MA; Broad Institute, Cambridge, MA and Brigham and Women's Hospital, Boston, MA.

Body: Therapies that target the estrogen receptor provide clinical benefit and improved survival for patients with estrogen receptor-positive (ER+) breast cancer, yet drug resistance remains a challenging problem, leading to disease relapse and mortality. In recent years, the selective estrogen receptor degrader (SERD) fulvestrant has become an important therapeutic option for patients with resistant ER+ metastatic breast cancer, and newer oral SERDs such as GDC-810 are currently being tested in clinical trials. The mechanisms of intrinsic and acquired resistance to SERDs remain to be fully elucidated.

We conducted a large-scale lentiviral open reading frame (ORF) screen to identify genes whose overexpression confers drug resistance to either fulvestrant or GDC-810 in the ER+ breast cancer cell line T47D. The lentiviral ORF expression library used in this study consists of 16,544 barcoded ORFs, including 2,767 ORFs with mutations. The initial screen yielded 72 genes resulting in resistance to fulvestrant and 85 genes resulting in resistance to GDC-0810, with 44 genes overlapping. The top ranked-genes included multiple genes belonging to the PI3K/Akt, ERbB/HER, and FGF/FGFR pathways as well as genes involved in cell cycle progression.

Fibroblast growth factor receptor 1 (FGFR1) amplifications are frequently observed in patients with ER+ breast cancer, and have previously been implicated in resistance to endocrine therapies. Several FGFs (FGF3, FGF6, FGF10, and FGF22) were among the top-ranked resistance genes for both fulvestrant and GDC-0810, suggesting that activation of the FGFR signaling pathway may render cells resistant to fulvestrant and GDC-810. In the presence of FGF2, overexpression of FGFR1 in ER+ breast cancer cells resulted in resistance to both fulvestrant and GDC-0810. The ability of an FGFR inhibitor to overcome FGFR-mediated resistance to SERDs is being tested. Additional potential resistance genes identified in the ORF screen are also being validated.

In summary, a whole-genome functional resistance screen has identified several candidate genes and pathways that may cause resistance to fulvestrant and GDC-810. Several of these candidates, such as FGFR1, are also found in patients who develop resistance to SERDs, suggesting rational combination therapies to overcome or preempt SERD resistance.

Title: Resistance to palbociclib depends on multiple targetable mechanisms highlighting the potential of drug holidays and drug switching to improve therapeutic outcome

Body: Background: Combination of CDK4/6 inhibitors and endocrine therapy has been shown to improve clinical outcome in advanced estrogen receptor-positive (ER+) breast cancer (BC) patients. However, most patients will progress with acquired resistance, making the identification of new therapeutic strategies and potential biomarkers of great importance. Here, we show for the first time that certain resistance mechanisms are amenable to drug holidays and drug switching while others cause irreversible resistance to further perturbation of G1/S and highlight the potential of targeting these tumors by blockade of G2/M with inhibitors of Wee1 or CDK7.

Methods: To identify adaptive mechanisms associated with resistance to palbociclib, MCF7 and T47D cells adapted to long term oestrogen deprivation (LTED), which either retain or lose expression of ER respectively, were grown in the presence of palbociclib until they became resistant (LTED$^{991R}$). Cell lines were subjected to exome sequencing, global gene expression analysis and siRNA knockdown of 709 cellular kinases to identify candidates associated with resistance. Candidate drug targets were evaluated in proliferation assays. Data was validated in vivo using MCF7-LTED xenografts.

Results: Exome data showed few genetic changes were associated with resistance to palbociclib. MCF7-LTED$^{991R}$ had a copy number (CN) gain of CCNE2 and ESR1 compared to MCF7-LTED while T47D-LTED$^{991R}$ showed loss of RB. Global gene expression analysis revealed increased expression of CDK4, CDK2, CDK7 and CCNE1 in MCF7-LTED$^{991R}$ and CCNE2 and CDK2 in T47D-LTED$^{991R}$. In order to assess if these changes were drug specific, cell lines were treated with another CDK4/6 inhibitor, abemaciclib. Strikingly, MCF7-LTED$^{991R}$ cells showed sensitivity, possibly as a result of increased CDK4 expression, for which abemaciclib has increased potency. We next assessed the plasticity of the 991R phenotype by giving the cells a drug holiday followed by re-challenge. T47D-LTED$^{991R}$ cells remained resistant whilst the MCF7-LTED$^{991R}$ cells were re-sensitised, an observation we confirmed in a MCF7-LTED xenograft after long term treatment with palbociclib. Finally, siRNA kinome knockdown highlighted CDK4, CDK7 and Wee1 as associated with the resistant phenotypes suggesting targeting of G2/M in both RB+ and RB- 991R tumours may provide benefit; this possibility was confirmed by increased sensitivity to THZ1 (CDK7 inhibitor) or MK1775 (Wee1 inhibitor).

Conclusion: Few genetic changes are associated with resistance to palbociclib in ER+ BC in vitro but kinase re-wiring provides resistance. RB loss of function appears an irreversible mechanism of resistance while gain of cyclin E, and overexpression of CDK2 and CDK4 are amenable to a drug holiday, leading to re-sensitisation to palbociclib in vitro and in vivo. Of note, the palbociclib-resistant cells that retained RB expression were sensitive to abemaciclib possibly as a result of increased expression of CDK4 acting as compensatory mechanism. Finally, LTED cell lines retaining ER that were resistant to palbociclib also showed a gain in ESR1 CN, highlighting the potential for combination therapy with an alternate endocrine agent, such as fulvestrant.

Title: Penfluridol reduces paclitaxel resistance in breast cancer by inhibiting HER2/β-catenin signaling

Gupta N, Gupta P and Srivastava S. Texas Tech University Health Sciences Center, Amarillo, TX.

Body: Breast cancer is the most common malignant carcinoma in women worldwide. It has been estimated that each year almost 182,000 cases of breast cancer are diagnosed and over 40,000 women die of breast cancer in the US, making it the second leading cause of cancer related deaths. Metastatic breast cancer is a major cause of mortality. Paclitaxel is a promising therapeutic agent for the treatment of patients with metastatic breast cancer. However, inherited or acquired resistance is a major limiting factor for successful therapy with paclitaxel in many patients. The mechanism of paclitaxel resistance remains obscured and has hindered the development of useful therapeutic strategies. HER2 is an oncogene, overexpressed in about 30% of breast cancer patients and plays role in drug resistance leading to poor prognosis. To identify more clinically relevant mechanism of paclitaxel resistance, we developed paclitaxel resistant MCF-7 and 4T1 breast cancer cell lines. We evaluated the cytotoxicity of paclitaxel in these cell lines to confirm resistance. Furthermore, we characterized the molecular changes in these cells as compared to parent cells using molecular techniques and cell-based assays. The continuous exposure to paclitaxel resulted in >100 fold resistance towards paclitaxel in MCF-7 and 4T1 cells. Western blot analysis showed enhanced HER2 expression in resistant cells. Interestingly, HER2 was substantially localized in the nucleus of resistant cells as compared to parent cells. We also observed enhanced expression of β-catenin in the resistant cells. β-catenin is known to promote cancer progression in HER2 over-expressing breast tumors. Hence we hypothesized that HER2/β-catenin mediates resistance to paclitaxel and suppression of HER2 and β-catenin signaling could inhibit paclitaxel resistance. In another study, we recently demonstrated that penfluridol suppresses the growth of triple negative metastatic breast cancer cells (Ranjan and Srivastava, Cancer Res 2016; 76(4):877-890). We therefore, treated paclitaxel resistant cells with penfluridol to see if resistant cells would be sensitive to penfluridol treatment. Our current results showed that penfluridol treatment not only suppressed the expression of HER2 in paclitaxel resistant cells but also inhibited β-catenin and its downstream effector molecules resulting in reduced survival of paclitaxel-resistant breast cancer cells. Our results further showed that penfluridol treatment synergistically enhanced the growth suppressive effects of paclitaxel. Taken together, our results provide a novel insight into the mechanism of resistance to paclitaxel and also open new avenue for application of penfluridol in cancer therapeutics. Further mechanistic and in vivo studies are in progress. It is important to note that penfluridol is an FDA approved anti-psychotic drug with an established safety and efficacy profile. Hence based on our observations, penfluridol can be a fast track agent that can be made available to the patients resistant to paclitaxel in relatively shorter period of time. [Supported in part by R01 grant CA129038 (to S.K.S.) awarded by National Cancer Institute, NIH].
Title: Tamoxifen-resistant breast cancer cells are resistant to DNA-damaging chemotherapy because of upregulated BARD1 and BRCA1

Liu Q, Zhu Y and Liu Y. Sun Yat-Sen Memorial Hospital, Sun Yat-Sen University, Guangzhou, Guangdong, China.

Body: Tamoxifen is the most widely used endocrine therapy in estrogen receptor (ER)-positive breast cancer patients. Tamoxifen resistance has been a major clinical problem and is accountable for relapse in about one third of these patients. Most of these recurrent patients will inevitably receive chemotherapy. However, the association between tamoxifen-resistance and chemosensitivity in breast cancer has never been explored. We found that both mRNA and protein expression of BARD1 and BRCA1 were significantly upregulated in tamoxifen-resistant MCF7 and T47D breast cancer cell lines, when compared with their parental lines. Furthermore, the tamoxifen-resistant cells were markedly more resistant to DNA-damaging chemotherapy including cisplatin and doxorubicin, but not to paclitaxel. Silencing BARD1 or BRCA1 by siRNAs or inhibition of BRCA1 phosphorylation by Dinaciclib restored the sensitivity to cisplatin and doxorubicin in tamoxifen-resistant cells. In addition, we identified that activated PI3K/AKT/ERK pathway in tamoxifen-resistant cells was responsible for the upregulation of BARD1 and BRCA1. BKM120, a PI3K inhibitor, decreased the expression of BARD1 and BRCA1 in tamoxifen-resistant cells and re-sensitized them to cisplatin and doxorubicin both in vitro and in xenografted mice. More importantly, higher BARD1 expression was significantly associated with poorer prognosis in breast cancer patients. BARD1 and BRCA1 were also significantly upregulated in recurrent breast cancer samples after tamoxifen compared with their primary counterparts. These results indicate an important role of BARD1 and BRCA1 in the chemoresistance of ER-positive breast cancer. Targeting PI3K/Akt pathway or BRCA1 phosphorylation may help to overcome the resistance to DNA-damaging chemotherapy in these tumors.
Title: CDK4/6 inhibitor resistant ER-positive cells remain dependent on estrogen signalling and retain sensitivity to endocrine therapy

Body: Background: Dysregulation of the cyclin D-CDK4/6-Rb pathway is a frequent feature of ER positive breast cancers and has been linked with endocrine resistance. Several randomised trials have shown that CDK4/6 inhibitors in combination with endocrine treatment can substantially improve the outcome of patients with metastatic ER positive breast cancer. With increased clinical use of CDK4/6 inhibitors acquired resistance is emerging as a major clinical challenge. It is critical to understand the sensitivity and responsiveness of these resistant cells to estrogen to consider continued use of endocrine therapy in combination with CDK4/6 inhibition.

Results: Long-term culture of the ER positive cell lines T47D and MCF7 with increasing doses of drug generated distinct clones with acquired resistance to either palbociclib or ribociclib. ESR1 expression was stable across all resistant clones. All clones continued to be reliant on estrogen for cell growth, with estrogen deprivation inducing cell death. Resistant clones still responded to estrogen stimulation. Estradiol treatment induced at least 2-fold transcriptional upregulation of pS2 and c-myc; the induction was inhibited by tamoxifen and fulvestrant treatment. Both palbociclib and ribociclib resistant clones remained sensitive to endocrine therapy, with tamoxifen IC50 values equivalent to the parental T47D and MCF7 cell lines.

Mechanisms of resistance were different between the different CDK4/6 inhibitors and within the two cell lines. Palbociclib resistant MCF7 and T47D clones all increase cyclin E protein levels, but only T47D transcriptionally upregulated cyclin E. MCF7 clones transcriptionally upregulated cyclin D, with corresponding protein increase. Therefore, CDK2/cyclin E complexes seem to drive progression in MCF7 cells, whilst CDK2/cyclin D complexes function in T47D cells. Ribociclib resistant clones presented with unchanged or even decreased CDK2 expression, but demonstrated notable increase in E2F1, indicating the requirement of a non-canonical CDK-cyclin pairing independent of CDK2.

Cell lines did not exhibit complete cross resistance to all CDK4/6 inhibitors. All ribociclib-resistant T47D and MCF7 clones conferred cross-resistance to palbociclib. The majority of clones were also resistant to abemaciclib, although one T47D clone retained abemaciclib sensitivity. All palbociclib-resistant clones were equally resistant to ribociclib. Conversely, whilst one T47D ribociclib clone exhibited marked cross resistance to abemaciclib, the majority of clones remained sensitive to treatment with abemaciclib. This highlights potential different resistant mechanisms for abamaciclib independent characterised cell cycle changes for palbociclib and ribociclib.

Conclusions: Cells resistant to CDK4/6 inhibitors remain dependent on estrogen signalling and retain sensitivity to endocrine therapy. We continue to show that resistance is mediated by non-canonical CDK-cyclin pairings. Palbociclib and ribociclib resistant clones confer cross-resistance to both Palbociclib and ribociclib but incomplete cross-resistance to abemaciclib.
Title: Chronic inhibition of signal transducer and activator of transcription 3/5 in treatment-resistant human breast cancer cell subtypes: Convergence on the reactive oxygen species/SUMOylation pathway and its effects on xCT expression and system $x_c^-$ activity

Linher-Melville K, Nashed MG G, Ungard R, Haftchenary S, Gunning PT T and Singh G. McMaster University, Hamilton, ON, Canada and University of Toronto Mississauga, Mississauga, ON, Canada.

Body: Pharmacologically targeting activated signal transducer and activator of transcription 3 (STAT3) and/or STAT5 has been an active area of cancer research. The cystine/glutamate antiporter system xc- contributes to redox balance and export of intracellularly produced glutamate in response to up-regulated glutaminolysis in aggressive breast cancer cells. We have previously shown that blocking STAT3/5 using the novel small molecule inhibitor SH-4-54, designed to target the SH2 domains of both proteins, increases expression of xCT, which encodes the active component of system xc-, thereby increasing antiporter activity in human breast cancer cells. The current investigation demonstrates that chronic treatment with SH-4-54, followed by clonal selection of treatment-resistant MDA-MB-231 and T47D breast cancer cells, elicits distinct subtype-dependent effects. xCT mRNA and protein levels, glutamate release, and cystine uptake are decreased relative to untreated passage-matched controls in the triple-negative MDA-MB-231 SH-4-54-resistant clones, with the inverse occurring in estrogen-responsive T47D cells. This “ying-yang” effect is linked with a shifted balance between phosphorylated STAT3 and STAT5, intracellular levels of reactive oxygen species (ROS), STAT5 SUMOylation/de-SUMOylation, and the expression of STAT3/5 target genes (assessed by NextGeneration RNA sequencing). STAT5 emerged as a definitive negative transcriptional regulator of xCT, while STAT3 activation was coupled with increased system xc- activity. Specifically, inhibiting constitutive STAT3 phosphorylation in MDA-MB-231 cells induces ROS, thereby affecting the SUMO pathway by favoring de-SUMOylation and STAT5 phosphorylation. Activated STAT5 is then able to serve as a repressor by binding to its recognition sequence within the xCT promoter, reducing xCT expression and thereby destabilizing an important redox balancing mechanism by limiting cystine uptake through system xc-. In contrast, in ERα-positive cells that initially respond to STAT5-mediated signaling, STAT3 becomes activated and xCT expression is up-regulated in response to chronic SH-4-54 treatment, potentially leading to a more aggressive cancer subtype. Further destabilizing the cellular redox status may therefore be critical to produce clinically meaningful outcomes linked to chronic treatment with potent STAT3/5 inhibitors like SH-4-54. We assessed this notion by treating SH-4-54-resistant MDA-MB-231 clones with specific ROS-inducing reagents, including capsazepine, bleomycin, and paclitaxel, which produced different effects on cell viability. We propose that careful classification of a patient’s breast cancer subtype is central to therapeutically targeting STAT3/5 as a means of treating breast cancer, particularly given that xCT is emerging as an important biomarker of aggressive cancers.
Title: ERα propelled drug-resistance-facilitating global DNA hypermethylation by promoting the DNMT1 gene expression

Sun Y, Si X, Liu Y, Lv J, Yang N, Ding H, Zhang XA A, Shao L, Cheng H and Sun L. Nanjing Medical University, Nanjing, Jiangsu, China; University of Oklahoma Health Sciences Center, Oklahoma, OK and Suzhou Hospital Affiliated to Nanjing Medical University, Suzhou, Jiangsu, China.

Body: Drug-induced aberrant DNA methylation is the first identified epigenetic marker involved in chemotherapy resistance. Tumor cells exposed to toxic concentrations of commonly used cancer chemotherapy agents usually develop global DNA hypermethylation, both in vitro and in vivo. Understanding how the aberrant DNA methylation is acquired would impact cancer treatment in theory and practice. In this study we systematically investigated whether and how ERα propelled aberrant global DNA hypermethylation in the context of breast cancer drug resistance. Our data demonstrated that anticancer drug paclitaxel (PTX) augmented ERα binding to the DNMT1 and DNMT3b promoters to activate DNMT1 and DNMT3b genes, enhancing the PTX resistance of breast cancer cells. In support of these observations, estrogen enhanced multi-drug resistance of breast cancer cells by up-regulation of DNMT1 and DNMT3b genes. Nevertheless, the aberrant global DNA hypermethylation was dominantly induced by ERα-activated-DNMT1, since DNMT1 over-expression significantly increased global DNA methylation and DNMT1 knockdown reversed the ERα-induced global DNA methylation. Altering DNMT3b expression had no detectable effect on global DNA methylation. Consistently, the expression level of DNMT1 was positively correlated with ERα in 78 breast cancer tissue samples shown by our immunohistochemistry (IHC) analysis and negatively correlated with relapse-free survival (RFS) and distance metastasis-free survival (DMFS) of ERα-positive breast cancer patients. This study provides a new perspective for understanding the mechanism underlying drug-resistance-facilitating aberrant DNA methylation in breast cancer and other estrogen dependent tumors.
Title: Synergistic suppression of triple negative breast cancer with the combination of PI3K inhibitor (alpelisib, BYL719) and CDK inhibitor (ribociclib, LEE011)

Yuan Y, Mortimer J, Xing Q, Yan J, Wen W, Han E and Yim JH H. City of Hope Beckman Research Institute, Duarte, CA.

Body: INTRODUCTION. Triple negative breast cancer (TNBC) is an aggressive form of BC that lacks effective targeted therapy. It is a biologically heterogeneous disease with several molecular subtypes: basal-like 1 (BL1), basal-like 2 (BL2), mesenchymal (M), mesenchymal-stem-like (MSL), immune-modulatory (IM) and unclassified (UNC). The PI3K/AKT/mTOR pathway affects cell proliferation, survival, and apoptosis through growth receptor interaction with downstream targets such as AKT and mTOR. TNBC frequently has activation of this pathway by mutation and other means across several subtypes. Recently the PI3K inhibitor alpelisib (BYL719) has been found to have efficacy in a combination study in ER positive metastatic BC (MBC) with a Phase 3 trial in progress. Ribociclib (LEE011) is a CDK inhibitor targeting cyclin D1/CDK4 and cyclin D3/CDK6 that recently met its primary endpoint in a phase 3 trial in a combination study in hormone receptor positive BC. As with all BC, TNBC has intact or mutant RB which affects susceptibility to CDK inhibitor. We hypothesize that targeting both PI3K with alpelisib and CDK with ribociclib may provide enhanced suppression of TNBC.

MATERIALS AND METHODS. HCC38 and MDA468 are TNBC subtype BL1; MDA468 is RB1 and PTEN mutant. HCC1187 is IM. BT549 is M, mutant RB1 and PTEN. Hs578T, MDA157, and MDA231 are MSL. Cells were treated with alpelisib and ribociclib alone with 2-fold increase in concentrations, or the combination, for 72h and assessed by MTT assay. Western blot was performed using probes for pAkt (T308 and S473), Akt, pS6K1, S6K1, pS6, S6, and β-actin.

RESULTS. Synergy in growth inhibition was seen combining alpelisib and ribociclib as reflected by combination indices <1 (Table). At least 3 subtypes, BL1, M, and MSL have cell lines that have synergy; however, the MSL subtype MDA157 is antagonistic and not RB1 mutant. In the 2 responsive MSL lines Hs578T and MDA231 ribociclib alone has no effect or increases phosphorylation of Akt by Western blot, but in combination with the PI3K inhibitor alpelisib, there is enhanced inhibition of phosphorylation of Akt with enhanced inhibition of the phosphorylation of the end target S6.

Conclusion. Our study demonstrates that alpelisib plus ribociclib can synergistically enhance suppression of BC across multiple subtypes of TNBC. Cancer cells within the same subtype may not demonstrate a synergistic response, depending on RB status. Nevertheless, if RB mutant cells are susceptible to ribociclib then synergy can be seen even in these cancer cells. Antagonism
can be seen independent of RB status in the same subtype. These findings point to a potential role for combination therapy with alpelisib and ribociclib in the treatment of TNBC.
Molecular iodine impairs chemoresistance and invasive mechanisms, enhances doxorubicin retention and induces downregulation of CD44+/CD24+ and E-Cad+/Vim+ subpopulations in MCF-7 cells resistant model

Carmen A, Alexander B, Brenda U-V, Evangelina D-G and Ángel Luis R. Instituto de Neurobiología, UNAM, Juriquilla, Queretaro, Mexico and Centro de Física Aplicada y Tecnología Avanzada, UNAM, Juriquilla, Queretaro, Mexico.

Body: The main problem in the treatment of breast cancer is the ability of the cells to become chemoresistant and metastatic. Both components involved complex mechanisms based on alterations of apoptosis, the cell cycle and drug metabolism, and its correlates with the cancer stem cell phenotype and/or epithelial-mesenchymal transition. In this study, Doxorubicin (DOX), a member of the anthracycline family used as first-line therapy for several cancers, given chronically to establish a low-dose DOX-resistant mammary cancer model to analyze the effect of molecular iodine (I₂) on the chemoresistant and invasive mechanisms. I₂ exerts an antitumor effect on different types of iodine-capturing neoplasm through its oxidant/antioxidant properties and formation of iodolipids. Wild-type breast carcinoma cells (MCF-7/W) were treated chronically with low DOX concentration (10 nM) to generate a clinically relevant model of DOX-resistance (MCF-7/D). After treatment with I₂ and DOX alone or in combination, the proliferation assay (Trypan Blue exclusion), RT-qPCR expression (p21, Bax, Bcl-2, Survivin, PPARγ, E-Cadherin and Vimentin), flow cytometry (CD24, CD44, E-Cadherin, and Vimentin) and DOX retention (DOX fluorescence) were performed. Tumorogenic capacity was analyzed by xenograft induction in Foxn1 nu/nu mice. MCF-7/D was established after 30 days of treatment when the culture showed a proliferation rate similar to that of MCF-7/W. These DOX-resistant cells also showed increases in p21, Bcl-2 and MDR-1 expression. Supplementation with 200 µM I₂ exerted similar effects in both cell lines: it decreased the proliferation rate by approximately 40%, and I₂ co-administration with DOX significantly increased the inhibitory effect (~ 60%) and also increased apoptosis (Bax/Bcl-2 index), principally by inhibiting Bcl-2 expression. The inhibition by I₂+DOX was also accompanied by impaired MDR-1 induction as well as by a significant increase in PPARγ expression. All these changes could be attributed to enhanced DOX retention and differential down selection of CD44+/CD24+ and E-Cad+/Vim+ subpopulations. I₂+DOX selected cells (CD44+/CD24+ and E-Cad+/Vim+) showed a weak induction of xenografts, indicating that the iodine supplements reversing the tumorogenic capacity of MCF-7/D. In conclusion, molecular iodine reduces the drug resistance and invasive capacity of mammary cancer cells exposed to DOX and represents an anti-chemoresistance agent with clinical potential. This work was partially supported by grant PAPIIT-UNAM IN201516. We thank Juana Cardenas for technical support. Alexander Bontempo is a student of Programa de Doctorado en Ciencias Biomédicas, UNAM and receives a fellowship from CONACYT 262489.
Title: Can polyploid tumor cells possessing stem cell features be induced in resistant breast carcinomas?

Gerashchenko BI I, Salmina K, Eglitis J and Erenpreisa J. R.E. Kavetsky Institute of Experimental Pathology, Oncology, and Radiobiology, Kyiv, Ukraine; Latvian Biomedical Research and Study Centre, Riga, Latvia and Faculty of Medicine, University of Latvia, Riga, Latvia.

Body: Cancer stem cells are believed to be responsible for radio- and chemoresistance of malignant tumors. In vitro studies demonstrate that ionizing radiation is capable of reprogramming cancer cells from non-stem state into stem state [1, 2]. Moreover, the embryonic stemness cassette was found to be expressed in tumor cells (including breast cancer cells) after they were polyploidized as a result of genotoxic stress [2, 3], thus prompting us to suppose that the polyploid cells and their descendants released by depolyploidization can possess stem cell characteristics. The aim of the current work is to test whether polyploid cells having stem cell features can be also induced in vivo, namely in locally advanced breast carcinomas as a result of neoadjuvant chemotherapy (NAC), assuming that this process is not autonomous, but rather stipulated by the tumor microenvironment. The study population consisted of 30 breast cancer patients of age ranged from 31 to 75 y.o. diagnosed in the Latvian Oncology Center of the Riga East University Hospital between 2013 and 2015. The tissue specimens were collected after the patients’ informed consent was obtained in accordance with the Ethics regulations. The clinico-pathologic information about these patients, including Ki-67 index and the status of ER, PR and HER2 receptors, was obtained from the aforementioned clinics. The majority of patients (n = 28) had locally advanced breast cancer, predominantly Stage III disease. Both diagnostic biopsy and operation material, such as primary tumors surgically removed after NAC using standard doses of paclitaxel and doxorubicin, were subjected to DNA content analysis with image cytometry. Ploidy-related parameters, such as DNA index and the percentage of cells exceeding 4.5c (presumably proliferating and polyploid cells), were determined. Immunofluorescence staining was applied to evaluate expression of such markers/factors as proliferation (Ki-67), stemness (SOX2 and NANOG) and invasiveness (CD44). At the time of diagnosis, 14 patients had primary tumors possessing near-triploid clones, and these cases in comparison with 16 other cases comprised of near-euploid clones had 4.5-fold increase of percentages of cells exceeding the ploidy of 4.5c (p < 0.05) and 1.3-fold increase of percentages of cells positive for Ki-67 (p > 0.05). Of 10 cases diagnosed as “triple-negative”, 6 were near-triploid. Among those cases that showed the resistance to NAC (grades 1 and 2 by Miller-Payne histopathologic scoring), 67% were near-triploid. Polyploidization, which in some resistant cases is gained by NAC, was likely to be attributed to near-triploid clones. Notably, polyploid cells were positive for Ki-67, SOX2, NANOG, and CD44. Thus, these non-quiescent polyploid cells can possess the invasiveness and self-renewal features that were also seen in descendants after depolyploidization. Perhaps, reversible polyploidy plays a definite role in gaining the resistance of tumor cells to chemo- and radiotherapy in vivo.

Title: An ex-vivo platform predicts anti-tumor outcome of metabolically-targeted, algorithm-driven combination therapy in triple-negative breast cancer

Body: Cancer cells undergo phenotypic cell state transitions in response to chemotherapy as a mechanism that can confer transient resistance. However, such cell state transitions can also unlock unique vulnerabilities that can be exploited using temporally-sequenced combination chemotherapy. Here, utilizing a primary breast cancer ex-vivo functional assay that captures tumor heterogeneity, we report that in response to a chemotherapeutic agent, a subset of cancer cells can mount an acutely-induced phenotypic adaptive resistance to future cytotoxic pressure via the transient acquisition of a unique metabolic state defined by augmented glycolysis together with mitochondrial proficiency. These cells activate two complex, temporally-interdependent pathways that enable a glucose shunt towards the pentose phosphate pathway (PPP), which confers an adaptive cross-tolerance to different chemotherapeutic agents. Mathematically modeling these pathways, and simulating drug schedules, we define a rationally-designed 3-drug combination therapy of metabolic inhibitors and cytotoxic agents, which results in improved cancer survival. Our findings highlight a new bioenergetics-based adaptive resistance mechanism through which cancer cells can survive combinations of chemotherapy. Administration of metabolic inhibitors in rational, temporal sequence with existing chemotherapy can emerge as a new paradigm in the treatment of cancer.
ESR1 mutations, ESR1 fusions and co-occurring alterations assessed in breast cancer tumors

Body: Background: ESR1 mutations and fusions arise in hormone receptor positive (ER+ and/or PR+) breast cancer (HR+ BC) patients after aromatase inhibitor (AI) therapy (low estrogen states), to become constitutively active in a ligand-independent manner. Patients with ESR1 mutations exhibit worse prognosis and outcome with no particular benefit of chemotherapy vs tamoxifen treatment (Augusto, et al. ASCO 2016). A retrospective analysis of the ESR1 mutation frequency and co-occurring alterations that could guide subsequent therapy approaches was investigated.

Methods: Molecular profiles of 416 breast cancer patients [HR+ (n=237), HER2+ (n=29) and TNBC (n=139)] were assessed. Protein expression (IHC) and gene amplification (ISH) were performed. Genomic testing included 592-gene hybrid-capture NGS [NextSeq Illumina platforms] and ArcherDx fusion assay based on anchored multiplex PCR (AMP) FusionPlex Solid Tumor. ESR1 variant (ESR1var) (mutation/fusion) profiles and HR+ BC patients lacking genomic ESR1 alterations (ESR1 WT) were compared; Pearson's chi-squared test was used to test for significant differences.

Results: An ESR1 mutation (point mutations, insertion-deletions [n=49] and fusions [n=4]) was detected in 13% (53 /416) of the specimens, and this constitutes 21% (50/237) of all HR+ breast cancers. Two TNBC patients exhibited ESR1 variants (H398Y in exon 7 and A491S in exon 9, both are classified as variants of unknown significance). ESR1 mutations were not detected in HER2+ BC. Seventy-seven percent of patients with ESR1 mutations were detected in metastatic specimens (p=0.03), with liver (19/53 or 36%) and bone (8/53 or 15%) specimens as the most frequent sources for ESR1 variant (ESR1var) positivity. The most common alleles detected were: D538G (24%), Y537S (18%), E380Q (14%) and L536H (4%); 15 other additional alleles were detected (each 2%). ESR1 fusions were detected in 4 ESR1 WT patients: ESR1-ATP2B2, ESR1-MKL1/ESR1-TNRC6B, ESR1-ARNT2 and ESR1-C6ORRF211. We next compared ESR1var (mutation/fusion) profiles to HR+ breast patients lacking genomic ESR1 alterations (ESR1 WT). ER expression was present in 100% and 96% of ESR1var and ESR1 WT BC, respectively, however expression of PR was negative in 22% and 38% of ESR1var and WT BC, respectively (p=0.05). Significantly higher rates of other gene amplification events observed in ESR1var vs. ESR1 WT BC included: c11orf30 [EMSY, BRCA2 interacting transcriptional repressor] (20% vs. 7%), CCND1 (51% vs.28%), CCND2 (6% vs. 0%), FGF3 (37% vs. 16%), FGF4 (40% vs. 12%) and FGF19 (40% vs. 15%), whereas cMYC was more frequently amplified in ESR1 WT BC (17% vs. 2%); all p-values <0.05. KRAS mutations were higher in ESR1var vs WT BC (4% vs. 0%; p=.004). Alterations in the PIK3CA pathway were common in both ESR1var and ESR1 WT BC: mutations in PIK3CA, AKT and PTEN were observed in 27% and 26%; 4% and 7%; 6% and 5%, respectively, and PTEN loss by IHC in 29% and 26%.

Conclusions: ESR1 mutations and fusions are detected in 21% of HR+ BC, the majority of which are in metastatic sites. Amplifications of genes involved in downstream regulatory pathways were present and may contribute to the poor prognosis of ESR1var HR+ BC. Correlation with antecedent therapy is currently underway.
Body: Background: Invasive lobular carcinoma (ILC) accounts for 10-15% of invasive breast cancers diagnosed annually. There is increasing evidence that endocrine treatment response might differ between Invasive Ductal Carcinoma (IDC) and ILC, and that patients with ILC have worse long-term survival when other prognostic factors are taken into account. One such factor is ER status, which is more likely to be positive in ILC (90-95%) compared to IDC (60-70%). There are few studies that have directly compared mRNA and protein levels between ER+ ILC and ER+ IDC.

Hypothesis: Differences in ER protein steady state levels, and/or turn-over rates contribute to differences in endocrine treatment response between patients with ILC vs IDC.

Methods: We utilized publicly available TCGA data to compare ER mRNA and protein levels between ER+ ILC (n=184) and IDC (n=534). Correlation analysis with Spearman's rank order coefficient (ρ) was used to study the relationship between mRNA and protein levels. METABRIC data were analyzed to compare ER mRNA levels between ER+ ILC (n=130) and IDC (n=1152). ER H-scores and mRNA levels were also analyzed from patients with ER+ ILC (n=180) and IDC (n=1183) seen at our local UPMC Magee Womens Hospital. Finally, ER mRNA and total protein levels, and RNA and protein turn-over rates were determined in 2 IDC and 2 ILC breast cancer cell lines, using qRT-PCR and immunoblots analysis.

Results: Analysis of ESR1 gene expression in the TCGA database revealed significantly lower levels of ER mRNA (Mann-Whitney, p<.0005) in ER+ ILC compared to IDC, whereas ER protein levels were similar in the two histological subtypes. The correlation between ER mRNA and protein levels is weaker in ER+ ILC (p=0.60) compared to ER+ IDC (p=0.69) tumors, though not statistically significant. The weaker correlation between mRNA and protein expression in ILC is more clear when analyzing all 130 RNA and protein pairs with available RRPA data, (ILC median ρ=0.28; IDC median ρ=0.34, p<.0005). In the METABRIC dataset, ESR1 mRNA levels were also found to be lower in ER+ ILC tumor samples compared to IDCs (Mann-Whitney, p<0.005). In concordance with these observations, the study of patients seen at our local hospital showed similar ER IHC H-scores for ER+ ILCs (H-score = 244) and IDCs (H Score = 248), despite there being significantly lower ESR1 mRNA in ILC (p<0.005). Finally, our in vitro data showed that rate of estrogen-mediated turn-over of ER protein was significantly lower in the ILC cell lines compared to the IDC cell lines, which might explain the lack of lower ER protein levels despite lower ER mRNA levels. We are currently confirming these findings in additional cell lines, and deciphering the mechanisms through the study of ER ubiquitin-modification and proteasome machinery comparing ILC and IDC.

Conclusion: We have provided functional and in silico data that collectively suggest altered ER protein turn-over in ILC compared to IDC. We are currently testing if and how this affects sensitivity of ILC cells to SERDs, and underlying mechanisms.
Title: S100β as a predictive biomarker and monitoring tool in endocrine resistant breast cancer

Charmsaz S, Hughes É, Byrne C, Bane F, Tibbitts P, McIlroy M, Hill AD D and Young LS S. Endocrine Oncology Research Group, Royal College of Surgeons, Dublin, Ireland and Beaumont Hospital, Dublin, Ireland.

Body: In estrogen receptor positive breast cancer, endocrine therapy is the standard line of treatment and even though it results in reduced recurrence and mortality, a significant number of patients will eventually relapse. Early detection of metastatic disease would significantly enhance management of endocrine resistant breast cancer. Here we investigate the potential of the calcium-binding protein S100β as a predictive biomarker and monitoring tool in endocrine treated patients. Furthermore, the efficacy of S100β inhibition as therapy in patients that fail first line endocrine therapy was examined.

Primary tumor tissue expression of S100β protein was assessed in a retrospective cohort of endocrine treated breast cancer patients. Expression of S100β indicated a significant reduction in time to disease recurrence (n=509, Wilcoxon p<0.0001, hazard ratio 2.43, 95% C.I. is 1.607 to 3.69, p<0.0001, Cox proportional hazard model).

S100β protein is also detectable in serum of breast cancer patients and elevated levels of serum S100β prior to removal of primary tumor is associated with poor disease free survival in endocrine treated patients (n=190, Wilcoxon p=0.0367, hazard ratio 2.68, 95% C.I. is 1.12 to 6.41, p=0.026, Cox proportional hazard model). Serum levels of S100β are significantly reduced after primary tumor resection (n=19, p=0.0003). In serial samples taken during the treatment period, elevated levels of S100β significantly associated with disease progression and with the emergence of metastatic disease (p=0.0031).

In an in-vivo model of endocrine resistant breast cancer, raised levels of S100β marked the emergence of disease progression. The oncogene steroid receptor co-activator 1 (SRC1) and its interaction with homeobox protein (HOXC11) regulates S100β production in a src-kinase dependent manner. Here, src-kinase inhibition reduced tumor burden with a concomitant reduction in serum S100β. We also observed a marked reduction in expression of proliferative marker Ki67 and S100β protein following the treatment of endocrine resistant patient tumor explants with src-kinase inhibitor.

Associations between elevated levels of serum S100β and subsequent disease progression in endocrine treated patients, suggests S100β as a monitoring tool for early detection of disease progression. Additionally high level of S100β can be used as a potential companion diagnostic tool for stratifying patients on endocrine therapy suitable for treatment with small molecule src-kinase inhibitor.
Title: Detection of $ESR1$ mutations in matched primary and metastatic samples from endocrine-resistant lobular breast cancer patients

Body: Background:
Invasive lobular breast cancer (ILBC) represents the second most common histology of breast cancer (BC) and accounts for 10-15% of all invasive cases. Since >90% of ILBCs express the estrogen receptor (ER, coded by the $ESR1$ gene), the vast majority of these patients receive endocrine therapy. $ESR1$ mutations have mainly been identified in metastases from ER-positive BC at a frequency ranging from 11 to 50% and were shown to be associated with resistance to endocrine therapy. Nevertheless, $ESR1$ mutations have never been assessed in metastatic ILBC, hence the present study.

Patients and methods:
We aimed at interrogating the five most commonly reported $ESR1$ mutations (Y537S/C/N, D538G, E380Q) by droplet digital PCR (BioRad) in matched primary, axillary and metastatic ILBC samples (N=212) from 69 endocrine-resistant patients collected retrospectively from five hospitals.

Results:
We present here the results for the two most frequent $ESR1$ mutations (Y537S and D538G); data from the remaining mutations will be available at the time of the conference. We observed Y537S and D538G mutations in metastases from three and four patients, respectively. For one patient, the sampled metastasis harbored both the Y537S and the D538G mutations, confirming that $ESR1$ polyclonality can be present in the same metastasis. For another patient, two metastases were sampled and the D538G mutation was only present in one metastasis. Intriguingly, for two patients we observed D538G mutations only in the primary tumor but not in the corresponding metastasis, and for another only in an axillary lymph node. We could hypothesize that the clone carrying the mutation in the early setting has been removed either by the primary surgery or subsequent adjuvant chemotherapy. The $ESR1$ Y537S and D538G mutational frequencies observed in our metastatic ILC cohort (3/69, 4.35% and 4/69, 5.80%, respectively) are not statistically different from the frequencies reported in breast cancer metastases in the literature across the different studies (6.62% and 6.20%, respectively). All patients with $ESR1$-mutated metastases received at least 4 years of endocrine therapy and all but one were treated with an aromatase inhibitor (AI). However, half of these patients received exclusively endocrine therapy in the adjuvant setting.

Conclusion:
This is to the best of our knowledge, the first metastatic ILBC series in which the most frequently reported $ESR1$ mutations are being investigated, and the largest series in which $ESR1$ mutations are being investigated in matched metastatic, primary tumor and axillary lymph node samples. The frequencies that we found for the Y537S and D538G mutations are in line with those reported in the literature in metastatic biopsies for the general BC population. We further demonstrated using multiple samples from the primary tumor and an ultra-sensitive technology that there was no patient presenting an $ESR1$ mutation both in the early and metastatic disease. Data on the remaining mutations (Y537S/N, E380Q) will complete these results.
Title: Identification of SAR439859, an orally bioavailable selective estrogen receptor degrader (SERD) that has strong antitumor activity in wild-type and mutant ER+ breast cancer models

Body: Estrogen receptor positive (ER+) breast cancer accounts for 70% of all breast cancers and is primarily treated with endocrine therapy. Approximately 40% of patients on endocrine therapy will become resistant via a number of mechanisms. There is evidence that in many cases ER continues to play a central role, including mutations in ER leading to a constitutively active receptor. Estrogen receptor degraders like fulvestrant are effective in shutting down ER signaling; however, poor pharmaceutical properties limit fulvestrant clinical activity and prevent it from achieving maximum receptor blockade. We describe the discovery of SAR439859, a novel, orally bioavailable SERD that is a potent antagonist and degrader of ER both in vitro and in vivo. SAR439859 has robust activity in multiple ER+ breast cancer cell lines including cells that are resistant to tamoxifen as well as cell lines harboring ER mutants. Across a large panel of ER+ cells, SAR439859 demonstrated broad and superior ER degradation activity than most SERDs undergoing clinical testing. This leads to a profound inhibition of ER signaling, better inhibition of cell growth and results in improved in vivo efficacy. SAR439859 demonstrated tumor regression in all ER+ BC models including MCF7-ESR1 mutant-Y537S model, as well as patient-derived xenograft model that is resistant to endocrine therapies. Furthermore, SAR439859 displays limited cross-resistance with other class of SERDs. Taken together, these results suggest that SAR439859 would be of therapeutic benefit in metastatic BC setting for patients harboring wild type or mutant ER. SAR439859 is being advanced toward the clinic.
Title: ER reactivation rapidly elicits cell death effects in anti-estrogen-resistant breast cancer

Hosford SR R, Kettenbach AN N, Varn FS S, Cheng C and Miller TW W. Dartmouth College, Lebanon, NH.

Body: Antagonism of estrogen receptor (ER) transcriptional activity using adjuvant anti-estrogen therapies has improved disease outcomes in many patients with ER+ breast cancer. However, cancer recurs in 1/3 of patients within 15 years of follow-up. While anti-estrogens can slow the progression of metastatic disease, this disease is almost uniformly fatal. Prior to the development of tamoxifen, high-dose estrogens were used to treat late stage breast cancer with response rates similar to those achieved with tamoxifen. Increased efficacy of estrogen therapy was observed in women who were farther past menopause, suggesting that tumor adaptation to low-estrogen conditions is associated with response to estrogen therapy. Similarly, withdrawal of anti-estrogen therapy in patients with anti-estrogen-resistant disease has shown clinical benefit.

MCF-7 cells with acquired resistance to fulvestrant (fulv; FR), and long-term estrogen-deprived (LTED) MCF-7 and HCC-1428 cells overexpress ER compared to parental controls. Upon withdrawal of fulv in FR cells or treatment with 17b-estradiol in LTED cells, ER transcriptional activity is re-engaged at higher levels than in parental cells, concomitant with drastically decreased cell proliferation and increased apoptosis in endocrine-resistant lines. ER reactivation coincides with an unfolded protein response (UPR) following fulv withdrawal (FR) or E2 treatment (LTED). However, treatment of LTED cells with a proteasome inhibitor protects against apoptosis induced by E2 treatment. Prior studies in other cancer subtypes have shown that proteasome inhibitor treatment can prevent expression of pro-apoptotic FasL, which is upregulated following ER reactivation in FR and LTED cells. Alternatively, inhibition of the proteasome may prevent degradation of anti-apoptotic Bcl-2 family proteins including Mcl-1, which is downregulated following FW in FR cells.

The WHIM16 PDX model was derived from a post-menopausal patient with anti-estrogen-resistant ER+/PR+ breast cancer that responded to 17b-estradiol therapy. WHIM16 PDX tumors grown in ovariectomized mice rapidly, completely regress upon 17b-estradiol treatment. Tumor regression is paralleled by increased Src activation, which is associated with ER turnover and has been implicated in 17b-estradiol-induced apoptosis. Src activation is also observed in FR cells following fulv withdrawal, and in LTED cells treated with E2. Treatment of LTED cells with the Src inhibitor dasatinib protects against E2-induced apoptosis, indicating Src activity may be required for the anti-cancer effects of 17b-estradiol.

Upon withdrawal of 17b-estradiol, clinically silent (non-palpable) WHIM16 tumors resume growth; however, tumors remain sensitive to repeat administration of 17b-estradiol. Long-term fulv-withdrawn FR cells show restored sensitivity to fulv, indicating that cycling of estrogen and anti-estrogen therapies may be an effective treatment strategy.
Title: The new oral SERD AZD9496 is efficacious in antagonizing ER and circumventing resistance to endocrine therapy

Nardone A, Weir H, De Angelis C, Cataldo ML, Fu X, Shea MJ J, Mitchell T, Trivedi M, Chamness GC C, Osborne CK Kent and Schiff R. Lester & Sue Smith Breast Center, Houston, TX; Dan L. Duncan Comprehensive Cancer Center, Houston, TX; Baylor College of Medicine, Houston, TX; AstraZeneca, Oncology iMED, Alderley Park, Macclesfield, United Kingdom and University of Houston College of Pharmacy, Houston, TX.

Body: Background: The selective estrogen receptor (ER) degrader (SERD) fulvestrant (Ful) is a potent ER antagonist that upon binding to ER induces its degradation. Ful has shown clinical efficacy in metastatic disease upon progression on previous endocrine therapies and superior activity compared to an aromatase inhibitor as first line therapy when given at a high dose, 500mg. However, major clinical limitations of Ful are its low bioavailability and its route of administration. Here, we assess the efficacy and the mechanism of action of the new oral SERD AZD9496 compared to Ful in our panel of endocrine-sensitive and -resistant (EndoR) in vitro and in vivo models.

Methods: The effects of AZD9496 and Ful were studied in vitro in various ER+ MCF7, ZR75-1, T47D, 600MPE, and MDAMB415 parental lines and in MCF7 and T47D derivatives made resistant (R) to estrogen deprivation (ED), tamoxifen (Tam), or Ful. Cell growth, Western blot, Q-RT-PCR, and ERE-reporter assays were conducted to assess treatment efficacy as well as ER levels and activity. Xenografts of parental MCF7 cells were established in ovariectomized nude mice with exogenous estrogen (E2). Mice were then randomized to continued E2 or ED, with and without AZD9496 or Ful. Mice bearing transplantable MCF7 EDR and TamR xenografts were randomized to continue original treatment or to switch to Ful or AZD9496, and tumor size was followed. Expression of classic and nonclassic/indirect ER-regulated genes was evaluated in RNA extracts of short-term-treated xenografts using the BioMark FLUIDIGM platform.

Results: AZD9496 inhibited cell growth (50-100%) of all ER+ parental cells and greatly, though not fully, degraded ER protein levels. AZD9496 also potently reduced ER-dependent exogenous and endogenous gene/protein expression in presence and absence of E2. In parental MCF7 xenograft-bearing mice, 10 days of AZD9496 resulted in a greater inhibition of tumor growth and in a greater reduction of levels of ER-dependent targets in comparison to Ful in the presence of E2. The effects of the 2 SERDs were similar in the absence of E2. In EndoR models that retain ER, AZD9496 inhibited cell growth in vitro by degrading ER, similar to Ful. Both SERDs also delayed tumor growth of EDR and TamR xenografts and effectively reduced levels of ER and ER-induced proteins, though no tumor regression was observed in the TamR model. Notably, AZD9496 failed to inhibit growth of FulR cells and xenografts. Expression analysis showed that the 2 SERDs potently inhibited classic ER activity, while simultaneously increasing expression of some genes known to be regulated by the nonclassic/indirect ER activity, including genes involved in escape pathways of endocrine resistance.

Conclusions: The oral SERD AZD9496 is a potent antiestrogen that antagonizes and degrades ER. AZD9496, like Ful, inhibits ER-dependent transcription and tumor growth in both naïve and resistant EDR and TamR models, but shows cross-resistance in FulR models. Both AZD9496 and Ful failed to completely reduce ER protein expression and to induce TamR tumor regression, suggesting that additional strategies to reduce ER levels and to enhance the inhibition of ER signaling and/or of co-operating survival mechanisms may be needed to improve treatment outcome.
The role of HER2 mutations in resistance to endocrine therapy in ER+ breast cancer

Nayar U, Cohen O, Oh C and Wagle N. Dana-Farber Cancer Institute, Boston, MA and Broad Institute of MIT and Harvard, Cambridge, MA.

Body: Resistance to endocrine therapies in estrogen receptor positive (ER+) metastatic breast cancer is widespread, and understanding the mechanisms whereby these tumors acquire resistance is a critical need. Through whole-exome sequencing of metastatic tumor biopsies from patients with endocrine resistant ER+ metastatic breast cancer, we identified 13 different HER2 mutations, including five in the kinase domain, four in the signaling domain, three in the extracellular domain, and one in the transmembrane region of the protein. Two of the kinase domain mutations (L755S and V777L) have been previously described and shown to be activating and resistant to reversible anti-HER2 targeted therapies; the remaining mutations have not been reported. In several of these patients, whole exome sequencing of a pre-treatment primary tumor did not identify the HER2 mutations seen in the corresponding metastatic tumor, suggesting that they were acquired during therapy. To examine the role of HER2 mutations in endocrine resistance, we generated ER+ breast cancer cell lines (MCF7 and T47D) stably expressing the HER2 mutants observed in our clinical data. Several mutants promoted enhanced growth in charcoal dextran-stripped media, which lacks estradiol and mimics treatment with aromatase inhibitor. In addition, several mutants conferred varying degrees of resistance to fulvestrant and tamoxifen. Taken together, these results suggest that HER2 mutations are associated with acquired resistance to endocrine therapies in patients with ER+ breast cancer. The ability of irreversible anti-HER2 agents as well as other agents that target the HER2 pathway to overcome this resistance is being tested for individual HER2 mutations in vitro. The results from these studies may provide a clinical rationale for therapeutic combination strategies in patients with refractory tumors that have acquired endocrine resistance through HER2 mutations.
Title: Genomic analysis to evaluate response to neoadjuvant anastrozole and fulvestrant in post-menopausal ER-positive HER2-negative breast cancer patients included in the UCBG CARMINA02 trial

Body: Background: CARMINA02 is a non-comparative multicenter phase II randomized trial evaluating the clinical response rate after up to 6 months of neoadjuvant endocrine therapy (NET) in HR+/HER2- patients with 1 mg anastrozole (Arm A) or 500 mg fulvestrant (Arm B). Secondary objectives included predictive markers of response and outcome. Between 2007 and 2011, 116 women with operable infiltrating breast adenocarcinoma T2-T4 N0-N3 M0 were randomized. Clinical response rates at 6 months (RECIST criteria) were 52.6% [95%CI 41-64%] in Arm A and 36.8% [95%CI 25-49%] in Arm B (Cancer 2016, in press). We aimed to identify the molecular predictive markers of resistance or sensitivity common to both treatments.

Methods: Ninety tumor RNA from clinical responder (n=34) and resistant patients (n=23) treated in arms A or B have been sequenced with Illumina Hiseq2500 technology leading to 2x100-nt paired-end RNA-seq reads. These samples are from pre-treatment (29 in arm A, 28 in arm B) and post-treatment tumors (6 months after, 17 in arm A and 16 in arm B). Alignment was performed with Tophat_2.0.6. Differential gene expression was analyzed with the Differential Expression analysis for Sequence count data package. Gene fusion was detected with ChimeraScan, TophatFusion and DeFuse tools. Variant calling including variations, insertions and deletions was processed following GATK recommendations for RNAseq datas. Quantitative RT-PCR experiments were done to confirm RNA-seq expression results in patient samples not selected for RNA-seq analysis (validation cohort).

Results: We first analyzed differentially expressed genes (DEGs) between responders and non-responders in pre-treatment or post-treatment samples to select potential predictive markers of response. We identified 51 DEGs before treatment common to anastrozole and fulvestrant. Among these 51 genes, SGK2 was the only gene more intensely expressed in responders than in non-responders. Then we compared DEGs between pre and post-treatment samples for responders or non-responders for both treatment arms. SGK2 expression remains stable after treatment. Furthermore we identified 7 DEGs specific to responders and 11 DEGs specific to non-responders. Concerning genes fusion detection predicted by at least 2 tools, none was specific to a response type. We noted a higher number of fusions in non-responders samples. Variants detected by RNA-Seq are being confirmed by DNA-Seq using a home-made next-generation sequencing panel including 95 genes frequently mutated in breast cancers (analysis ongoing).

Conclusion: High expression of SGK2, encoding a kinase induced in response to signals that activate PI3kinase, may represent a predictive marker of sensitivity to NET. DEGs associated with NET response or resistance belong to cell cycle, DNA replication and repair, cell death and drug metabolism. Ongoing DNA-seq datas will complete this genomic analysis. This research was conducted with support from AstraZeneca and Institut Curie.
Title: Utility of the orally bioavailable selective estrogen receptor degrader AZD9496 in ESR1 mutant preclinical models of estrogen receptor positive breast cancer

Body: Approximately 70% of breast cancers express estrogen receptor alpha (ERα) and anti-hormonal therapies which either block the production of estrogen (e.g. anastrozole) or directly block ERα function (e.g. tamoxifen) remain the mainstay of treatment for these patients. While these therapies are highly effective resistance can occur. A common resistance mechanism to anti-hormonal agents is the mutation of ESR1, the gene that encodes ERα, which leads to ligand independent activity. Evidence is emerging that the selective estrogen receptor degrader (SERD) fulvestrant is effective in patients with ESR1 mutations. However, given the low bioavailability of fulvestrant and the still detectable levels of ER in clinical samples after treatment with fulvestrant it is hypothesised that SERDs with improved pharmacokinetic properties which are able to drive greater degradation of ERα may provide additional clinical benefit. We have previously described the discovery and characterisation of the orally bioavailable SERD AZD9496, which is currently in phase I clinical trials in ER+ breast cancer patients. Here we report the preclinical activity of AZD9496 in cell line and patient derived xenograft models expressing clinically relevant ESR1 mutations. We have engineered MCF-7 cells to express Y537S ESR1 which confers the ability to proliferate in the absence of estradiol, consistent with ligand independent activation of ER signalling. AZD9496 is able to inhibit proliferation of these cells and downregulate progesterone receptor protein expression at low nanomolar concentrations. Furthermore, when MCF-7 Y537S ESR1 cells are implanted as xenografts they grow in the absence of exogenous estradiol, are as sensitive to AZD9496 as parental MCF7 xenografts and demonstrate downregulation of ER dependent biomarkers. AZD9496 also has anti-tumour and pharmacodynamic efficacy in patient derived xenograft models expressing D538G ESR1. Taken together, these data strengthen the body of data suggesting that SERDs may be active in patients with tumours containing ESR1 mutations and supports the inclusion of this patient population in AZD9496 clinical trials.

Title: ER is required for mTORC1 inhibitor-induced feedback activation of PI3K/AKT in ER+ breast cancer cells and patients’ tumors

Yang W, Chen VS S, Schwartz GN N, Marotti JD D, Rosenkranz KM M, Gui J and Miller TW W. Norris Cotton Cancer Center, Geisel School of Medicine at Dartmouth, Lebanon, NH.

Body: The mTORC1 inhibitor everolimus (afinitor) is approved for the treatment of patients with advanced/metastatic ER+/HER2-breast cancer in combination with the steroidal aromatase inhibitor exemestane following progression on a non-steroidal aromatase inhibitor. The BOLERO-2 and TAMRAD studies demonstrated that combined everolimus/anti-estrogen therapy provided longer PFS compared to anti-estrogen alone. However, it has not been clarified whether continued treatment with an anti-estrogen backbone is beneficial in the setting of mTORC1 inhibition.

Upon activation by mTORC1, p70S6K phosphorylates the insulin-like growth factor-1 receptor (IGF-1R)/insulin receptor (InsR) effector IRS-1 to promote IRS-1 degradation, which in turn decreases activation of phosphatidylinositol 3-kinase (PI3K), AKT, and mTORC1. IGF1R, IRS1, and IRS2 are ER-inducible genes, and crosstalk between the ER and IGF-1R pathways has been described. We hypothesized that mTORC1 inhibition with everolimus will upregulate IGF-1R/InsR/IRS-1/2 signaling to activate PI3K/AKT and promote cancer cell survival, while combined inhibition of ER and mTORC1 will block PI3K/AKT activation by decreasing IGF-1R and IRS-1/2, providing rationale for combined targeting of ER and mTORC1.

In 3 ER+ breast cancer cell lines, everolimus treatment increased phospho-AKT levels. ER inhibition with fulvestrant suppressed the induction of P-AKT by everolimus. IGF-1R/InsR inhibition with OSI-906, and RNAi-mediated knockdown of IGF-1R, InsR, or IRS-1/2, decreased everolimus-induced P-AKT. Everolimus sensitized IGF-1R/InsR to IGF-1 that was suppressed by fulvestrant but enhanced by 17b-estradiol. Although fulvestrant decreased IGF-1R and InsR protein levels, phospho-receptor tyrosine kinase profiling showed that fulvestrant increased P-IGF-1R and P-InsR. Acting downstream of IGF-1R/InsR, fulvestrant prevented everolimus-induced PI3K/AKT activation by blocking binding between the p85 regulatory subunit of PI3K and IRS-1, possibly by decreasing IRS-1/2 levels. In summary, everolimus-induced activation of PI3K/AKT requires IGF-1R/InsR/IRS-1/2 signaling facilitated by ER. Combined treatment with fulvestrant and everolimus synergistically inhibited growth in 4 ER+ cell lines.

To determine whether ER promotes PI3K/AKT activation induced by mTORC1 inhibition in patients’ tumors without exposing patients to everolimus, we analyzed live tumor tissues from post-menopausal patients with ER+/HER2- breast cancer treated +/- letrozole for 10-21 d before surgical tumor resection. Tumor cores (1 mm diameter) were used for ex vivo culture in DMEM +/- everolimus +/- OSI-906 for 1 h, and lysates were analyzed by immunoblot. Everolimus significantly increased P-AKT in tumors from untreated patients (n=10). OSI-906 did not affect P-AKT, but OSI-906 suppressed everolimus-induced P-AKT. In tumors from letrozole-treated patients (n=7), neither everolimus nor OSI-906 affected P-AKT. These data collectively suggest that ER activation is required for activation of PI3K/AKT induced by mTORC1 inhibition, and provide rationale for therapeutic combinations of anti-estrogens and mTORC1 inhibitors.

Title: Both spliced and unspliced XBP1 regulates breast cancer cell fate response to antiestrogen via NFkappaB signaling

Body: Unfolded protein response (UPR), a stress-induced survival mechanism, may be used by cancer cells to avoid cell death. Antiestrogen therapy, widely applied in the treatment of estrogen receptor-positive (ER+) breast cancer, induces endoplasmic reticulum stress (ER stress) that leads to activation of each of the three arms of the UPR. One critical prosurvival activator that is regulated by two arms of the UPR is the transcription factor X-box binding protein 1 (XBP1). XBP1 exists in two isoforms, the transcriptionally inactive unspliced XBP1(U) and the spliced, active XBP1(S). Overexpression of XBP1(S) confers estrogen independence and antiestrogen resistance in ER+ breast cancer cells and XBP1(S) expression correlates with poor clinical responsiveness to Tamoxifen in ER+ breast tumors. However, the underlying signaling mechanisms regulated by XBP1, which may mediate its effects on antiestrogen resistance, are unknown. We show that depletion of endogenous XBP-1 by siRNA increases apoptosis, decreases autophagy, requires down-regulation of p65/RelA, a component of the pro-survival NFkappab complex. Using novel spliced and non-spliceable forms of XBP1, we show that XBP1(U) and XBP1(S) both regulate NFkappab activity via ERalpha signaling in breast cancer cells. XBP1(S), but not XBP1(U), also can regulate p65/RelA expression independent of ERalpha. Antiestrogen resistance as conferred by XBP1 overexpression in MCF-7 cells requires the activation of NFkappab signaling; inhibition of NFkappab signaling by either the small molecule NFkappab inhibitor Parthenolide or p65/RelA siRNA sensitizes XBP1 overexpressing cells to Tamoxifen. The activation of XBP1 and the downstream NFkappab signaling is likely to contribute to the TMEM33 overexpression induced apoptosis, as both NFkappab signaling and XBP1(S) are elevated in TMEM33 overexpressed MCF7 cells. Thus, we have identified a critical regulatory link between the UPR/XBP1 pathway and pro-survival NFkappab signaling that is a major contributor to endocrine responsiveness in ER positive breast cancer.
Title: Protein tyrosine kinase 6 (PTK6) promotes survival of endocrine therapy-resistant ER+ breast cancer cells

Irie HY Y, Park SH H, Katsyv I, Zhang W and Nayak A. Icahn School of Medicine at Mount Sinai, New York, NY.

Body: Background/Rationale: The non-receptor tyrosine kinase PTK6/Brk is highly expressed in the ER+/Luminal breast cancer subtypes. PTK6 expression has prognostic significance for patients with ER+ disease; higher transcript levels are associated with poorer survival. The functions of PTK6 in the context of ER+ breast cancer and sensitivity to endocrine therapy have not been explored. We sought to determine the functional roles of PTK6 in ER+ breast cancer cells, including those that are relatively resistant to current endocrine therapies. Methods/Results. We modulated the expression of PTK6 using both gain- and loss-of-function approaches. Enhanced expression of PTK6 in Tamoxifen-sensitive ER+ breast cancer cells was sufficient to confer relative Tamoxifen resistance. Furthermore, downregulation of PTK6 in ER+ breast cancer cells, including those that have acquired resistance to Tamoxifen, induced apoptosis, as evidenced by an increase in AnnexinV+ cells and increased levels of cleaved PARP. PTK6 downregulation impaired growth of Tamoxifen-resistant variants of ER+ MCF7 and T47D cells (MCF7TamR and T47DTamR) in 3D Matrigel culture, and virtually abrogated primary tumor growth of MCF7TamR xenografts. Mechanistically, p38MAPK activation is critical for PTK6 downregulation-induced apoptosis of ER+ breast cancer cells, as p38 inhibition partially rescues cells from PTK6 shRNA-associated apoptosis. Conclusions: Our studies highlight the critical role that PTK6 plays in the survival of ER+ breast cancer cells, including those that are resistant to endocrine therapy. Enhanced PTK6 expression in ER+ breast cancer cells is sufficient to promote endocrine therapy resistance, which could contribute to the poorer prognosis associated with higher PTK6 expression in ER+ patient tumors. As small molecule PTK6 inhibitors are becoming available, our studies support further evaluation of PTK6 as a candidate therapeutic target for endocrine therapy resistant ER+ breast cancers.
Zoledronic acid sensitized breast cancer cells to fulvestrant via ERK/FOXO3a/HIF-1α inhibition through nuclear FOXO3a translocation

Jia X, Liu G, Shen Z and Shao Z. Key Laboratory of Breast Cancer in Shanghai, Fudan University Shanghai Cancer Center, Shanghai Medical College, Fudan University, Shanghai, China.

Body: Background: Previous studies have shown that HIF-1α conferred endocrine resistance and zoledronic acid decreased HIF-1α expression in estrogen receptor positive breast cancer. We investigated the combination effect of zoledronic acid and fulvestrant and the possible mechanism for the inhibition of HIF-1α by zoledronic acid.

Materials and methods: We established a mouse xenograft model stably expressing HIF-1α received PBS, fulvestrant, zoledronic acid and fulvestrant plus zoledronic acid during the whole experimental period. The tumor volume was compared and the expression of HIF-1α and FOXO3a was detected by immunohistochemistry and western blot. Cell proliferation, clonogenic survival, western blot and immunofluorescence were determined by fulvestrant and zoledronic acid. All statistical tests were two-sided.

Results: The combination of zoledronic acid and fulvestrant was shown to be synergistic in the mouse xenograft model. As such, zoledronic acid demonstrated synergy in combination with fulvestrant in vitro (Figure 1A). Zoledronic acid did not inhibit the tumor growth of MCF-7 cells stably expressed HIF-1α. Furthermore, zoledronic acid inhibited ERK1/2 phosphorylation, while the PI3K/AKT pathway was not significantly affected (Figure 1B). The combination of zoledronic acid and AZD6244, a MEK/ERK pathway inhibitor restored the inhibition of HIF-1α by zoledronic acid. However, the combination of zoledronic acid and BKM120, a PI3K inhibitor did not restore the inhibition of HIF-1α by zoledronic acid. Importantly, zoledronic acid increased FOXO3a phosphorylation and nuclear FOXO3a translocation with no changes in total FOXO3a expression in vitro (Figure 1C). In addition, the inhibition of HIF-1α by zoledronic acid was partial restored in human breast cancer T47D (Figure 1D) and MCF-7 cells (Figure 1E) transiently transfected with FOXO3a-specific short-interfering RNA (siRNA).

Conclusion: This study showed that zoledronic acid significantly increased the sensitivity of breast cancer cells to fulvestrant through inhibition of ERK/FOXO3a/HIF-1α pathway.
Title: The PI3K-inhibitor, copanlisib, has selective activity in luminal breast cancer cell lines and shows robust combined activity with hormonal blockade and CDK-4/6 inhibition in ER+ breast cancer cell line xenografts

Body: Background: Genetic and epigenetic alterations in the PI3K/mTOR and cyclin D:CDK-4/6:Rb signaling axes occur frequently in breast cancer and have been attributed to resistance to both ER- and HER2-directed therapeutics. Pharmacologically targeting CDK-4/6 in combination with hormonal blockade provides clinical benefit in patients with advanced ER+ breast cancer. In this study, we evaluated the activity of the pan-class I PI3K inhibitor, copanlisib (BAY-80-6946), with potent alpha and delta activity as a single agent or in combination with CDK-4/6 inhibition and hormonal blockade in a panel of breast cancer cell lines.

Methods: The growth inhibitory activity of copanlisib was evaluated against a large panel of 48 breast cancer cell lines molecularly characterized by genomic, transcriptomic and proteomic profiling. IC\textsubscript{50} values were determined from direct cell counts using a Z1-particle counter. The activity of copanlisib in combination with hormone blockade and CDK-4/6 inhibition, by palbociclib, was assessed in two cell line xenograft models of ER+ breast cancer; MCF7(\textit{PIK3CA}\textsuperscript{-E545K}) and ZR751(\textit{PIK3CA}\textsuperscript{WT}). For xenograft studies, tumor bearing mice were treated once weekly (BID) by intravenous injection with clinically achievable doses of copanlisib (10 mg/kg) as single agent or in combination with tamoxifen or fulvestrant with or without 75 mg/kg daily palbociclib for 21 days.

Results: A broad range of IC\textsubscript{50} values (0.491-895 nM), with a high degree of separation between sensitive and resistant histologically defined subgroups were determined for copanlisib, indicating the potential for a wide therapeutic window. Luminal subtype, the presence of activating mutations in \textit{PIK3CA}, high levels of ER, HER2, HER3 and EGFR protein enriched for sensitivity to copanlisib. Activating mutations of KRAS and BRAF were associated with resistance to copanlisib. Single agent copanlisib induced significant tumor growth inhibition (TGI) relative to vehicle control in each of the xenograft models. Modest increases in anti-tumor activity were achieved when copanlisib was combined with hormonal blockade by either tamoxifen or fulvestrant. However, robust tumor regressions were observed with the triple combinations of copanlisib-palbociclib-tamoxifen and copanlisib-palbociclib-fulvestrant. Furthermore, these triple combinations achieved a statistically significant improvement in anti-tumor activity over the standard of care combination of palbociclib plus fulvestrant. Each of the single agent and treatment combinations tested were well tolerated in animals.

Discussion: These preclinical data illustrate the potent and selective activity of the pan class I PI3K inhibitor copanlisib in luminal breast cancers and support the clinical investigation of copanlisib in combination with CDK-4/6 inhibition and hormonal blockade in ER+ breast cancer.
Steroid receptor co-activator 1 mediation of cancer cell reprogramming in endocrine resistant breast cancer

Body: Cancer cells undergo dynamic and frequently reversible modifications and this cellular plasticity permits reprogramming in response to long term endocrine treatment. A well-established theory, the cancer stem cell theory; suggests that within an ER positive tumour cell population are a small number of stem cells which are capable of infinite self-renewal and are insensitive to treatment with standard endocrine regimes. However, emerging reports that pluripotent cells can be generated from adult somatic cells (Takahashi, 2007) alludes to an alternate mechanism for cancer cells to reprogramme and evade endocrine treatment.

To investigate the role of tamoxifen in promoting cellular reprogramming and endocrine resistance in breast cancer, we isolated single luminal A breast cancer CD24+CD44- clones from endocrine sensitive MCF-7 cells. The clones were expanded in the presence and absence of tamoxifen. Extensive profiling of cells following long-term exposure to tamoxifen revealed a resistant phenotype similar to that reported in other established models.

Steroid receptor co-activator 1 (SRC-1) is a master regulatory protein which has been shown to be central to the development of endocrine resistance. The mechanisms of which are still poorly understood (Walsh et al., 2012). Utilising genome-wide transcriptomic sequencing this study investigated whether SRC-1 can regulate transcriptional networks which mediate reprogramming in individual cells to induce survival adaptability and drug resistance in breast cancer.

RNA-sequencing was carried out in a model of endocrine resistance (shNon-Targeting versus shSRC-1). There were 1,731 genes up-regulated by SRC-1, of which 153 were identified as transcription factors (TFs)/chromatin remodellers. Combining the transcriptomic profiling with ChIP-sequencing we identified a transcriptional network pertinent to SRC-1. Molecular characterisation identified E2F7, NFIA, DEK, SMAD2, SMARCA1, ASCL1 and TRPS1 as key drivers of SRC-1 mediated endocrine resistance. Each TF was confirmed as a direct target of SRC-1, via promoter specific binding and were found to be drivers of endocrine resistant cell migration. Furthermore, all TFs were necessary in mammosphere formation and their promotion of cellular de-differentiation was observed by 3D acinar organisation and flow cytometry. To elucidate the core TFs required for cancer cell reprogramming, their effect on the pioneer reprogramming TFs (OCT4, SOX2, cMYC and KLF4) was investigated. SMAD2, SMARCA1, ASCL1 and TRPS1 have emerged as pivotal regulators of endocrine resistant cell reprogramming.

This study has unravelled an SRC-1-mediated TF network responsible for promoting the cellular reprogramming of breast cancer cells. Concerted activity of this network is responsible for driving de-differentiation of cells and enhancing their stem-like, highly migratory and proliferative tumour initiation population. This study provides important information regarding the mechanism of cellular reprogramming in ER positive endocrine resistant cancer and may lead to potential novel therapeutic targets.
Title: Global transcriptional repression by the coactivator SRC-1 mediates disease progression in treatment-resistant breast cancer

Ward E, Varešlija D, Fagan A, Hill A and Young L. Royal College of Surgeons, Dublin, Ireland and Beaumont Hospital.

Body: Despite the effectiveness of endocrine therapy in treating estrogen receptor (ER) positive breast cancer, nearly 40% of breast cancer patients may develop resistance which can lead to metastatic disease progression. Steroid receptor co-activator-1 (SRC-1), a key regulator of ER signalling, is overexpressed in 35% of breast cancer patients and is strongly associated with the development of endocrine resistant metastasis\(^1\). Recent studies highlighted the ability of SRC-1 to also act as transcriptional repressor. SRC-1 can therefore bi-directionally regulate gene expression to promote the resistant phenotype\(^2\).

This study employed a genome-wide multi-omics sequencing approach to determine the SRC-1 repression signature in endocrine resistance and elucidate the mechanism by which SRC-1 mediates this repression. RNA-sequencing identified 736 genes significantly downregulated by SRC-1, with common functional pathways such as differentiation, cell morphogenesis and extracellular matrix enriched in the gene set. Parallel global methylation sequencing analysis revealed distinct differentially methylated regions specific to SRC-1 repressed target genes. Mechanistic studies in endocrine resistant cells revealed a role for methylation proteins, DNMTs and MBD, in SRC-1 directed repression. Through combined analysis of our global sequencing data we identified a network hub of five differentiation genes directly repressed by SRC-1. High expression of this signature predicts enhanced recurrence free survival in tamoxifen treated patients \((n=335, \ p=0.032)\). A reduction in expression of these genes was shown to have functional output on proliferation, migration and mammosphere formation. Finally, we use tumour explant models to show that targeting DNA methylation can be used to reverse the SRC-1 driven suppression of this differentiation hub.

Here we report a novel mechanism by which SRC-1 may be driving endocrine resistant tumorigenesis. Our genome-wide discovery approach revealed a global epigenetic re-programming pathway whereby concerted differential DNA methylation is potentiated by the activation of SRC-1 in the presence of tamoxifen in the endocrine resistant setting. This study suggests that therapeutic strategies of combined targeted epigenetic therapy with estrogen deprivation could be a successful strategy to prevent acquired resistance to endocrine therapy.
The impact of circulating androgens on the androgen receptor in aromatase inhibitor resistant breast cancer

Aromatase Inhibitor (AI) therapy is the gold standard first line therapy for post-menopausal breast cancer. Following AI treatment the conversion of circulating androgens into estrone can be diminished by >99%, completely altering the tumour steroid microenvironment. Estrogens have been extensively studied in terms of the role of sex steroids as causative agents of breast cancer but interestingly, a case–control study nested within the European Prospective Investigation into Cancer and Nutrition reported that elevated levels of both serum androgens and estrogens are associated with increased breast cancer risk (E2 RR: 2.28 and androstenedione RR: 1.94). Also clinical studies have reported increases in the serum levels of androstenedione (4AD) in patients that recur on AI therapy.

In order to begin to address the role of circulating androgens and the androgen receptor (AR) in AI resistant breast cancer, RNA sequencing was performed on AI resistant (MCF7-aro-LetR) cells cultured with 4AD in the presence of letrozole. Gene expression analysis was performed using the cBioPortal software found that PI3K signalling pathways were upregulated in response to 4AD treatment as well as the upregulation of pathways involved in exocytosis and hormone secretion. We found elevated levels of PI3K and AR in endocrine resistant breast cancer compared to sensitive cell lines and that our AI resistant LetR cells showed significant reduction in cell growth in response to the combined pan class PI3K inhibitor BEZ235 and anti-AR treatment. Clinically, we evaluated the potential role of PI3K signalling in AI resistance a breast cancer patient TMA (n=488) was stained immunohistochemically for phospho-AKT and AR. The protective effect conferred by high AR expression in the total patient population (p=0.02) and tamoxifen treated population (p=0.05) was lost in the AI treated population (p=0.49). For p-AKT staining, patients that were positive for p-AKT significantly associate with the more aggressive luminal B classification yet exhibit an inverse association with luminal A subtype. Kaplan Meier analysis revealed that AR is associated with a more favourable outcome in p-AKT negative patients but that this is lost in the context of elevated p-AKT. Furthermore, interrogation of the breast invasive carcinoma TCGA dataset (n=963) revealed that patients with upregulated AR mRNA and wildtype PI3K exhibited more invasive disease compared with those harbouring a PI3K mutation (p=0.02) (n=56). Further investigations into the AR interacting partners will help elucidate potential mechanisms of action and the role of androgens and AR in facilitating breast cancer tumourigenesis.
Menopause occurs in all women between the ages of 45 and 55 and often results in undesirable vasomotor symptoms. Hormone replacement therapy (HRT) can alleviate these symptoms, including hot flashes, difficulty sleeping, fatigue, and vaginal atrophy, and also prevents osteoporosis. PremPro, a HRT formulation that combines conjugated equine estrogens (CE) with medroxyprogesterone acetate, was found to increase the risk of breast cancer in the Women's Health Initiative (WHI) trial. Due to the perceived risk based largely on the results of the WHI trial, the number of women taking HRT has dramatically decreased. Studies suggest that breast cancer cases from PremPro treatment were primarily due to the outgrowth of occult tumors, not the formation of new disease. Duavee, a new form of HRT that combines CE and bazedoxifene (BZA), a selective estrogen receptor modulator (SERM) and degrader (SERD), has been approved by the FDA for treatment of moderate to severe hot flashes and to reduce the risk of osteoporosis. Importantly, this CE+BZA mixture not only relieves symptoms associated with menopause, but it also does not stimulate the breast or uterus. Several preclinical studies suggest that CE+BZA might be protective in the breast, however the mechanism of action of this new combination therapy is not known. Our goal, therefore, is to elucidate the underlying molecular mechanisms by which CE+BZA differentially affects estrogen receptor alpha (ERα) action in the mammary gland, using transcriptome and whole genome occupancy analysis in breast cancer cell lines. We are also studying the effects of CE+BZA on early mammary cancer progression in the polyoma middle T antigen (PyMT) transgenic mouse model, which is sensitive to estrogens. In addition, we are studying the effects of CE+BZA in an ERα-positive patient-derived xenograft (PDX) mouse model. We have determined that CE modulates gene expression in MCF7 cells similar to 17β-estradiol (E2), and that BZA is able to inhibit these effects. We have also observed that CE increases ERα occupancy, similar to E2, at response elements associated with some estrogen target genes, whereas CE+BZA decreases this occupancy. In the PyMT mouse model, CE+BZA delays the onset of mammary tumors in ovariectomized mice and prolongs their survival when compared to E2 and CE treatment alone. In the PDX model, the CE+BZA tumor growth curve is below vehicle, although it does not quite reach statistical significance. An improved understanding of the molecular mechanisms of CE+BZA action in hormone sensitive breast cancer cell and animal models should have important implications for women considering HRT.
**Title:** Predicting therapeutic effect by on tumor invasion lymphocytes (TILs) in endocrine therapy for stage IV breast cancer

Kashiwagi S, Asano Y, Goto W, Takada K, Takashima T, Morisaki T, Noda S, Onoda N, Ohsawa M, Hirakawa K and Ohira M. Osaka City University Graduate School of Medicine, Osaka, Japan and Deparment of Diagnostic Pathology, Osaka City University Graduate School of Medicine, Osaka, Japan.

**Body:**

**Background:** Breast cancer with distant metastasis at first presentation (stage IV disease) is often encountered in the outpatient department. With recent advances in multimodal therapies for breast cancer, long-term survival can now be expected even in stage IV breast cancer with distant metastasis. However, a goal in treating metastatic disease is prolongation of survival while maintaining good quality of life (QOL). Endocrine therapy is suitable for this purpose. The tumor immune environment not only modulates the effects of immunotherapy, but also the effects of other anticancer drugs and treatment outcomes. These immune responses can be evaluated with tumor-infiltrating lymphocytes (TILs), which has frequently been verified clinically. In the present study, we hypothesized that TILs would be useful as predictive marker of the therapeutic effect in endocrine therapy as well. In this study, the prediction of the therapeutic effect by TILs in endocrine therapy for stage IV breast cancer was clinically verified.

**Materials and Methods:** Data from 40 patients who underwent endocrine therapy as the initial drug therapy for stage IV breast cancer were used. The correlation between TILs evaluated according to the standard method, and prognosis, including the efficacy of endocrine therapy, was investigated retrospectively. Patients with $\geq$50% lymphocytic infiltration were considered to have lymphocyte-predominant breast cancer (LPBC).

**Results:** Among all 40 patients, TIL levels were high in 13 (32.5%) and low in 27 (67.5%) patients. Nine patients (22.5%) had LPBC, and 31 patients (77.5%) had non-LPBC. Investigation of the clinical pathological features of patients showed no significant differences between the high TIL and low TIL groups. There were also no significant differences between LPBC and non-LPBC patients. An analysis of outcomes comparing the high TIL and low TIL groups showed no prolongation in progression-free survival (PFS) ($p=0.171$, log-rank), time to treatment failure (TTF) ($p=0.054$), or overall survival (OS) ($p=0.641$). LPBC patients had significant prolongations of PFS ($p=0.005$), TTF ($p=0.001$), and OS ($p=0.027$) compared to non-LPBC patients. On receiver operating characteristic (ROC) curve analyses, results were better with LPBC (AUC: 0.700) than with TILs (AUC: 0.606).

**Conclusion:** The present findings suggest that a high level of lymphocytic infiltration in the tumor stroma may serve as a predictor of the therapeutic effect of endocrine therapy for patients with stage IV ER-positive breast cancer.
Title: Androgen receptor in tamoxifen-resistant breast cancer is affected by SUMO

Bahnassy S, Kumar S, Ren J, Frutiz G, Karami S and Bawa-Khalfe T. Center for Nuclear Receptor & Cell Signaling, University of Houston, Houston, TX.

Body: Resistance to tamoxifen is a major problem in treating women with estrogen receptor-positive (ERa+) breast cancer (BCa). Previous studies report elevated levels of the androgen receptor (AR) in tamoxifen-resistant (TamR) human mammary tumors. Inversely, in vitro overexpression of AR in ERa+-MCF-7 cells potentiates growth in the presence of tamoxifen. AR is a target for small ubiquitin like modifiers (SUMO) posttranslational modification (PTM). Prostate cancer (PCa) studies, show that SUMO-PTMs can have diverse effects on AR transcriptional activity, by modifying the AR itself or its co-regulators. SUMOylation regulates the AR's interaction with chromatin and modulates its function in a gene selective manner. Although SUMO-1 inhibited the AR transcriptional activity, SUMO-3 strongly enhanced the transactivation of AR in LNCaP cells but negatively affected the AR transcriptional activity in primary prostate epithelial cells. On the other hand, SUMO modifications and its subsequent effects on the AR in breast tumors and in particular TamR-BCa is unknown. Our objective is to understand how SUMO-PTMs affect AR activity in TamR-BCa. Others report that high Ubc9, a SUMO E2 conjugating enzyme, correlates with with aggressive phenotypes of BCa and that PIAS3, a SUMO E3 ligase, expression increases in breast tumors. Consistently, we now report that global SUMO2/3-conjugation is enhanced while the full-length SUMO protease SENP7 (SENP7L) is reduced in TamR-BCa cells. Collectively, these observations would suggest reduced SUMO dynamics in TamR-BCa as compared to tamoxifen-sensitive (TamS) BCa cells. Unlike PCa cells that favor unmodified over SUMOylated AR, we report that AR SUMOylation is potentiated in TamR-BCa cells. Functionally, SUMOylation of AR augments its chromatin binding and enhances its transcriptional activity. Our results suggest that the level of unmodified to SUMOylated AR is dramatically altered with onset of TamR and drives a functionally distinct population of AR in TamR versus TamS BCa. Consistently these biochemical reactions that define protein diversity could have a major impact on drug resistance in BCa.
Title: RAD1901 demonstrates anti-tumor activity in multiple models of ER-positive breast cancer treatment resistance

Body: Estrogen receptor positive (ER+) breast cancer makes up approximately 70% of all newly diagnosed breast cancers and ER remains the single most useful predictive and prognostic marker for these patients. In fact, dependence on ER signaling is retained in recurrent disease and even in disease treated with multiple lines of anti-endocrine agents. Indeed, inhibiting estrogen synthesis (e.g. with aromatase inhibitors) and modulating ER pathway activity (e.g. with tamoxifen) continue to be mainstays in the standard of care for ER+ breast cancer patients both in adjuvant and metastatic setting. While patients initially respond well to these agents, a majority of patients with metastatic disease will relapse. Therefore, it is critical to improve our understanding and model the specific mechanisms that can lead to treatment resistance. Mutations in the ligand binding domain of ESR1 have been described as a mechanism that contributes to clinical resistance to aromatase inhibitors. In addition, some ESR1 mutations can lead to a conformational change of the receptor, leading to decreased binding of tamoxifen, thereby reducing its activity. Recently, selective estrogen receptor degraders, or SERDs, have gained widespread attention as a novel treatment strategy for ER+ disease. Indeed, fulvestrant has been shown to degrade ER and cause tumor growth inhibition in many ER+ breast cancer models. However, in the clinic, fulvestrant appears to be limited by PK exposure properties and this, combined with its intramuscular route of administration underscore the need for an oral SERD with improved PK properties. Recently, we have described RAD1901, a novel, orally available, non-steroidal small molecule SERD that is able to degrade ER and effectively cause tumor growth inhibition in multiple patient-derived xenograft models (PDX) models, including two that harbor a Y537S mutation in ESR1. To further validate that RAD1901 has the potential to be used in the advanced disease setting, we tested its anti-tumor activity in preclinical models representing the most common ESR1 mutations (D538G, E380Q, S463P, Y537N/C). In addition, we have tested RAD1901 in multiple cell line models of anti-endocrine resistance. These include long-term estrogen deprived cells that model progression of disease on aromatase inhibitors, as well as tamoxifen-resistant models. Here, we present anti-tumor activity of RAD1901 both as a single agent and as part of rational clinical combinations (eg. CDK4/6, PI3K/Akt/mTOR inhibitors) in multiple models of anti-endocrine resistance. These results combined with previous studies demonstrating RAD1901 efficacy in treatment naïve models provide strong preclinical evidence for clinical testing of RAD1901 in both adjuvant and metastatic setting. RAD1901 is currently under clinical investigation for the treatment of ER+ breast cancers in post-menopausal women (NCT02650817, NCT02338349).
Title: Combination therapy of targeted anticancer pathways and estrogen receptor ligands and their responses in \textit{de novo} and tamoxifen resistant cell models

Gutgesell LM M, Xiong R, Thatcher GRJ RJ and Tonetti DA A. University of Illinois at Chicago, Chicago, IL.

Body: Approximately 75% of breast cancers are classified as Estrogen Receptor positive (ER+). Tamoxifen, a selective estrogen receptor modulator (SERM), is the standard of care for many of these ER+ breast cancer patients. Unfortunately, tamoxifen resistance occurs in almost 50% of patients within 5 years of treatment, and endocrine-independence accompanying resistance also negates the effects of aromatase inhibitors. Combination therapy is increasingly used in non-cytotoxic therapeutic approaches in many types of cancer. The potential exists that endocrine resistance can be lessened, eliminated, or overcome through targeted therapy in combination with endocrine therapy. Inhibition of kinase signaling (e.g. via CDK4/6 or PI3K) and other pathways (e.g. HSP90) are expected to be effective in combination with endocrine therapy. We have discovered a variety of ER ligands with potential as endocrine therapeutic agents, based upon a single chemical scaffold with a diverse set of pharmacological responses: including SERMs, selective ER downregulators (SERDs), selective estrogen mimics (SEMs), and selective human ER partial agonists (ShERPAs). To predict which agents in combination with these endocrine-targeted ligands would be of potential therapeutic benefit it was necessary to develop 3D spheroidal cultures of ER+ breast cancer cell lines: including endocrine-dependent lines; and cell lines made endocrine-independent either by extended exposure to tamoxifen or extended deprivation of estradiol. In contrast to 2D cultures, drug response in 3D spheroidal cell cultures was predictive of response to treatment in mouse xenograft studies. Growth of endocrine-dependent cell lines was, as expected, inhibited by SERDs; and endocrine-independent, tamoxifen-resistant cell lines were also sensitive to SERD treatment, although one cell line was largely resistant. Growth of all three tamoxifen-resistant cell lines was inhibited by SEMs/ShERPAs. Importantly, regardless of the type of endocrine therapeutic agent studied, concentrations leading to saturation of the target (ER) did not cause cell death. Equally, all endocrine therapies studied benefited from combination treatment with other agents, leading to enhanced cell death.
Identification of preclinical mechanisms driving acquired resistance to selective ERa degraders (SERDs), CDK4/6 inhibitors, or to combinations of both agents

O'Brien T, Xiao Y, Ong C, Daemen A and Friedman L. Genentech, South San Francisco, CA.

Body: Estrogen positive (ER⁺) breast cancer accounts for the majority of all breast cancers and standard practice is treatment with endocrine therapy. Recently a series of CDK4/6 inhibitors have emerged that can be effectively combined with estrogen modulators to treat ER⁺ breast cancer patients. The most advanced of these compounds, palbociclib, is now approved in the US in combination with letrozole or fulvestrant. Even though these combinations are effective, invariably patients will relapse. Our understanding of the mechanisms of acquired resistance to CDK4/6 inhibitors is still relatively nascent, and it is not known whether acquired resistance to combination treatments (e.g. palbociclib with fulvestrant) will be the same as mechanisms for the individual single agents. Additionally, it is not known if tumors that no longer respond to one combination regimen will remain sensitive to other standard of care treatments.

To pre-clinically address these questions we generated cell lines that have acquired resistance to three Selective Estrogen Receptor Degraders (SERDs) and to two CDK4/6 inhibitors, palbociclib and abemaciclib. Additionally, we also generated cells with acquired resistance to the combination of fulvestrant and palbociclib. Characterization of cells resistant to each of these treatments will be presented. Initial data indicate that MCF7 cells with acquired resistance to SERDs have increased PI3K signaling and MEK/ERK signaling and have increased sensitivity to inhibitors of these pathways when treated with single agents. These cells are also more sensitive to palbociclib relative to parental cells. All 11 clones with acquired resistance to abemaciclib lose Retinoblastoma (Rb) expression and 20/24 palbociclib-resistant clones lose Rb expression, indicating the importance of Rb to CDK4/6 inhibitor activity. Interestingly, palbociclib resistant clones have decreased sensitivity to fulvestrant and to PI3K inhibitors, and investigation is under way to determine if that relates to slower doubling times for the clones.

Detailed characterization of resistant clones reveals a surprisingly complex interaction between ERa and CDK4/6 signaling, and further results, including acquired resistance to drug combinations, will be presented. These preclinical studies may inform biomarkers of sensitivity and resistance to endocrine agents and CDK4/6 inhibitors.
Title: Role of \( H19 \), a long non-coding RNA, in development of resistance to endocrine therapy in breast cancer cells

Body: Introduction:
Majority of breast cancer tumors are Estrogen receptor positive (ER+) where antiestrogen therapies (endocrine therapies) are the best therapeutic strategy to treat this type of tumors. However, eventually over 30% of patients will develop resistance to endocrine therapies resulting in disease relapse. We recently showed that the long noncoding RNA, H19, is an estrogen target gene that plays a significant role in estrogen-induced proliferation of the normal and malignant ER+ cells. We therefore hypothesize that \( H19 \) expression is also important to the proliferation of endocrine therapy resistant cells. In this study, we examined if estrogen-independent \( H19 \) expression is important to the development of endocrine therapy resistance.

Objective:
The overall objective of this project is to use therapy sensitive (MCF-7) and therapy-resistant (LCC9) breast cancer cells as model systems to examine the role of long non-coding RNA \( H19 \) in development and maintenance of resistance to endocrine therapy.

Methodology and Results:
We examined the expression of \( H19 \) in ER+ breast cancer cells (MCF7) that under the selective pressure of fulvestrant (ICI, ER down regulator) acquire resistance to ICI. We observed that while \( H19 \) expression was initially decreased as expected, its expression subsequently increased in the ICI-resistant MCF7 cells. Interestingly, \( H19 \) knockdown in MCF7 cells significantly decrease their proliferation as determined by Flowcytometry and made them more sensitive to ICI. We also examined \( H19 \) expression in the ICI-resistant LCC9 cells and found that ICI treatment increased \( H19 \) expression. Interestingly, \( H19 \) knockdown in the LCC9 cells decreased their proliferation and surprisingly made them sensitive to ICI treatment. Previous observations indicate that NOTCH4 receptor (NR4) may be involved in endocrine therapy resistance. Interestingly we found that in presence of ICI, NR4 expression is increased and that forced activation of NR4 markedly increases \( H19 \) expression in LCC9 cells.

Conclusion:
Altogether these observations suggest that \( H19 \) plays an important role in the development of endocrine therapy resistance and further our understanding of the cellular and molecular mechanisms involved in endocrine therapy resistance. These and similar studies could potentially lead to the development of new therapies to treat therapy resistant tumor cells. Further experiments would reveal if signalling pathways that regulate \( H19 \) expression independent of estrogen are useful therapies against endocrine therapy resistant tumors.
Body: Background: The estrogen receptor (ERα) plays an integral role in the progression of luminal type breast cancers and while targeted endocrine therapies provide effective initial treatment many patients develop acquired resistance to treatment even with continued ER receptor expression. Recently studies identified ER mutations as a possible mechanism for acquired resistance and several activating point mutations have been identified including Y537S (ESR1\textsuperscript{Y537S}) resulting in hormone independent proliferation in preclinical studies. However, lack of validated ESR1-mutant cell lines has limited detailed mechanistic studies of these mutations in endocrine-resistant ER+ breast cancer. Previously we established and evaluated a patient derived xenograft (PDX) designated ST941 representing ESR1\textsuperscript{Y537S}-mutated ER+ breast cancer (Wick et al, SABCS 2015). To better understand the role of ESR1-mutations in endocrine resistant breast cancer we established an immortalized cell line from ST941 designated ST941/C to use for in vitro mechanistic assays and correlative in vivo studies.

Methods: The ST941/C cell line was generated from harvested low-passage ST941 PDX tissue using published methods. Once established the line was characterized by immunohistochemistry and NGS and its tumorigenicity assessed. Drug sensitivity studies were carried out evaluating relevant endocrine and chemotherapy agents and results compared with in vivo drug studies. Timepoints for cell proliferation assays were Days 4, 7 and 10 following cell plating using standard MTS assay. Endpoints for in vivo studies were a mean group tumor volume of ~1 cm\textsuperscript{3} or sixty days following treatment initiation.

Results: Subcutaneous cell injection into athymic nude mice produced xenografts which grew in the absence of exogenous hormone. The ST941/C cell line and resulting xenograft retained immunohistologic and NGS characteristics of the parent model including receptor expression and ER mutation. Both the cell line and xenograft were insensitive to most endocrine therapies including tamoxifen, fulvestrant and aromatase inhibitors and reported correlative activity towards docetaxel and other chemotherapies.

Conclusion: We have established and evaluated an ESR1-mutant cell line designated ST941/C which is tumorigenic in nude mice and potentially useful for mechanistic and correlative in vivo studies to better understand acquired resistance in endocrine-treated ER+ breast cancer.
Title: Delineating novel molecular pathways driving endocrine resistance in breast cancer

Body: Background
Estrogen receptor (ER) is a main driver of tumor progression in ER+ metastatic breast cancer (MBC). The use of endocrine therapy can effectively control the disease in a large proportion of patients. However, the majority of MBC eventually become resistant and progress. To elucidate the mechanisms of acquired resistance to endocrine treatment is key in order to better select therapeutic partners and delay disease progression.

Methods
A panel of ER+ breast cancer cell lines initially sensitive to the selective estrogen receptor degrader (SERD) fulvestrant was exposed to increasing concentrations of this drug over several months to induce resistance. Cell proliferation was determined with the xCELLigence system. Protein expression was measured by phospho-kinase array and western blotting. RNA expression was evaluated by gene expression microarray analysis (Illumina) and validated by RT-qPCR. Cell cycle distribution was analyzed by flow cytometry.

Results
Using an unbiased approach to identify pathways that drive endocrine resistance, both the parental and the resistant cell models were studied. As expected, fulvestrant treatment resulted in G1-cell cycle arrest in the parental cell lines. In stark contrast, resistant cells bypassed fulvestrant-induced proliferation block despite a lower expression of genes driving mitotic progression compared to untreated parental cells. This gene expression pattern was coupled with a reduction of ER protein level in the resistant cells, which was in line with a significant decrease in the expression of ER-target genes. Our phospho-screen analysis showed a genotype specific down-modulation of p53 and up-regulation of several signaling components of mitogenic pathways in resistant cells compared to parental cells.

Conclusions
Our results suggest that acquired endocrine resistance is driven by multiple cell-specific mechanisms rather than a common molecular underpinning. Strikingly, there is one unique feature in our models, which is a cellular switch towards an ER-independent gene expression program. Ongoing in vitro and in vivo studies, aimed at further characterizing these cellular models, will provide valuable insights into the heterogeneity underlying the response to endocrine treatment observed in MBC patients.
Reprogramming of metabolic pathways is one of the central hallmarks of cancer cell growth and survival to support anabolic and energetic demands. Rapidly proliferating tumor cells utilize increased amounts of glucose for energy generation and macromolecule biosynthesis, yet it is still poorly understood how increased glucose-flux accentuates aggressive metastatic tumor. Understanding the molecular and genetic regulators of these metabolic-programs is critical to discover new drug targets for cancer therapy. Here, we report that the oncogenic transcriptional coregulator steroid receptor coactivator-3 (SRC-3) is a critical sensor of increased tumor glycolysis and re-programs transcriptional responses to support breast cancer growth and metastasis. From an unbiased kinome-wide RNAi library screen, we identified the glycolytic enzyme PFKFB4 as a direct stimulator of SRC-3 activity. PFKFB4 is a bifunctional metabolic enzyme that contains both ‘kinase’ and ‘phosphatase’ domain, yet the functional role of these regulatory domains in tumor metabolism is not clear. Glucose stimulation promotes PFKFB4-dependent phosphorylation of SRC-3 (pSRC-3) which then enhances transcriptional coactivation by this coregulator. Mechanistic studies revealed that SRC-3 and PFKFB4 mutually cooperate to maintain high levels of purine biosynthesis by transcriptionally upregulating rate-limiting enzymes transketolase (TKT), adenosine monophosphate deaminase-1 (AMPD1) and xanthine dehydrogenase (XDH). Knockdown of PFKFB4 or SRC-3 significantly decreased the expression of these enzymes resulting in reduced proliferation of breast tumor cells, and this functional deficiency could be rescued by exogenous addition of purines. Chromatin immunoprecipitation (ChIP) studies identified increased occupancy of pSRC-3 on target gene promoters, which overlapped with activating transcription factor 4 (ATF4) binding sites in the proximal promoter region. Immunoprecipitation of ATF4 identified increased interaction with pSRC-3 in glycolytic breast tumor cells, whereas knockdown of PFKFB4 or expression of a phospho-deficient SRC-3 mutant significantly reduced the SRC-3/ATF4 association. These findings suggest that upon enhanced glycolysis, PFKFB4 induced activation of SRC-3 by phosphorylation promotes expression of purine biosynthetic genes primarily by coactivating ATF4. Importantly, ablation of either SRC-3 or PFKFB4 suppresses in vivo breast tumor growth and metastasis, and these tumorigenic-effects cannot be simulated by a phospho-deficient SRC-3 mutant suggesting the PFKFB4-SRC-3 axis may be therapeutically exploited for treating breast cancer patients.

Title: Quantitative ERα measurements in TNBC from the I-SPY 2 TRIAL correlate with HER2-EGFR co-activation and heterodimerization

Gallagher RI I, Yau C, Wolf DM M, Dong T, Hirst G, Brown-Swigart L, ISPY-2 TRIAL Investigators, Buxton M, DeMichele A, van't Veer L, Yee D, Paoloni M, Esserman L, Berry D, Park J, Petricoin EF F and Wulfkuhle JD D. George Mason University, Manassas, VA; University of California San Francisco School of Medicine, San Francisco, CA; Quantum Leap Healthcare Collaborative, San Francisco, CA; University of Pennsylvania School of Medicine, Philadelphia, PA; University of Minnesota School of Medicine and Berry Consultants, LLC.

Body: Background: We have previously described that TNBC patients whose tumors have both HER2 Y1248 phosphorylation (pHER2) “high” and phospho-EGFR Y1173 (pEGFR) “high” have increased response (pCR) to neratinib in the I-SPY2 TRIAL. We hypothesize that the paradoxical finding of a response prediction signature comprised of HER2 activation in a HER2 IHC/FISH-negative population means there must be a ligand-driven biochemical event responsible for the HER2 phosphorylation because HER2 mutations were also not found to be significant. Exploratory analysis of additional cellular signaling events and protein expression levels in pre-treatment, LCM-purified tumor epithelium by reverse phase protein microarray (RPPA) included semi-quantitative measurement of total levels of estrogen receptor alpha (ERα), which has been previously shown to be able to act as a membrane non-genomic signaling molecule through direct interaction with various tyrosine kinases including EGFR and HER2. Since ERα has been previously shown to act as a ligand and co-stimulate (activate) HER2 and EGFR when present at low levels, we investigated whether or not RPPA-measured ERα levels in the TNBC cohort analyzed to date were higher in tumors with both pHER2 “high” and pEGFR “high” levels and thus provide evidence explaining how HER2-EGFR activation is occurring in TNBC.

Methods: Using RPPA analysis, we measured 118 analytes in lysates of LCM tumor epithelium obtained from the pre-treatment biopsy samples of 86 TNBC (Allred=0) patients in the I-SPY2 TRIAL analyzed to date. Cutpoints for pEGFR and pHER2 were determined previously by ROC analysis for pCR correlation in the neratinib treated TNBC population, and used here to dichotomize the pHER2 and pEGFR data in the larger TNBC population. Wilcoxon Rank Sum testing was performed using the continuous variable total ERα data and compared the TNBC that were both pHER2 and pEGFR “high” (N=39) to the rest of the TNBC population (N=47). Total ERα values were then divided into “high” and “low” groups based on the TNBC population median value in order to determine frequency/percentages within each class. Our study is exploratory with no claims for generalizability of the data, and calculations are descriptive (e.g. p-values are measures of distance with no inferential content).

Results: Total ERα values were obtained in 84/86 TNBC tumors analyzed. Total levels of ERα were higher (p< 0.006) in TNBC tumors with pHER2 and pEGFR “high” levels. 68% (26/38) of tumors in the pHER2 and pEGFR “high” group had ERα levels above the population median compared to 35% (16/46) in the rest of the TNBC population.

Conclusion: Our exploratory analysis reveals that ERα levels are significantly higher in TNBC with pHER2 and pEGFR activation and may be behaving as a direct signaling ligand in TNBC and driving HER2-EGFR signaling. This ERα-pHER2/pEGFR association was missed by current ER and HER2 clinical laboratory testing techniques, and if validated in larger independent study sets could suggest that utilization of new protein-based techniques defining ER more quantitatively could be helpful to understand tumor biology and therapeutic response prediction, especially in the context of TNBC that are ostensibly ER negative.
Title: A novel progesterone receptor (PR)-RNA polymerase III association represses estrogen-dependent growth in breast tumor patient-derived xenografts

Finlay-Schultz J, Gillen AE E, Brechbuhl HM M, Ivie J, Bentley DL L, Kabos P and Sartorius CA A. University of Colorado Anschutz Medical Campus, Aurora, CO; School of Medicine, University of Colorado Anschutz Medical Campus, Aurora, CO and University of Colorado Anschutz Medical Campus, Aurora, CO.

Body: **Background:** Progesterone (P) is an important hormone for development and normal function of the breast; however, its role in established breast cancers is less clear. P has been implicated in regulating tumor cell growth, signaling, differentiation state, and stem/progenitor properties in breast cancer cells. Progesterone receptors (PRs) are considered positive prognostic indicators yet potential targets for treatment, although the dilemma of positive or negative targeting persists. P can either inhibit or stimulate breast cancer cell growth in the absence of estrogens (E), and usually blocks E mediated growth. Recent studies using breast cancer cell lines have deciphered a mechanism by which P suppresses E dependent growth through modulation of the estrogen receptor (ER) cistrome through a physical ER/PR association. However, the ER/PR association is weak to undetectable in our ER+PR+ breast cancer patient-derived xenografts (PDX). We therefore hypothesize that PR can regulate E-dependent breast cancer growth independent of direct interference of ER transcription. The purpose of this study was to use unbiased genomics and proteomics of breast cancer PDX to uncover additional mechanisms of P repression of breast cancer growth.

**Methods:** These studies used two luminal ER+PR+ PDX (UCD4 and UCD65) that contain high levels of ER and PR (>90%), and where P inhibits E-dependent growth. Tumors were grown in vivo in female NSG mice under continuous placebo, E (17b-estradiol), E plus P, or E plus the synthetic progestin medroxyprogesterone acetate (MPA) for 8-10 weeks. RNAseq, chromatin immunoprecipitation sequencing (ChIPseq), and rapid immunoprecipitation followed by mass spectrometry of endogenous proteins (RIME) were performed to analyze differential transcriptional, cistromic, and protein-protein interactions in E compared to E plus P or MPA treated tumors. Co-immunoprecipitation (co-IP) and ChIP were used to verify results.

**Results:** Both P and MPA potently inhibited E-dependent growth of both tumor lines. Gene expression studies found that both hormones reversed transcription of over one third of the estrogen/ER transcriptome in both tumors. RIME for PR uncovered significant interactions between PR and multiple RNA polymerase III subunits (POLR3). Co-IP using POLR3A and POLR3B confirmed PR associates with the POLR3 holoenzyme. Furthermore, ChIPseq revealed that PR binds to one third of POLR3 regulated tRNA genes. PR also associated with Maf1 in one tumor, a known POLR3 suppressor.

**Conclusions:** Here we describe a novel association of PR with POLR3 in two luminal breast cancer PDX, an interaction not described in breast cancer cell lines. Our data suggest this is a negative regulatory interaction that may occur through recruiting a POLR3 repressor. These data implicate multifaceted P control of E dependent tumor growth; in addition to antagonizing E regulated genes at the transcription level, P can regulate translation through depletion of amino acid carrying tRNAs, thus slowing protein synthesis. Identifying which tumors utilize this growth-suppressive mechanism may pinpoint appropriate candidates for progestin therapy and/or provide a prognostic tool for predicting tumor progression.
Impact of androgen receptor expression in fluoxymesterone-treated, estrogen receptor–positive metastatic breast cancer exposed to contemporary hormonal therapy

Kono M, Fujii T, Lyons GR Ray, Huo L, Bassett R Jr, Gong Y, Karuturi MS Sri, Tripathy D and Ueno NT T. Section of Translational Breast Cancer Research, The University of Texas MD Anderson Cancer Center, Houston, TX; Morgan Welch Inflammatory Breast Cancer Research Program and Clinic, The University of Texas MD Anderson Cancer Center, Houston, TX; Biostatistics, Houston, TX and Pathology, Houston, TX.

Body: Background: The use of the nonselective androgen fluoxymesterone in patients with metastatic breast cancer (MBC) diminished after the 1960s because of its adverse events and a limited understanding of its biological effects. Although fluoxymesterone has had efficacy against tamoxifen-resistant disease in clinical studies, its role in the era of contemporary hormonal therapy is unclear. Recent studies have shown that the androgen–androgen receptor (AR) complex acts as a suppressor of estrogen receptor (ER)+ breast cancer. We hypothesized that fluoxymesterone is effective against MBC that progresses despite contemporary hormonal therapy and that the drug has more clinical benefit in patients with ER+AR+ disease than in patients with ER+AR- disease. We evaluated the survival outcomes of patients with MBC who received fluoxymesterone after contemporary hormonal therapy failed and evaluated the association between ER/AR status and survival outcomes in these patients.

Methods and Materials: We included 103 patients treated with fluoxymesterone who had already received at least one prior hormonal or cytotoxic treatment for MBC between January 1, 2000, and December 31, 2014, at a single institution. A pathologist reviewed these patients' tumors' ER and AR expression levels by immunohistochemical staining. Progression-free survival (PFS) was defined from the start of fluoxymesterone treatment to the date of disease progression or last follow-up. We used Cox regression analysis to examine univariate and multivariate correlates of PFS.

Results: Patients received a median of 3 (range: 0-10) prior hormonal therapies (aromatase inhibitors, tamoxifen, and/or fulvestrant) before fluoxymesterone. Of the 103 patients, 33 (32%) discontinued fluoxymesterone because of physician decision or adverse events, which included toxicity in 14 patients, and 70 (68%) were eligible for tumor response assessment by Response Evaluation Criteria in Solid Tumors. Of these 70 patients, 2 (3%) had a complete response, 7 (10%) had a partial response, and 21 (30%) had stable disease for at least 6 months, yielding a clinical benefit rate of 43%. The median PFS was 3.9 months (95% confidence interval: 3.2–5.3 months). The multivariate analysis revealed no significant association between PFS and the type or number of prior treatments. Thirty-nine patients (38%) had archived tumor slides available for AR staining. All 39 patients had ER+ disease; 5 had ≤1%, 5 had >1% but <10%, 18 had ≥10%, and 11 had no AR nuclear expression. AR positivity defined by the presence of any AR+ cells, ≥1% AR+ cells, or ≥10% AR+ cells was not significantly associated with survival outcome.

Conclusions: Fluoxymesterone showed objective tumor response and prolonged control of ER+ MBC refractory to contemporary endocrine therapy. The number and type of prior treatments did not impact the drug's clinical benefit, and AR+ status did not influence the clinical outcome. Fluoxymesterone should be considered for patients whose ER+ MBC progresses despite contemporary hormonal therapy, regardless of their AR status.
Body: PTHrP affects mammary development and breast cancer. PTHrP is expressed in basal myoepithelial cells until late pregnancy, when it also becomes expressed in alveolar epithelial cells. During lactation, PTHrP is secreted into milk and into the circulation, and regulates systemic calcium and bone metabolism. Secretion of PTHrP by breast cancers stimulates bone resorption, promoting the skeletal metastases and/or development of hypercalcemia. Less is known about the contribution of PTHrP to development and/or progression of primary breast cancers. Recent GWAS reports have identified the PTHrP gene as a breast cancer susceptibility locus. Using data from the Cancer Genome Atlas (TCGA) Project and a Yale tissue microarray (YTMA49) we have found that increased breast tumor PTHrP expression predicts a more aggressive phenotype and increased mortality, signifying the clinical relevance of high tumor PTHrP levels. In an attempt to define how PTHrP affects breast cancer, we assessed the effects of PTHrP overexpression on the development of mammary tumors in mice. We developed a tetracycline-regulated, MMTV-driven transgenic model of PTHrP overexpression targeted to mammary epithelial cells (MMTV-rtTA;tetO-hPTHrP). Surprisingly, we found that PTHrP overexpression in luminal epithelial cells causes alveolar hyperplasia, secretory differentiation and milk production in virgin mice, associated with a lower number of luminal progenitor cells and basal stem cells upon FACS analysis. Additionally, Signal Transducer and Activator of Transcription 5 (Stat5) is highly activated in the setting of PTHrP-induced alveolar hyperplasia. This activation is functionally relevant as evidenced by higher levels of β-Casein mRNA and protein, the transcription of which is regulated by activated Stat5 (pStat5). This effect of PTHrP was reversible upon withdrawal of doxycycline (Dox). Addition of Dox to primary mammary epithelial cell cultures from these mice recapitulated the findings. Knocking out PTHrP receptor (PTH1R) in these mice did not affect this phenotype, suggesting that PTHrP acts in a receptor-independent manner. Overexpression of PTHrP in MMTV-PyMT mice dramatically accelerated formation of mammary tumors reducing both latency of tumor formation and survival of the mice. It caused a higher rate of proliferation and a lower rate of apoptosis in vivo. All MMTV-rtTA;tetO-hPTHrP;MMTV-PyMT mice developed palpable tumors in all mammary glands within 3 weeks of age, became hypercalcemic and died before 4.5 weeks of age. These mice had higher levels of pStat5 and βCasein. Tumor cells cultured ex vivo and cell lines established from these tumors overexpressed PTHrP when stimulated with Dox. PTHrP overexpression, and not exogenous PTHrP, caused higher levels of proliferation, pStat5, and β-Casein. This PTHrP-induced activity of Stat5 was blocked by treatment of these cells with a pharmacological inhibitor of Jak2, a tyrosine kinase upstream of Stat5. Additionally, T47D cells transfected with PTHrP showed higher levels of pStat5, suggesting that PTHrP could activate Stat5 signaling regardless of the cell type. We show that PTHrP overexpression results in Stat5 activation and increased proliferation in breast cancer cells in a cell-autonomous fashion and independent of its receptor.
Title: Prognostic value of androgen receptor and FOXA1 co-expression in non-metastatic triple-negative breast cancer

Body: Background
Androgen receptor (AR) is expressed in 8-53% of triple negative breast cancer (TNBC). Its prognostic value in this subgroup is controverted. FOXA1 is essential for expression of 50% of estrogen receptor (ER)–related genes. Microarray studies identified the subgroup of molecular apocrine or luminal androgen receptor tumors that express AR and luminal genes including FOXA1 but nor ER. Preclinical data suggested that FOXA1 may direct AR to sites normally occupied by ER in luminal tumors, inducing an estrogen-like gene program stimulating proliferation. We have already shown that TNBC with AR/FOXA1 co-expression seem to behave like luminal tumors.

We aimed at evaluating co-expression AR/FOXA1-associated profiles and its prognostic value in a large retrospective series of patients with non-metastatic TNBC with a long follow-up.

Patients and methods
AR and FOXA1 expression were evaluated by immunohistochemistry in tissue microarrays of 300 patients with non-metastatic TNBC treated in our center between 2002 and 2012. Positivity threshold was set at ≥10% staining.

Results
Median age was 57.7 years (range 28.5-98). 46.2% of tumors were classified T1 and 64% pN0. We found 83.2% of ductal carcinomas, 5% of lobular carcinomas and 11.8% of other histological types. SBR grade 1-2 represented 21.4%. A basal-like phenotype (cytokeratins 5/6 and/or EGFR+) was observed in 63.7% of cases. In 161 evaluable patients, a PIK3CA mutation (exon 9 or 20) was observed in 16.2% of cases. In 124 evaluable patients, a deletion of PTEN was observed in 25% of cases. Adjuvant chemotherapy was delivered in 74.5% of patients.

37.7% of patients had AR+ tumors and 29.7% had AR+ and FOXA1+ tumors. AR+/FOXA1+ tumors were more frequently: found in older patients (p<0.001), lobular (p<0.001) and of lower nuclear grade (p<0.001) than others TNBC. AR+/FOXA1+ tumors exhibited less frequently basal-like phenotype (45.8%) than AR+/FOXA1- (77.3%) and AR-/FOXA1- (70.1%) tumors (p<0.001). AR+/FOXA1+ tumors exhibited more frequently PIK3CA mutations (35.8%) than AR+/FOXA1- (16.7%) and AR-/FOXA1- (5.9%) tumors (p<0.001). AR+/FOXA1+ tumors exhibited less frequently PTEN deletion (6.8% vs 16.7% for AR+/FOXA1- vs 36.5% for AR-/FOXA1- tumors, respectively, p=0.001).

With a median follow-up of 5.5 years, recurrence-free survival (RFS) was significantly lower for patients with AR+/FOXA1+ tumors (p=0.046). 3-years RFS were 84.2% and 85.3% for AR+/FOXA1+ and the others TNBC, respectively. 5-years RFS were 67.4% and 79.4% for AR+/FOXA1+ and the others TNBC, respectively. Tumor size, nodal status and adjuvant chemotherapy were also statistically correlated to RFS. Tumor size, nodal status, histology and adjuvant chemotherapy were significantly associated with overall survival.

Conclusions
In this large series, almost 30% of TNBC had an AR/FOXA1 co-expression with distinct clinicopathological characteristics and a worse outcome than others TNBC with higher risk of late recurrences. These biomarkers could be useful to identify a subgroup of TNBC and could have therapeutic implications: anti-androgen are under investigation, FOXA1 could be another therapeutic target and PI3K inhibitors should be evaluated in this specific subgroup, alone or in association with anti-androgens.
Title: Flutamide reduced tumor progression and altered steroid hormone secretion in human and canine inflammatory breast cancer cell lines

Body: Background: Inflammatory breast carcinoma (IBC) is a special type of breast cancer with a poor survival rate and accounts for 6% of diagnosed breast cancers. The role of androgens on breast cancer is on rise in research, trying to propose anti-androgen therapeutic strategies. The aim of this study was to determine the effects in vivo and in vitro of flutamide (anti-androgen drug) on cell proliferation, tumor progression and steroid production in two cancer IBC triple negative cell lines (SUM-149 and IPC-366, human and canine, respectively). Material and Methods: IPC-366 was cultured in Dulbecco's modified Eagle medium nutrient mixture F-12 Ham (DMEM/F12) and SUM149 was maintained in Ham's F-12 media. Flutamide concentrations added to the culture media were: 5 µM, 10 µM, and 15 µM for 72 hours. Additionally, IPC-366 and SUM149 xenotrasplanted mice were used for in vivo assays with the same flutamide concentrations administrated subcutaneously. Steroid hormones determination in culture media and tumor homogenates (pregnenolone (P5), progesterone (P4), dihydroepiandrostenedione (DHEA), androstenedione (A4), testosterone (T), dihydritestosterone (DHT), 17β-estradiol (E2) and estrone sulphate (SO4E1)) were assayed by EIA previously validated. Immunohistochemical (IHC) analysis of the steroidogenic enzymes CYP11A1, 3β-HSD, CYP19A1, 17β-HSD and 5α-reductase were assayed. Results: Percentage of cell proliferation showed a decrease in all treatments in IPC-366 and SUM149. In vivo tumor progression was reduced in around 65% in IPC-366 and SUM149 xenotrasplanted mice. Regarding hormonal secretion assayed in pellets and homogenates, in treated groups there was an increased in steroid secretion as showed the high levels found in P5, P4 and A4. T and DHT concentrations were higher in treated groups, in contrast to E2 levels that decreased. 17β-HSD and 5α-reductase by IHC showed a high expression in treated groups. Conclusion: IPC-366 and SUM149 treated with flutamide reduced the proliferation of neoplastic cells, reduced tumor progression in xenotrasplanted mice and altered steroid hormone secretion by increasing T production and decreasing in E2 levels. These results open a future approach for IBC and triple negative breast cancer.
Title: Steroid receptors and steroidogenic enzymes in human breast cancer: Associations with breast cancer subtypes and clinical outcome

McNamara KM M, Guestini F, Sauer T, Lindstrøm JC C, Sasano H and Geisler J. Tohoku University, School of Graduate Medicine; Akershus University Hospital (AHUS); Oncology (AHUS); University of Oslo, Institute of Clinical Medicine and Helse Sør-Øst Health Services Research Centre (AHUS).

Body: Introduction: The majority of breast cancer (BC) cases are believed to be highly steroid dependent. Therefore exploitation of currently untapped steroid pathways could potentially contribute to our search for novel targeted breast cancer therapies. Given the growing understanding of the importance of both intratumoral steroid metabolism and impact of alternate steroid receptors in BC biology, we evaluated selected steroidogenic pathways in a cohort of 140 BC cases from Akershus University Hospital, Norway. In this study we immunolocalized both the androgen receptor (AR) and glucocorticoid receptor (GR) in addition to steroid sulfatase (STS) and 17β hydroxysteroid dehydrogenase 2 (17βHSD2). We also evaluated immunoreactivity of Ki-67 and CYP19/aromatase. We correlated these factors with the occurrence of distant metastasis or local relapse, and survival adjusted by age at surgery. We also examined whether any of these pathways were enriched in the classical breast cancer subtypes (Luminal A, Luminal B, HER-2 positive, triple-negative BC). Logistic and Cox regression analysis was employed to examine interactions between the above factors.

Results: In an analysis looking at possible interactions between recurrence and the factors above, the status of intratumoral STS was significantly inversely associated with distant metastasis (OR=0.17, p<0.001) and local relapses (OR=0.17, p<0.001), while that of 17βHSD2 trended towards correlation with the presence of metastasis (OR=3.47, p=0.055) and relapse (OR=3.14, p=0.07). Interestingly, ER and PR were not correlated with metastasis or relapse, but HER2 status positively correlated with distant metastasis during follow-up (OR=2.15, p=0.02) and trended to be associated with local relapses as well (OR=1.99, p=0.054). When evaluated according to the established breast cancer subtypes the only significant changes detected between subgroups were for AR and STS. AR was positive in a lesser proportion of the cases in the TNBC subgrouping (p=0.01), while STS was depleted in the luminal B and enriched in the HER2 subtypes (p=0.027). In an analysis of survival, STS was the only factor examined that was significantly associated with survival outcomes of the patients. Positive intratumoral STS status was significantly associated with improved survival (HR=0.27, p<0.001). The inverse of this was also noticed for 17βHSD2 but the correlation did not reach statistical significance (HR=2.1, p=0.16).

Discussion and Conclusions: The results of our present study suggest that the intratumoral metabolism of estrogens through STS is associated with significantly lower incidence of relapse and/or distant metastasis and correspondingly a better prognosis. The inverse is also true when evaluating the trends noted with the expression of 17βHSD2 adding consistency to our finding above. The enrichment of STS in the HER2 overexpressing subtype of breast cancer is intriguing, especially given the possible role of HER-2 positivity in endocrine resistance. All in all, our results suggest that extended endocrine information about the intratumoral steroid metabolism of a given tumour may have so far unused prognostic potential and impact on clinical decision making.
Glucocorticoid receptor modulation affects ER+ breast cancer cell proliferation

Tonsing-Carter E, Bowie KR R, West DC C, Harkless RV V, Hernandez KM M and Conzen SD D. The University of Chicago, Chicago, IL; Center for Research Informatics, The University of Chicago, Chicago, IL and The University of Chicago, Chicago, IL.

Early-stage ER+ breast cancer with high tumor glucocorticoid receptor (GR) expression is associated with improved long term relapse-free survival compared to tumors with low GR expression. In addition, activation of GR inhibits estradiol-mediated ER+ BC cell proliferation. This finding led us to hypothesize that GR and ER engage in nuclear receptor cross-talk to affect pro-proliferative gene expression, thus contributing to a better outcome in ER+/GR+ BC patients. To better understand the mechanisms by which ER/GR co-activation contributes to this more indolent phenotype, we performed ChIP-sequencing and gene expression analyses in ER+/GR+ BC cell lines (MCF-7 and T47D).

We found that co-activation of ER and GR led to decreased ER+ BC cell proliferation in vitro. Furthermore, following co-activation of ER/GR, there was decreased gene expression of key cell cycle genes (e.g. CDK6, CDK2 and CCNE1) compared to ER-activation alone. Studies are underway to determine if this decrease in gene expression is associated with less CDK activity as well as a slowing of cell cycle progression.

We also wanted to know if GR activation with a pure agonist versus a mixed GR modulator was required for decreasing ER-mediated cell proliferation. Based on our previous work (DC West et al. MCR 2016), we hypothesized that ligand-mediated GR activation could be working by preventing access of ER to regulatory regions of pro-proliferative genes rather than causing direct GR agonist-mediated gene expression. To examine this question, we used a GR modulator, mifepristone (expected to alter ER-mediated gene expression indirectly). Indeed we found that a GR modulator also reduced ER-mediated cell proliferation. We are currently testing the mechanisms by which GR modulators affect estradiol-mediated cell cycle gene expression.

Taken together, these studies suggest that modulation of GR activity could be an effective approach to decrease ER+ tumor cell proliferation. Xenograft studies are underway to examine whether the addition of GR modulation to tamoxifen will improve tumor shrinkage compared to tamoxifen alone.
Body: Introduction

In metastatic breast cancer (MBC), discordant expression levels of the human epidermal growth factor receptor 2 (HER2) have been noted between primary tumors (PT) and matched metastatic lesions. Reassessment of HER2 status during treatment decisions in patients with advanced disease might help to optimize outcome. Circulating tumor cells (CTCs) offer the potential to provide a repeatedly accessible source of tumor cells for the real-time assessment of actual tumor characteristics. However, little is known on the concordance of HER2 expression on CTCs measured by immunofluorescence and the amplification status. Here we report on a preclinical study, using five spiked breast cancer cell lines, comparing semi-quantitative HER2 scoring on CellSearch (Riethdorf 2010) with objective DEPArray analysis, and subsequent FISH analysis on DEPArray-sorted tumor cells. At the moment these data are also being generated for 10 patient CTC samples. Expression and amplification status of CTCs will be compared with primary tumor tissue.

Materials and methods

MDA-MB-436, MCF-7, BT-20, KPL-4, and SKBR3 cells (increasing HER2 status) were spiked into donor blood and subjected to CellSearch enrichment. HER2/FITC intensity was scored manually on the CellSearch analyzer. All cell lines were injected into the DEPArray and exposure settings were optimized (FITC: exposure time 800 ms, gain 5%). These settings are further used for all preclinical and clinical samples. HER2 scoring was based on relative fluorescent units (rfu) of the HER2/FITC signal with background subtraction. Cells were sorted into pure batches of HER2 positive (DAPI+/CK+/HER2+/CD45-) and negative (DAPI+/CK+/HER2-/CD45-) tumor cells. Cytospins were formalin fixed and subjected to DAKO IQFISH.

Results

HER2 expression on CellSearch turned out to be very heterogeneous within the same cell line. DEPArray data was highly reproducible for all cell lines (p<0.001) and also showed a broad range of FITC rfu within the HER2 positive cell lines. Significant differences were observed between every cell line (p<0.001). The SKBR3 cell line sample also harbored a minor population of HER2- cells while this was the most positive cell line. However with FISH analysis, both HER2- and HER2+ SKBR3 cells were highly amplified (absolute HER2 count of 12-20 and HER2/CEN17 ratio of >4). MDA-MB-436 and MCF-7 cells showed no gene amplification on FISH, while in KPL-4 there was a HER2/CEN17 ratio of >2.

Four patient samples with HER2 positive status on CellSearch have been run on the DEPArray. For patient 1, 1005 CTC were analyzed, 32.4% were HER2+. This was 53 (69.8% HER2+), 352 (5.7% HER2+), and 622 (6.7% HER2+) for patient 2-4 respectively. These numbers are comparable with CellSearch analysis.

Discussion

HER2 expression analysis by immunofluorescence is comparable between CellSearch and DEPArray, however DEPArray has the advantage that it is user-independent and highly reproducible. Furthermore, CTCs can be sorted into pure batches for downstream analysis. The FISH technique on DEPArray sorted cells is now optimized and will be used to determine the correlation between the immunofluorescent HER2 scoring and the actual amplification status of the CTCs. These data will be incorporated prior to upcoming SABCS.
Clinical outcomes of estrogen-receptor negative breast carcinoma are associated with protein hormone-cognate receptor gene expression

Daniels MW W, Wittliff JL L and Brock GN N. University of Louisville, Louisville, KY.

Background: Since certain protein hormones appear to be associated with progression of breast cancer cells \textit{in vitro}, we employed a global approach by evaluating relationships between genes for these hormones and their cognate receptors in human breast cancer biopsies as independent predictors of risk of recurrence. Our goal is to derive clinically relevant molecular signatures correlating various ER/PR subtypes.

Methods: Microarray analyses of LCM-procured carcinoma cells from 247 de-identified biopsies determined expression of genes for 61 protein hormones (the ligands) and 81 cognate receptors. Total RNA was extracted, purified and amplified from cells to determine expression of 22,000 genes. Univariable and multivariable Cox regressions were determined using expression levels of each hormone/receptor gene. Kaplan-Meier plots were constructed with an adjusted p-value <0.30 (discovery cutoff) for each gene candidates with/without ER status of the lesion. Cox regression analyses with/without interaction models deciphered candidates of hormone-receptor complexes that predicted risk of recurrence as well as overall survival using clinical follow-up that extended as much as 12 years. LASSO was used to derive gene subsets to predict overall survival (OS) and progression free survival (PFS) within ER/PR subtypes.

Results: Expression levels of 7 genes for protein hormones and 10 receptor genes were significant for OS at an adjusted p-value of <0.30 while expression of 15 hormone and 19 receptor genes were significant for PFS without regard to ER/PR subtypes. When expression levels were considered with ER status only, 3 genes for ER+ lesions and 6 genes for ER- lesions were identified that predicted OS/PFS. Categorization of cancers according to combined ER and PR status revealed one gene for ER+/PR+, 3 genes for ER+/PR- and 2 genes for ER-/PR- associated with PFS/OS. After stratifying gene expression into above/below median for the linear predictor, Kaplan-Meier plots revealed patient groups with each signature for ER+/PR+, ER-/PR- and ER- lesions that exhibited significantly different survival. Molecular signatures comprising 16 genes for ER+/PR+ carcinomas, 10 genes for ER-/PR- lesions and 6 genes for ER- carcinomas predicted clinical outcomes with C-indices of 0.79, 0.76 and 0.71, respectively.

Conclusion: We revealed many breast carcinomas synthesize mRNA species for various protein hormones and their cognate receptors by determining gene expression \textit{directly} on pure populations of these cells procured by LCM. We report a novel ten-gene ER-/PR- signature containing four genes in common with that of a six-gene ER- only signature that predicts breast cancer recurrence. Collectively, results of mRNA expression suggest that often breast carcinomas exhibit substantial elements of endocrine autonomy for regulating progression, warranting investigation of protein products of gene candidates in isolated populations of breast carcinoma cells.
Title: Therapeutic targeting of RAGE in the tumor and tumor microenvironment inhibits breast progression and metastasis

Body: Background: The Receptor for Advanced-Glycation End-products (RAGE) is highly expressed in various cancers and its expression is correlated with poorer outcomes in breast cancer. We have previously implicated RAGE in breast cancer, but whether RAGE drives breast cancer progression and metastasis either through tumor cell intrinsic effects, non-tumor cells of the tumor microenvironment, or both, is not fully understood. More importantly, studies are lacking that target RAGE therapeutically in cancer, and may therefore represent a novel treatment for breast cancer metastasis.

Methods: Using multiple human and murine breast cancer models we dissected the tumor intrinsic versus tumor microenvironment role of RAGE in metastasis. RAGE was targeted in tumor cells using multiple shRNAs, in non-tumor cells by global gene knockout in mice, and both by therapeutically targeting with the novel RAGE inhibitor FPS-ZM1. In vivo orthotopic models included the NSG (NOD-SCID-gamma) xenograft mouse model (with MDA-MB-231 cells; herein 231), BALBc (4T-1 and 67NR), and C57BL6 wild-type and RAGE knockout (RAGE -/-) mice (with MMTV-PyMT spontaneous breast cancer derived AT-3 cells).

Results: We first tested how RAGE impacts tumor cell intrinsic mechanisms using either RAGE shRNAs or FPS-ZM1 in 231, 4175 (231 isogenic highly metastatic cells) and 4T-1 cells. RAGE shRNA and FPS-ZM1 both decreased RAGE MAP-kinase signaling, transwell invasion and soft agar colony formation, without affecting proliferation. In vivo, RAGE shRNA knockdown in 231 cells did not affect tumor growth, but inhibited metastasis to lung and liver. RAGE shRNA knockdown in 4175 cells, decreased orthotopic tumor growth, and reduced tumor angiogenesis and tumor recruitment of leukocyte / macrophages. Furthermore, RAGE shRNA knockdown dramatically decreased metastasis of 4175 cells to lung and liver in a time and sized matched manner compared to shRNA controls. Similarly, RAGE knockdown in 4T-1 cells reduced cell invasion and colony formation, and inhibited lung metastasis from the orthotopic site in BALBc immunocompetent mice.

To test the non-tumor cell microenvironment role of RAGE, we performed syngeneic studies with orthotopically injected AT-3 cells in RAGE +/- and RAGE -/- C57BL6 mice. RAGE -/- mice displayed striking impairment of tumor cell growth compared to RAGE +/- mice, along with decreased MAP-kinase signaling, tumor angiogenesis and inflammatory cell recruitment.

Finally, to test the combined inhibition of RAGE in both tumor cell intrinsic and non-tumor cells of the microenvironment, we performed in vivo treatment of 4175 tumors with FPS-ZM1 (1mg/kg, twice per week). Compared to vehicle, FPS-ZM1 inhibited primary tumor growth, inhibited tumor angiogenesis and inflammatory cell recruitment, and most importantly prevented metastasis to lung and liver.

Conclusion: These data clearly demonstrate a role for RAGE in breast cancer progression and metastasis through distinct effects in the tumor cell and non-tumor cells of the tumor microenvironment. Furthermore, our data from drug inhibitor studies highlight the combined targeting of RAGE in the tumor and tumor microenvironment, and as a viable therapeutic means for breast and other metastatic cancers.

Title: ONC201 kills breast cancer cells by inhibiting mitochondrial respiration

Greer YE E, Gilbert SF F, Islam C, Ji Y, Gattinoni L, Stuelten C, Voeller D and Lipkowitz S. Women's Malignancies Branch, Center for Cancer Research, National Cancer Institute, Bethesda, MD; Experimental Transplantation and Immunology Branch, Center for Cancer Research, National Cancer Institute, Bethesda, MD and Laboratory of Cellular and Molecular Biology, Center for Cancer Research, National Cancer Institute, Bethesda, MD.

Body: Background: ONC201 is a small molecule originally identified as a TRAIL inducing compound (Allen et al., Sci. Trans. Med 2013). Two recent studies reported that ONC201 also induces an atypical stress response mediated in part by ATF4 and CHOP (Klein et al., Sci. Signal 2016 and Ishizawa et al., Sci. Signal 2016). ONC201 is currently being tested in phase1/2 clinical trials in multiple cancer types. In this study, we tested the effects of ONC201 on human breast cancer cells.

Methods: We tested ONC201 in 18 human breast cancer cell lines that represent ER+, HER2 amplified, TNBC basal A and TNBC basal B breast cancer. Cell death was analyzed by MTS assay after 5 days of treatment. Cells were treated with GST-TRAIL in parallel for comparison. Z-VAD-FMK was used as a pan-caspase inhibitor. To verify the mechanism of action of ONC201, siRNA against death receptors (DR) 4 and 5 were transfected to cells and tested in MTS assay and Western blotting. Seahorse XF analyzer and live cell imaging were used to further characterize the effect of ONC201.

Results: ONC201 reduced cell viability in breast cancer cell lines in all subtypes tested with IC50s ranging from 0.8-5 uM, similar to what has been reported for other cancer cell types. Unexpectedly, ONC201 did not induce caspase 3 or PARP cleavage, and its toxicity was not inhibited by Z-VAD-FMK, nor by siRNA knockdown of DR4 or DR5. By contrast GST-TRAIL induced caspase 3 and PARP cleavage and GST-TRAIL-induced cell death was inhibited by Z-VAD-FMK and by siRNA knockdown of DR5. Live cell imaging revealed ONC201 induces cell membrane ballooning followed by rupture, whereas GST-TRAIL induced classic apoptosis morphology. Together these results suggest that ONC201 kills breast cancer cells via a caspase-independent, DR4/5-independent mechanism distinct from TRAIL-induced apoptosis. Western blots revealed that ONC201 induces ATF4 and CHOP, consistent with the recently published observations. ONC201 also induced phosphorylation of AMP-dependent kinase (AMPK) in multiple breast cancer cell lines, suggesting that cellular ATP level is decreased by ONC201. ATP depletion by ONC201 was confirmed by direct measurement of cellular ATP. Seahorse XF analysis found that ONC201 inhibited mitochondrial oxygen consumption rate (OCR) but did not inhibit glycolysis as measured by the extracellular acidification rate. Long exposure to ONC201 significantly attenuated OCR, while acute treatment did not inhibit OCR. These data suggest that ONC201 inhibits mitochondrial oxidative phosphorylation via an indirect mechanism. Western blots demonstrated that ONC201 decreases expression of multiple mitochondrial proteins involved in oxidative phosphorylation. Both ONC201-induced toxicity and ATP depletion were enhanced when cells were cultured in non-glucose (galactose) medium. This is consistent with ONC201-induced inhibition of mitochondrial respiration. Supplementing glucose to cells grown in galactose medium partially rescued ONC201-dependent ATP depletion and cell death, and reversed ONC201-induced phospho-eIF2, ATF4 and CHOP induction.

Conclusion: Together, these data demonstrate that ONC201 can kill breast cancer cells by a novel mechanism involving inhibition of mitochondrial respiration.
Title: The short term effects of an AKT inhibitor (AZD5363) on biomarkers of the AKT pathway and anti-tumour activity in a breast cancer paired biopsy study (STAKT trial)

Roberston JFR FR, Cheung KL, Ahmed S, Coleman RE, Evans A, Holcombe C, Rea D, Rauchhaus P, Skene A, Littleford R, Jahan A, Kelly S, Lindermann JPO PO, Horgan K, Foxley A, Rugman P and Pass M. University of Nottingham, Nottingham, United Kingdom; University of Dundee, Dundee, United Kingdom; University of Sheffield, Sheffield, United Kingdom; Royal Liverpool University Hospital Liverpool, United Kingdom; King's Mill Hospital, Nottingham, United Kingdom; Leeds General Infirmary, Leeds, United Kingdom; Weston Park Hospital, Sheffield, United Kingdom; Leicester Royal Infirmary, Leicester, United Kingdom; Royal Bournemouth & Christchurch NHS Foundation, Bournemouth, United Kingdom; Poole Hospital NHS Foundation Trust, Poole, United Kingdom; Royal Derby Hospital, Derby, United Kingdom; University of Birmingham, Birmingham, United Kingdom; Derriford Hospital, Plymouth, United Kingdom and AstraZeneca, Melbourn, United Kingdom.

Body: Background: AKT is an important intracellular control point through which Type 1 growth factors (HER family) and IGFR signalling from the membrane exert their influence on tumours, including estrogen receptor positive (ER+) breast cancer. Mutations in PIK3CA, AKT and PTEN are prevalent in breast cancer and can directly impact on AKT signalling. AKT has also been implicated in resistance to signal transduction inhibitors, including endocrine therapies. AZD5363 is an inhibitor of AKT 1, 2 and 3 which is in Phase 2 trials for breast and other cancers.

Design: The study was designed to address the extent to which AZD5363 impacts key biomarkers on the AKT pathway, and the degree to which those impacts translate to effects on markers of anti-tumour efficacy (Ki67) in ER+ breast cancer. STAKT is a multicentre, two-stage, double blind, randomised, placebo controlled, biomarker window trial conducted in women with ER+ breast cancer. Stage 1 assessed the effect of AZD5363 at a dose of 480mg bd p.o. versus matching placebo. Up to 30 patients per arm were allowed in order to reach 24 evaluable patients (12 per study arm) with assessable paired biopsies. Tumour biopsies were obtained at baseline, and following 4.5 days of AZD5363 / placebo exposure. The primary endpoint markers were pPRAS40, pGSK3b and Ki67. Biomarker assessment was performed by immunohistochemistry by laboratory staff blinded to treatment arm and also whether the biopsy was from baseline of post AZD5363/placebo. PK sampling was performed during the study period.

Stage 2 is ongoing with the focus on the biomarker effects of lower doses of AZD5363.

Results:
35 patients were recruited to Stage 1 with 24 patients established as evaluable. Patient characteristics and demographics are shown in Table (to be updated prior to abstract review).
Un-blinded data from Stage 1 will show the changes in each of the primary endpoints (pPRAS40, pGSK3b and Ki67) for AZD5363 480 bd mg versus placebo, the pharmacokinetics and the adverse event profile of AZD5363.

Conclusions
This study will report short-term biomarker and pharmacokinetic data with AZD5363 in women with early breast cancer.
Modification and reversal of the aggressive behavior of triple negative breast cancer by caffeic acid phenethyl ester (CAPE)

Omene C, Patel M, Illa Bochaca I and Barcellos-Hoff MH. NYU Langone Medical Center, NYU School of Medicine, New York, NY and University of California, San Francisco, San Francisco, CA.

CAPE is the major active component of propolis, a widely available, safe, honeybee natural product with anti-inflammatory, antioxidant, and antitumor properties. We have previously shown diverse effects of CAPE in breast cancer. We postulated that CAPE may be useful in chemoprevention for women at high risk for triple-negative breast cancers (TNBC) and evaluated this in a radiation chimera mouse model in which the tumor spectrum is shifted to TNBC.

The radiation chimera model consists of surgically clearing the mammary epithelium from the inguinal glands of 3-week old BALB/c mice, the mice were irradiated with 1 Gy or sham irradiated at 10–12 weeks of age, and bilaterally transplanted 3 days later with syngeneic Trp53 null mammary fragments. Mice were placed on a CAPE diet or a control diet at 1 month post transplantation that was maintained for the course of the experiment. Mammary tumor development was monitored by palpation for up to 18 months. The first tumor was resected at 1 cm³ and mice monitored for tumor recurrence or second tumor formation. Tumors were immunostained for estrogen receptor (ER) status and ER negative tumors were selected from all the groups for RNA sequencing.

No difference in body weight or tumor incidence was observed between mice on the CAPE versus control diet. Host irradiation significantly accelerated tumor growth rate compared to the control sham irradiated mice. CAPE treatment blocked this effect, but did not affect the control tumor growth rate. Resected tumors in CAPE treated mice recurred at significantly longer intervals (average of 40 days in the control group versus 90 days with CAPE treatment) and much less frequently than tumors from mice on a control diet. Mean expression analysis showed that CAPE induces a distinct gene expression pattern in ER negative tumors from irradiated mice. As previously described, the transcriptional profile of ER negative tumors was enriched in immune response genes in tumors from nonirradiated mice on a control diet, while irradiation suppresses these genes. Interestingly, this difference was abrogated in mice on the CAPE diet where we found that CAPE reverses the suppression of immune response genes in the ER negative tumors from the irradiated mice.

These findings support the potential use of CAPE to modify the aggressive behavior of TNBC. This may be due to effects on the immune system in which CAPE acts to re-establish anti tumor immunity. Thus, CAPE may be useful in chemoprevention both for women at high risk for TNBC and to prevent or delay TNBC breast cancer recurrence.
Title: Receptor-mediated binding of HER2-targeted antibody-liposomal doxorubicin conjugate MM-302 increases liposome binding, nuclear doxorubicin, DNA damage and efficacy relative to untargeted PEGylated liposomal doxorubicin (PLD/Doxil)

Body: Background: Liposomal encapsulation of doxorubicin increases drug payload, extends circulation time (PK/PD) resulting in increased tumor accumulation and reduces systemic toxicity, notably cardiotoxicity. Once in the tumor microenvironment, targeting moieties provide a means to enhance liposome uptake by tumor cells overexpressing the desired target. MM-302 is a HER2-targeted antibody–liposomal doxorubicin conjugate designed to specifically deliver doxorubicin to HER2-expressing tumor cells. HER2 overexpression (“HER2-positive”) is detected in 20-25% of breast cancer tumors and associated with a particularly aggressive subtype of the disease. MM-302 demonstrated an acceptable safety profile and promising activity in a Phase I study in HER2-positive metastatic breast cancer (NCT01304797) and is now being evaluated in a Phase II trial in the same setting (NCT02213744).

Methods: A panel of cell lines representing a range of HER2 levels from “0” to “3+” were treated in vitro with MM-302 or untargeted PLD. Bound liposome, nuclear doxorubicin, DNA damage response (γH2AX, p-p53, CHK2), apoptosis (cl. CASP3 and cl. PARP), secreted cytokines and cell viability were evaluated with a combination of high throughput microscopy, Meso Scale Discovery (MSD) assay, ELISA and CTG assay. In vivo, single cell HER2 levels were determined by IHC for multiple human xenograft models. Additionally, xenograft tumors treated with MM-302 or PLD were dissociated and single cell binding of liposome was evaluated by FACS while p-p53, p-CHK2 and cytokine levels were tested by MSD/ELISA. Changes in tumor volume of BT474-M3 and SUM-190 breast cancer xenografts treated with MM-302 or PLD were determined.

Results: Cells expressing ~150K to 2 million HER2 receptors/cell demonstrated preferential binding of MM-302 and subsequent accumulation of nuclear doxorubicin, relative to PLD. Increased DNA Damage Response (γH2AX, p-p53, p-CHK2), apoptosis (cleaved PARP, cleaved Caspase 3) and cell death correlated with bound MM-302 in vitro. Levels of the secreted cytokines IL-6 and IL-8 were associated with bound MM-302, but not PLD. In vivo, cell-bound MM-302 and DNA-damage response (p-p53/p-CHK2) increased with HER2 level while bound PLD was consistently low, regardless of HER2. MM-302 significantly reduced BT474-M3 and SUM-190 tumor volume relative to PLD.

Conclusions: MM-302 was bound by all cell lines expressing HER2 to a significantly greater extent than PLD, with resultant delivery of doxorubicin to nucleus, DNA-damage, and ultimately cell death. The benefit of HER2-targeting by MM-302 is also evident in vivo at the single-cell level and manifests itself in greater tumor reduction.
Title: Development of iNPG-pDox for metastatic breast cancer treatment

Ferrari M, Xu R, Zhang G, Mai J and Shen H. Houston Methodist Research Institute, Houston, TX and Huazhong University of Science and Technology, Wuhan, China.

Body: Metastatic triple negative breast cancers have traditionally been treated with chemotherapy. However, these drugs have narrow therapeutic windows due to low drug accumulation in the tumor tissue, poor pharmacokinetic profile, and severe toxicity to the normal tissues. Repeated treatments at sub-optimal dosages are counter-effective and too often lead to therapy resistance. We have developed an injectable nanoparticle generator (iNPG) that overcomes multiple biological barriers to cancer drug delivery (Xu et al. Nature Biotechnology 2016; 34: 414-418). The iNPG is a discoidal micrometer-size particle that can be loaded with chemotherapeutics. We conjugated doxorubicin to poly(L-glutamic acid) via a pH-sensitive cleavable linker, and load the polymeric drug (pDox) into iNPG to assemble iNPG-pDox. Once released from iNPG, pDox aggregates spontaneously into nanoparticles in an aqueous solution. The intravenously injected iNPG-pDox accumulates at tumors and releases pDox nanoparticles that are internalized by tumor cells. Inside the cell, pDox nanoparticles are transported to the perinuclear region and cleaved into Dox, thereby avoiding excretion by drug efflux pumps. We compared therapeutic efficacy between iNPG-pDox and the current clinic anthracycline drugs in mouse models of metastatic MDA-MB-231 and 4T1 tumors. While the current drugs offered marginal survival benefit, treatment with an equivalent dosage (normalized based on doxorubicin content) of iNPG-pDox significantly extended animal survival, including long-term survival in 40% of the 4T1 tumor mice and 50% of the MDA-MB-231 tumor mice. This result demonstrates the power of incorporating concurrent actions in drug design including drug enrichment in the tumor tissue, in situ reconstitution of drug nanoparticle, vesicular transport to circumvent the efflux pumps, and pH-dependent drug release.
Combination of doxorubicin with S1P signaling modulator FTY720 significantly suppressed obesity-associated breast cancer

Katsuta E and Takabe K. Breast Surgery, Roswell Park Cancer Institute, Buffalo, NY.

Body: Background:
Obesity is one of the biggest health issues in the US. It has been shown that obesity-associated breast cancer is more aggressive with poor prognosis, which is partly explained by the low-grade inflammation caused by obesity. Recently we have published that sphingosine-1-phosphate (S1P), a signaling lipid mediator, link inflammation and cancer in colitis-associated colon cancer model. We hypothesized that addition of S1P modulator that block S1P signaling thus suppress the effect of obesity-mediated inflammation should enhance anti-cancer effect of doxorubicin, which is a typical anti-cancer drug for breast cancer used as a standard of care.

Methods:
Female B6.cg-Lepob (OB/OB) mice fed with high fat diet for 2 weeks prior to implantation of cancer cells were used as an obesity model, and litter mate control mice fed with normal diet were used as a control. 1 x 10^6 murine mammary adenocarcinoma E0771 cells were inoculated into #2 rt. fat pads as previously described (Katsuta et al JSR 2016). 9 days after inoculation, both OB/OB and control mice were randomized into 4 groups in each group; vehicle, Doxorubicin, FTY720 and Combination of Doxorubicin and FTY720. Doxorubicin was administrated by i.p. injection at a dose of 5 mg/kg on Day 0 and 3. FTY720 was administered everyday by gavage at a dose of 1 mg/kg during the entire course. Tumor growths were measured daily by caliper measurements. Tumor weights were measured on 21 days after cell inoculation.

Results:
The body weight of obesity model was significantly heavier than control mice at the time of cancer cell inoculation (44.1 g vs 19.4 g; p < 0.001). In non-treatment group, tumor weight in obesity group was significant heavier than control mice [KT1] (1232 mg vs 966 mg; p = 0.049), which is consistent with the dogma that obesity worsen cancer progression. As expected, tumor weight in non-treatment group is heavier than any treatment group, and that in combination treatment of doxorubicin and FTY720 is lightest in both of obesity group and control group. Interestingly, tumor reduction rate in obesity group compared with non-treatment group is significant greater than control group (Doxorubicin: 83% vs 19%, p = 0.001; FTY720: 80% vs 46%, p = 0.027, Doxorubicin + FTY720: 93% vs 64%, p = 0.011). Over 15% weight loss were seen in obesity doxorubicin group and obesity combination treatment group.

Conclusion:
Modification of S1P signaling by FTY720 was shown to enhance the effect of doxorubicin particularly in obese mice, which implicate a novel approach to treat obesity-associated breast cancer.
HDAC6 deacetylates HMGN2 to regulate Stat5a activity and breast cancer growth

Clevenger CV V, Craig JM M, Fiorillo AA A, Feeney YB B, Harrell JC Chuck and Medler TR R. Virginia Commonwealth University, Richmond, VA; George Washington University, Washington, DC; Northwestern University, Chicago, IL and Oregon Health Sciences University, Portland, OR.

Body: Stat5 is a transcription factor utilized by several cytokine/hormone receptor signaling pathways that promotes transcription of genes associated with proliferation, differentiation, and survival of cancer cells. However, there are currently no clinically approved therapies that target Stat5, despite ample evidence that it contributes to breast cancer pathogenesis. Previous research in our lab has shown that the high mobility group nucleosome binding domain 2 (HMGN2) protein serves as a Stat5 co-activator. The activity of HMGN2 has been previously shown to be regulated by acetylation. Here, we show that deacetylation of HMGN2 on lysine residue K2 by histone deacetylase 6 (HDAC6) promotes Stat5-mediated transcription and breast cancer growth. Conversely, in vitro HDAC6 inhibition by pharmacologic and knock-down approaches enhanced HMGN2 acetylation with a concomitant reduction of in vitro Stat5-mediated signaling and global gene expression, and breast cancer growth. In vitro and in vivo treatment of traditional and patient-derived xenograft models with HDAC6 inhibitors resulted in a highly significant reduction of tumor growth. Translationally, it was also found that high levels of acetylated K2 were present in normal human breast tissue, which was lost in primary breast cancers and lymph node metastases. This suggests that blockade of HMGN2 deacetylation as described above is a novel treatment for breast cancer, given that existing HDAC6 inhibitors have a favorable toxicity profile in Phase I trials of other tumor types. Altogether, these results reveal a novel mechanism through which HDAC6 regulates the transcription of Stat5 target genes and demonstrates the utility of HDAC6 inhibition as a potential breast cancer therapeutic.
Title: Selection of presumed CD49f antagonists and their biological evaluation in breast cancer cells

Velasco-Velázquez M, Velázquez-Quesada I, Aguirre-Alvarado C, Guerrero-Rodríguez S, Ruiz-Moreno A, Ramirez-Salinas G, Segura-Cabrera A and Pérez-Tapia M. School of Medicine, National Autonomous University of Mexico, Mexico City, Mexico; National Polytechnic Institute, Mexico City, Mexico; CONACYT, Mexico City, Mexico and Institute of Ecology AC, Xalapa, Veracruz, Mexico.

Body: Breast cancer is the second cause of cancer death in women and the large majority of those deaths are due to drug resistance and/or recurrence. The cancer stem cell (CSC) model suggests that tumor stem-like cells play key roles in resistance and recurrence in breast cancer patients. Thus, CSCs have been pointed as targets for new anti-cancer therapies. CD49f is an integrin subunit that participates in the CSC-niche interaction. Knock-down of CD49f in breast cancer cells impairs mammosphere formation in vitro and tumorigenesis in vivo, suggesting that this protein is needed for maintenance of stemness.

Aiming to target breast CSC, we used consensus docking to select potential CD49f antagonists from a collection of 13,000+ drugs with previous clinical evaluations. Seven compounds with the lowest consensus Z score were selected for in vitro biological validation. Cell adhesion assays showed that four of the selected drugs (5193, 1382, 7631, and 12723) decrease the binding of CD49f+ MDA-MB-231 breast cancer cells to laminin, suggesting that those compounds antagonize the receptor. Mammosphere formation assays showed that compounds 5193, 1382, and 12723 limit the clonogenic capability of CD49f+ breast cancer cells in vitro. Compound 5193 was highly toxic in 2D cell viability assays. On the other hand, the clonogenic impairment produced by compounds 1382 and 12723 is independent of bulk cell line cytotoxicity, suggesting a direct impact on the CSC pool. The analyses of the effect of these drugs on the expression of breast CSC markers and CD49f-activated pathways are on their way. Thus, we have identified some drugs that might be repurposed to target breast CSC. Since the pharmacokinetics and toxicology of those drugs is known, they could easily be ready for clinical trials. We demonstrated that in silico screening is useful to identify antagonists of receptors with relevant roles in breast CSC biology.

This work was supported by CONACYT 221105, PAPIIT-UNAM IN228616, and Red temática de células troncales y medicina regenerativa.
Title: Selinexor, a selective inhibitor of nuclear export, demonstrates efficacy in preclinical models of triple negative breast cancer

Body: Background: Approximately 15% of all breast cancers are categorized as triple negative (TNBC) for which the only chemotherapy is known to be effective, yet often fails to achieve remission. Nuclear exporter XPO1 (Exportin1 or CRM1) is a promising target for cancer therapy that mediates the transport of multiple tumor suppressors and cell cycle regulators that have been known to be relevant predictors in the mechanism and severity of TNBC. Given the pressing need for novel therapies for this disease, we sought to determine the antitumor effects of selinexor, a novel inhibitor of nuclear export, on triple negative breast cancers in vitro and in vivo as well as to address its mechanism of action.

Methods: 26 breast cancer cell lines of different breast cancer subtypes were treated with selinexor in vitro. Using cell proliferation assays the half maximal inhibitory concentration (IC$_{50}$) was calculated using isobologram curves after 3 days of treatment; sensitivity was defined as IC$_{50}$ <1000nM. We then assessed mechanistic effects on apoptosis and cell proliferation using flow cytometry analysis with annexin V and propidium iodide and using western blot analysis we also studied its effects on markers of inhibition of apoptosis. In vivo efficacy was studied as single agent and in combination with standard chemotherapy agents in TNBC patient derived xenografts (PDXs) with varying levels of sensitivity to chemotherapy as well as with varying statuses of TP53 and PIK3CA, and gene expression subtypes.

Results: Selinexor demonstrated growth inhibition in all fourteen TNBC cell lines tested; TNBC cell lines were more sensitive to selinexor (median IC$_{50}$ 44nM, range 11 - 550nM), compared to ER+ cells lines (median IC$_{50}$ of 13000 nM, range of 40nM - > 1000 nM; P=0.017). Treatment with selinexor decreased expression levels of XPO1, as well as survivin and XIAP, and induced apoptosis. In multiple TNBC cell lines selinexor was synergistic with paclitaxel, carboplatin, eribulin and doxorubicin in vitro (median combination index 0.6, range 0.5-0.8). Selinexor as a single agent reduced tumor growth in vivo in 4 of 5 different TNBC PDX models with a median tumor growth inhibition ratio score (T/C) of 48% (range 34-59%) and demonstrated greater antitumor efficacy in combination with paclitaxel or eribulin with an average T/C score of 27% and 12% respectively.

Conclusions: Selinexor is a promising therapeutic agent for triple negative breast cancer and it has potential as a combination agent with standard chemotherapy.
Title: Are we missing actionable targets in breast cancer? Novel insights into recurrent Ret alterations

Body: Background: Recurrent gene fusions in breast cancer have been rarely reported suggesting that they either are not present or are not easily detected by standard sequencing methods. Comprehensive genomic profiling (CGP) by hybrid capture-based, high depth next-generation sequencing approaches, can be used to detect recurrent rearrangements and other genomic alterations involving target genes. We found that CGP can identify recurrent alterations involving RET, a known oncogenic tyrosine receptor kinase, in a subset of breast cancer.

Methods: CGP using FoundationOne platform was performed interrogating the entire coding region for up to 315 cancer-related genes and introns of up to 28 genes involved in rearrangements at a depth of 500-1000X in formalin-fixed, paraffin embedded tumor tissue (Foundation Medicine, MA). Engineered representative RET fusion vectors were synthesized and expressed in non-tumorigenic cell lines (breast MCF10A and mouse 3T3 fibroblasts), and cells were evaluated for RET kinase signaling, drug response, and tumorigenicity. Patient-derived xenografts (PDX) generated from two triple negative breast cancers (TNBCs) were used in an ex vivo assay (Response3DX™, Molecular Response LLC, San Diego, CA).

Results: Twenty-two RET rearrangements were identified in 8119 (0.27%) breast cancer cases. Of these, 5 rearrangements were activating RET fusions including CCDC6-RET (n=4) and NCOA4-RET (n=1), that have been described in other cancer types. Five other cases had clear evidence of genomic rearrangement involving RET, but the 5’ partners could not be definitively identified. The remaining twelve cases had complex rearrangements of RET including internal duplications. RET amplification was also observed, both in TNBC and in a HER2+ breast cancer at onset of resistance to HER2-targeted therapy. Both NCOA4-RET and a novel RASGEF1A-RET fusion were characterized in vitro. Non-tumorigenic cells engineered to stably overexpress either RET fusions demonstrated transformed phenotypes. The fusions were constitutively active, as shown by endogenous phosphorylation of the kinase domain, and drove activation of downstream signaling as shown by increased phosphorylation of ERK and AKT. Cells transformed by RET-fusions were exquisitely sensitive to treatment with RET inhibitors. Interestingly, a PDX model of RET-amplified TNBC was sensitive to treatment with a PIK3CA inhibitor. An index case of ER+/PR-/HER2+, metastatic breast cancer that had radiographic evidence of disease progression while on trastuzumab, pertuzumab, and anastrazol was found to have a NCOA4-RET fusion by CGP. Subsequent treatment with with cabozantinib plus anarazol led a rapid clinical and radiographic response.

Conclusions: CGP can identify recurrent RET rearrangements in breast cancer that act as primary oncogenic drivers and can be therapeutically targeted. RET alterations may also play a role in acquired resistance to HER2-targeted therapies, suggesting a role for combined RET and HER2-targeted therapy in this setting. Our data demonstrate that RET alterations can be identified by clinical-grade CGP and are promising candidates as therapeutic targets in selected breast cancer patients.

Title: GPNMB activates EGFR to overcome Mek-inhibition: Implications for the development of rational targeted therapy combinations in triple negative breast cancer

Rose A, Annis M, Perkins D and Siegel P. McGill University, Faculty of Medicine, Montreal, QC, Canada and Goodman Cancer Research Center, Montreal, QC, Canada.

Body: Background:
TNBC is an aggressive subtype that constitutes ~15% of all BC. Currently there are no targeted therapies available for patients with. As such, there is much interest in developing targeted therapies for this disease.

Recently we identified GPNMB as a transmembrane protein that promotes breast tumor growth and metastasis. CDX-011 is an antibody drug conjugate that targets GPNMB, and has recently shown promising clinical activity in patients with GPNMB+TNBC. In subset analyses of the EMERGE trial, patients with high GPNMB expressing TNBC had a median OS of 10 vs. 5.5 months for CDX011 versus chemotherapy, respectively. Response rates to CDX011 correlated with degree of GPNMB expression.

These findings support the hypothesis that TNBC with high GPNMB will respond better to CDX011. As such, we sought to identify therapies with intrinsic activity against TNBC that would also induce GPNMB expression, in order to synergize with CDX-011.

We have recently shown that MAPK pathway inhibition induces GPNMB expression in melanoma. Therefore we sought to determine whether Mek inhibition (Mek-i) induced GPNMB in TNBC and the targeted therapies could synergize with CDX-011.

Results:
We interrogated the TCGA breast datasets to determine whether the MAPK pathway is more frequently altered in TNBC. Indeed, this pathway is altered in 94% of Basal compared to 60% LumA, 83% LumB, 73% Her2 subtypes. Furthermore, we show that a Mek-activation transcriptional signature is significantly higher in basal compared to Her2 or Luminal subtypes. Indeed, we show that Fra, a downstream target of activated Erk, is most highly expressed in BC cells of the basal subtype.

We used immunoblot and FACS analysis to assess GPNMB expression in response to Mek-i; trametinib and cobimetinib markedly induced GPNMB protein expression in 12 of the 14 TNBC cell lines tested. Moreover, we show that in the TCGA dataset, low expression of the Mek-activity signature correlates with higher GPNMB, specifically within the basal subtype, thus providing clinical corroboration for our in vitro observations. We go on to show that Mek-i mediated GPNMB up-regulation is regulated by TFE3.

We find that EGFR is upregulated in response to Mek inhibition in several TNBC cells. GPNMB heterodimerizes with EGFR in immunoprecipitation experiments. Using siRNA to knockdown GPNMB or ectopic GPNMB overexpression, we found that GPNMB is both necessary and sufficient for enhanced EGFR activation in response to Mek-i in TNBC.

Finally, we used CRISPR-CAS9 to delete genomic GPNMB from murine lung-metastatic TNBC cell lines. 533LM2 grow in syngeneic Balb/c mice. Here we show that GPNMB is required for tumor growth and metastasis in vivo. Mek-i slows tumor growth; but the combination of GPNMB deletion with Mek-i led to tumor regression, and significantly impaired tumor growth and metastasis relative to all other groups.

Conclusions:
Together our data show that the MAPK pathway is hyperactivated in TNBC; inhibiting this pathway impairs tumor growth, but enhances GPNMB, which facilitates mammary tumor growth and metastasis in the setting of Mek-i. These data provide rationale for combined targeting of GPNMB and the MAPK pathway in TNBC.
Title: WNT4 mediates endocrine response and resistance in invasive lobular carcinoma cells

Sikora MJ J and Oesterreich S. University of Pittsburgh, Pittsburgh, PA and University of Colorado-Anschutz, Aurora, CO.

Body: Invasive lobular carcinoma (ILC) is a breast cancer subtype affecting ~30,000 U.S. women annually. Over 90% of ILC are estrogen receptor (ER)-positive; however, endocrine therapy may have poorer efficacy in a subset of ILC patients versus invasive ductal carcinoma (IDC) patients. This prompted us to assess global ER activity in ILC cell lines MDA MB 134VI (MM134) and SUM44PE (44PE) to identify novel mediators of ER signaling. These analyses identified the Wnt ligand WNT4 as an ILC-specific ER target gene, with an ILC-specific ER binding site (ERBS) at the WNT4 locus. Considering the critical role of WNT4 in normal mammary gland expansion, we hypothesize that ILC cells utilize WNT4 signaling to drive endocrine response and resistance.

We assessed whether WNT4 is necessary for ILC cell growth using siRNA. WNT4 knockdown completely blocked estrogen-induced growth in ILC cells but not IDC cells. In parallel, the WNT4 ERBS was only occupied in ILC cells in response to estrogen, but progesterone-induced WNT4 in IDC was not associated with this ERBS. This suggests that, via the ILC-specific WNT4 ERBS, ILC cells drive estrogen-regulated proliferation by hijacking a developmental Wnt pathway. Wnt pathways typically activate $\beta$-catenin; however, we observed $\beta$-catenin dysfunction in ILC cells and that WNT4 cannot activate $\beta$-catenin. Thus, WNT4 signals in ILC cells via a novel non-canonical pathway.

Using long-term estrogen-deprived (LTED) variants of MM134 and 44PE (4 and 2 lines, respectively), we assessed WNT4 in ILC endocrine resistance. WNT4 is over-expressed, but uncoupled from ER, in all MM134-LTED. Conversely, WNT4 is reduced in 44PE-LTED but remains ER-regulated; ER occupies the WNT4 ERBS only in 44PE-LTED cells and not MM134-LTED. Using siRNA, MM134-LTED (high WNT4) are growth-inhibited by WNT4 knockdown, while 44PE-LTED (low WNT4) are insensitive. However, WNT4 knockdown sensitizes 44PE-LTED to endocrine therapy. Taken together, uncoupling and upregulating WNT4 or WNT4/ER cross-talk may represent convergent endocrine resistance mechanisms in ILC. Further characterization of ILC-LTED cells demonstrated WNT4 expression is driven by activated NFκB signaling in MM134-LTED, and implicated the pluripotency factor Oct4 in regulating WNT4 in 44PE-LTED cells. In both parental ILC cells and ILC-LTED cells, WNT4 leads to suppression of CDKN1A/p21, which is critical for ILC cell proliferation; CDKN1A knockdown partially reverses the effects of WNT4 knockdown. Clinical observations suggest that ER regulates unique pathways in ILC. We identified WNT4 as a downstream effector of endocrine signaling in ILC, with critical roles in both estrogen-induced growth and endocrine resistance. WNT4 signaling may represent a novel target to modulate endocrine response specifically for ILC patients.
Title: CDK8 inhibition improves the efficacy of ER- and HER2-targeted drugs in breast cancer

McDermott MS S, Chumanevich A, Liang J, Chen M, Altilia S, Hennes C, Roninson IB B and Broude EV V. University of South Carolina, Columbia, SC.

Body: Over 70% of breast cancer patients are estrogen receptor (ER) positive and 25% of patients over-express HER2 making these patients susceptible to therapeutic intervention with ER- and HER2-targeted therapies, respectively. However, intrinsic and acquired resistance to targeted therapies is a significant clinical issue and new therapeutic approaches aimed to preventing and overcoming resistance are urgently needed. We have previously shown that high expression of CDK8, a transcription regulating kinase, is associated with shorter relapse free survival in both ER and HER2 positive breast cancer. We have found that CDK8 inhibition by a selective small molecule inhibitor (Senexin B), by shRNA knockdown or by CRISPR/CAS9 knockout, strongly inhibits estrogen signaling in ER-positive breast cancer cells. Senexin B produces a synergistic growth inhibitory effect with an antiestrogen fulvestrant in all the tested ER-positive breast cancer cell lines in vitro and in MCF7 xenograft model in vivo. Senexin B treatment also inhibited invasive growth of MCF7 xenografts. CDK8 inhibition suppressed the emergence of estrogen independence upon long-term estrogen deprivation. A highly synergistic growth inhibitory effect occurred when Senexin B was combined with an anti-HER2 monoclonal antibody (a biosimilar of trastuzumab) or with the HER2/EGFR small molecule inhibitor lapatinib. These synergistic effects were observed in all HER2 positive breast cancer cell lines tested including those that exhibit innate and acquired resistance to HER2 targeting therapy. Furthermore, combining lapatinib with Senexin B completely abrogated the emergence of acquired lapatinib resistance. Taken together these results suggest that CDK8 inhibition, when combined with either ER- or HER2-targeted therapies, offers a rational approach to improving the efficacy of targeted drugs in breast cancer.
Title: Inhibition of HDAC6 as targeted therapy for breast cancers

Silva J, Kalinsky K, Quayle S and Yang M. Mount Sinai School of Medicine, New York, NY; Columbia University, NYC, NY and Acetylon Pharmaceuticals, Boston, MA.

Body: Due to their unique biology, the homeostasis of cancer cells presents different requirements from non-transformed cells. Targeted therapies that interfere with these requirements have been successfully used as highly selective and low toxic anticancer strategies. Recently, we have identified and validated that viability of inflammatory breast cancers (IBC) depends on histone deacetylase 6 (HDAC6) function. Thus, HDAC6 inhibitors, which are currently being tested in advanced clinical trials for other tumor types, represent a novel targeted therapeutic option for these patients. We reasoned that additional breast cancers, other than IBCs, may present the same dependency and that identification of patient populations that can benefit from HDAC6 targeted therapy would be necessary in order to rapidly transition this finding into the clinic. By using system biology strategies to interrogate the regulatory circuit of breast cancer cells we have found that HDAC6 activity is highly increased in HDAC6-dependent cells, acting as a master regulator. We have also developed an algorithm (HDAC6-score) based on mRNA expression profiling to evaluate the HDAC6 activity of individual tumor samples. Thus, the HDAC6-score works as a biomarker to easily identify cancers with high HDAC6 activity that are likely to depend on HDAC6 function. Using our HDAC6-score algorithm we have analyzed ~3,000 primary breast cancers. Interestingly, we have found that a group of ~20% of breast cancers that is enriched in hormone receptor positive (HR+) and HER2 positive (HER+) tumors presents an HDAC6-score predictive of good response to HDAC6 inhibitors. To validate our findings, we correlate the HDAC6-score and the growth inhibitory response to the leading HDAC6 inhibitor, Ricolinostat, in preclinical breast cancer models in vitro and in vivo. Our preclinical studies confirmed the high levels of HDAC6 activity in HR+ and HER2+ breast cancer cells as well as their sensitivity to HDAC6 inhibition.

Based on our data we have partnered with Acetylon Pharmaceuticals to formally evaluate the anticancer activity of Ricolinostat in breast cancer patients and the predictive value of the HDAC6 score in a clinical trial that has been recently open (the design of this trial will be presented).

Clinical considerations: Despite the success of Pan-histone deacetylase inhibitors (HDACis) against cutaneous T-cell lymphoma, these inhibitors suffer from ineffectively low concentrations in solid tumors and cardiac toxicity due to its activity against HDAC1, HDAC2 and HDAC3, hindering their progress in the clinic. More-selective HDAC inhibitors represent a novel and promising class of anticancer drugs with wider therapeutic indexes. The leading HDAC6 inhibitor Ricolinostat, which is in Phase II trials for multiple myeloma and lymphoma, has a 20-fold more potency for HDAC6 inhibition than other class-I/II histone deacetylases. Thus, Ricolinostat can be dosed more frequently with better tolerability than non-selective FDA-approved HDACis.
Title: Inhibition of death-associated protein kinase 1 enhances chemotherapy action against triple-negative breast cancer

Zhao D, Zhao J, Mazumadar A, Bollu L, Shepherd J, Ma Y, Zhang Y, Hill JL L, Savage MI I and Brown PH H. University of Texas MD Anderson Cancer Center, Houston, TX.

Body: Background: Triple negative breast cancers (TNBCs) are the most aggressive ER negative breast cancers with limited therapy strategies and poor prognosis. P53 gene is frequently mutated in approximately 80% of TNBCs. To identify novel molecular targets for ER negative breast cancer, particularly the more aggressive TNBC, we conducted a human kinome screen and identified death-associated protein kinase 1 (DAPK1) as one of the kinases that are highly expressed in ER negative breast cancer. Deletion or inhibition of DAPK1 suppresses growth of p53-mutant but not p53-wildtype breast cancer cells. Here we investigate whether DAPK1 inhibition will enhance chemotherapy action against p53-mutant TNBCs.

Experimental design and methods: We performed experiments to test cell growth of p53-mutant TNBCs that were treated with DAPK1 siRNA or DAPK1 inhibitors in combination with different doses of chemotherapy drugs including 5-FU (5-Fluorouracil), doxorubicin, cisplatin, PARP inhibitor (BMN673), paclitaxel, gemcitabine and vinorelbine.

Results: Our results show that DAPK1 inhibitors enhance the growth inhibitory effects of cisplatin and PARP inhibitor in p53-mutant TNBCs. Furthermore, combined DAPK1 inhibition (via siRNA knockdown) with cisplatin synergistically inhibits cell growth of p53-mutant TNBCs.

Conclusion: DAPK1 is a novel, promising target for the treatment of triple-negative p53-mutant breast cancer. Our studies demonstrate that DAPK1 inhibition sensitizes TNBCs to the cytotoxic effects of cisplatin or the PARP inhibitor. We are now conducting studies to determine whether DAPK1 inhibition will sensitize TNBC tumors and patient-derived TNBC xenografts to the effects of cisplatin and PARP inhibition. These studies suggest that the combination of DAPK1 inhibition with drugs that interfere with DNA repair will be useful for the treatment of the most aggressive form of breast cancer, triple-negative breast cancer.

Funding: This study was funded by a Susan G. Komen Promise grant (SAB12-00006 to P.H. Brown), a MD Anderson Knowledge Gap Moonshot grant (to P.H. Brown) and a Breast Cancer Research Foundation grant (BCRF 15101807, 2015–2016 to P.H. Brown).

Title: Molecular subtype-specific expression of long noncoding RNA regulates proliferation of basal-like breast cancer cells

Body: Background: Basal-like breast cancer (BLBC) disproportionately affects younger women and African American women, displaying aggressive clinical behavior with poor outcomes. BLBC is difficult to treat due to its lack of defined molecular targets, and with current treatment, patients often develop metastatic disease. A growing body of evidence points to long noncoding (Inc) RNAs as mediators of tumor progression, suggesting a new class of targets in cancer therapy. While dynamic changes in IncRNA expression are observed across many types of cancer, our understanding of their role in cancer biology is limited. The aim of this study is to identify IncRNAs differentially expressed in BLBC and to characterize the functional features of candidate IncRNA.

Methods: Breast tumors and normal breast tissues were recruited from the U of Chicago Breast Cancer Tissue Bank under IRB approved protocols. Microarray profiling was done using Human LncRNA Array v3 (Arraystar) containing 30,586 IncRNAs and 26,109 mRNAs. Non-poly(A) RNAs were included with ribo-zero RNA-seq (Illumina HiSeq 4000). Molecular subtype of breast tumors was determined by PAM50 intrinsic classifier. In addition, CpG methylation of IncRNA promoter regions was analyzed with TCGA HumanMethylation450 Array data from 588 breast tissues. We performed in vitro studies using antisense oligonucleotide (ASO) knockdown and CRISPR-on overexpression in BLBC cell lines. Phenotypic consequences of perturbations of specific IncRNA expression were assessed using proliferation, apoptosis, cell cycle and homologous recombination assays.

Results: Microarray profiling of breast tissues from 30 African American women revealed a unique IncRNA signature in basal-like tumors compared to non-basal like tumors. Hundreds of IncRNAs were specifically expressed in BLBC, with >100-fold differences in some IncRNAs compared to tumors from other subtypes or normal breast tissues. Through statistical and in silico analyses we selected IncRNAs displaying increased expression in basal-like tumors (vs non-basal tumors) and BLBC cell lines (vs non-basal cell lines) with a trend of higher expression in cells isolated from women of African ancestry for functional studies. RNA-seq of 50 additional breast tissues recapitulated the distinct IncRNA clustering within the basal-like subtype. TCGA analysis of CpG islands in several IncRNA promoter regions revealed hypo-methylation when compared to non-BLBC, signifying subtype specific epigenetic regulation. ASO knockdown of candidate IncRNAs significantly increased apoptosis and decreased proliferation while CRISPR-on overexpression decreased cell sensitivity to doxorubicin treatment. Depletion of specific IncRNAs caused an increased proportion of cells in G2 phase of the cell cycle, indicating that overexpression of particular IncRNAs may contribute to aberrant cell cycle progression. Cis and trans-regulation of gene expression by IncRNAs is currently under investigation through RNA immunoprecipitation and genome-wide gene expression profiling.

Conclusion: We propose that subtype specific IncRNAs function as onco-RNAs specific to BLBC, driving cellular proliferation and increasing resistance to DNA damaging chemotherapies through regulation of the cell cycle.
Synergistic effect of combinatorial treatment with maraviroc and tocilizumab on TNBC tumor growth and metastasis in mouse xenograft model

Jin K and Popel AS S. Johns Hopkins University, SOM, Baltimore, MD.

Body: Triple negative breast cancer (TNBC) as a metastatic disease is currently incurable. Unfortunately reliable and reproducible methods for testing drugs against metastasis are not available. We have previously developed a robust metastatic model in which mice are pretreated with tumor cell-conditioned media (TCM) from human TNBC cells (MDA-MB-231 and SUM149) for 2 weeks prior to tumor cell inoculation. In this model we found reproducible metastases in lymph nodes (LN) and lungs within 4-5 weeks after orthotopic tumor inoculation [1]. We have discovered that the TNBC cells secrete large amounts of interleukin-6 (IL-6) that “educates” lymphatic endothelial cells (LEC) in the LN and lungs. Stat3, a transcription factor, gets activated and induces the synthesis of CCL5 and VEGF among other factors. CCL5 recruits the tumor cells to the LN and lungs; VEGF helps build blood vessels in the LN to facilitate tumor cell survival; VEGF produced in the lung helps the tumor cells extravasate into the lung. We have confirmed the importance of these factors by showing that inhibitors of these factors significantly inhibit metastasis.

In this report, using Maraviroc (CCR5 inhibitor) and cMR16-1 Ab (murine surrogate of the anti-IL-6R antibody), we investigated the effect of the combination treatment on the tumor growth and metastasis of orthotopic tumor xenografts generated from MDA-MB-231-Luc-D3H2LN cells. 2x10⁶ TNBC cells tagged with luciferase were suspended in 100 µl PBS/Matrigel (1:1) and injected s.c. into female 3- to 4-week-old BALB/c nu/nu athymic mice pretreated with tumor cell-conditioned media (TCM) from TNBC cells for 2 weeks. We administered the Maraviroc (8 mg/kg Maraviroc, orally daily) and cMR16-1 Ab (i.p. 3-days per week) for 5 weeks. Our data show that tumor growth was dramatically inhibited by cMR16-1 Ab. Further, the drug combination of Maraviroc with cMR16-1 Ab caused significant reduction of TNBC tumor growth in mice compared to single agents. In addition, we measured thoracic metastases by adding luciferin to mice and measuring luminescence ex-vivo in the IVIS imager. Significantly, both single treatment of Maraviroc and the combination of Maraviroc with cMR16-1 abrogated the thoracic metastasis compared to control and single treatment of cMR16-1.

These findings implicate IL-6 and CCL5 signaling as a critical event in TNBC tumor growth and metastasis via crosstalk between cancer cells and stromal components. Further, these studies suggest that IL-6 and CCL5 act as key regulators orchestrating TNBC metastatic breast cancer. Therefore, we have provided evidence that supports the hypothesis that functional inhibition of the IL-6 and CCL-5 signaling pathway has the potential to circumvent TNBC growth and metastasis.

Title: The role of CBP/FOXM1 in triple negative breast cancer

Ring A, Nguyen C, Lenz H-J, Tripathy D, Lang JE E and Kahn M. University of Southern California, Los Angeles, CA and The University of Texas MD Anderson Cancer Center, Houston, TX.

Body: Background: Accurate assessment of prognostic and predictive biomarkers (estrogen receptor, progesterone receptor, HER2) plays a critical role in the clinical management of breast cancer. Triple negative breast cancers (TNBCs) lack the expression of all three targets, and no targetable molecular pathways have been identified to date. Hence, TNBCs are treated with non-targeted, cytotoxic chemotherapeutic agents (e.g. paclitaxel), and are characterized by high rates of drug resistance and metastatic relapse. CREB binding protein (CBP) has been implicated in cell growth and malignant transformation in various cancers. CBP is an important co-activator in the β-catenin driven transcription, including the Wnt signaling pathway, which has been implicated in TNBC biology. The Kahn lab has developed a specific CBP-binding small molecule inhibitor, ICG-001. We hypothesized that CBP-signaling plays an important role in TNBC biology and may provide a novel therapeutic target.

Methods: We used TOP-flash assay to quantify Wnt signaling activity in TNBC. ICG-001 treatment combined with RNA Seq was used to characterize the role of CBP in TNBC cell line models. Co-immunoprecipitation (CoIP), protein and gene expression studies, as well as gene knock-down were used for validation. In vitro drug resistant cell line models as well as in vivo cell line (n=40 mice) and patient derived xenografts (PDX) in NOD scid gamma mouse models (2 patients, n=40 mice per patient) (treatment groups: control, paclitaxel, ICG-001, paclitaxel+ICG-001, n=5 mice per condition, primary and secondary implantation) were used to establish the effect of CBP inhibition via ICG-001 in TNBC on drug resistance and metastasis. We used the TCGA breast cancer data set to substantiate the experimental results.

Results: We demonstrated that gene expression in TNBC is CBP, but not Wnt signaling dependent, and can be disrupted via ICG-001. RNA Seq analysis of TNBC cells treated with ICG-001 revealed Forkhead box M1 (FOXM1) as a potential downstream regulator. CoIP demonstrated that CBP binding to the FOXM1/β-catenin transcriptional complex. Treatment with ICG-001 revealed that CBP/FOXM1 binding, but not FOXM1/β-catenin binding, is critical for FOXM1 expression. The PDX mouse models demonstrated that FOXM1 expression correlates with response to chemotherapy and disease recurrence in vivo. Treatment with ICG-001 sensitized FOXM1 high tumors to chemotherapeutic treatment and statistically significantly reduced tumor growth in serial transplantation experiments. Comparison of clinical data with FOXM1 expression in tumor samples from patients indicated that high levels of FOXM1 were associated with disease relapse and poor survival outcomes.

Conclusion: CBP/FOXM1 binding is critical for FOXM1 expression. Targeting CBP/FOXM1 binding via ICG-001 could provide a novel therapeutic strategy in TNBC. The use of clinically annotated tissue microarrays containing a total of 430 breast tissue cores (51 TNBC cases) is currently pending to correlate nuclear protein expression of CBP and FOXM1 with survival outcomes in TNBC. FOXM1 and CBP could potentially be of value as predictive biomarkers in TNBC. These results could provide a clinical-translational rational for patient stratification based on CBP and FOXM1 expression for clinical trials exploring the therapeutic potential of FOXM1 inhibition via ICG-001 in combination with chemotherapy.
Title: Inhibition of Pin1 or CDK-mediated Smad3 phosphorylation reduces triple negative breast cancer cell EMT, migration and invasion

Thomas AL L, Hamdan R, Hong A, Lind H, Oppat K, Rosenthal E, Thomas AJ J and Jeruss JS S. University of Michigan, Ann Arbor, MI and Northwestern University, Chicago, IL.

Body: Introduction: Triple negative breast cancer (TNBC) is an aggressive subtype associated with poor outcomes. Accordingly, there is an urgent need to develop novel and targeted therapeutics for patients with this disease subtype. Cyclins D and E and the corresponding activation of CDK4/2 represent promising therapeutic targets for the treatment of TNBC. CDK4/2 can non-canonically phosphorylate Smad3, a key TGFβ signaling intermediate, and this phosphorylation is associated with the promotion of cell migration and EMT in cyclin-overexpressing breast cancers. Additionally, CDK-mediated Smad3 phosphorylation facilitates an interaction between Smad3 and Pin1. Pin1 is a cis-trans isomerase that is also overexpressed in aggressive breast cancers and can enable TNBC cell migration. Based on these findings, we hypothesized that blockade of the CDK-mediated Smad3-Pin1 interaction, either through inhibition of Pin1 or CDK-mediated Smad3 phosphorylation, would abrogate TNBC cell migration and invasion.

Methods: Pin1 expression was knocked-down (KD) in MDA-MB-231, MDA-MB-436, and Hs578T TNBC cells by transfection with Pin1-targeting siRNA (siPin1) or control non-specific siRNA (siNS). KD efficiency was confirmed with immunoblotting. Pin KD/TNBC cell migration and invasion assays were performed on uncoated or Matrigel-coated trans-wells, respectively. Media containing 10% FBS was used as a chemoattractant. Following Pin1 KD, immunoblotting was used to evaluate EMT-associated protein expression. To inhibit CDK-mediated Smad3 phosphorylation, TNBC cells were treated with 600 nM of CDK2 inhibitor (CDK2i) for 72 hours. Immunoblotting was then performed to determine Smad3 phosphorylation and EMT-associated protein expression. Co-immunoprecipitation assays were used to examine the impact of CDK2i treatment on the Smad3-Pin1 interaction. Finally, following CDK2i treatment, assays were performed to determine the ability of TNBC cells to migrate and invade.

Results: KD of Pin1 expression in TNBC cells resulted in a decrease in cell migration and invasion when compared to control cells in all the study cell lines. This corresponded with changes in EMT-associated protein expression, including increased levels of ZO-1 and claudin and decreased β-catenin. CDK2i treatment produced a decrease in Smad3 T179 site non-canonical phosphorylation and inhibited Smad3-Pin1 binding. CDK2i treatment also abrogated TNBC cell migration and invasion, paralleling expression changes in EMT-associated proteins with an increase in claudin and decrease in β-catenin.

Conclusions: Inhibition of the Smad3-Pin1 interaction, through KD of Pin1 expression or CDK2i-mediated blockade of non-canonical Smad3 phosphorylation, reduced TNBC cell EMT-type changes, demonstrated by increased expression of the tight junction proteins ZO-1 and claudin and decreased β-catenin, a key player in the WNT pathway. These findings also correlated to a reduction in TNBC cell migration and invasion. Collectively, these data show that the Smad3-Pin1 interaction, facilitated by CDK-mediated Smad3 phosphorylation, is associated with pro-migratory TGFβ signaling. Inhibition of this interaction, with CDK2 inhibitor treatment, may provide an important therapeutic option for TNBC patients.
