Landscape of the breast tumour microenvironment at single-cell resolution

Alexander Swarbrick\textsuperscript{1,2}, Sunny Z Wu\textsuperscript{1,2}, Daniel Roden\textsuperscript{1,2}, Ghamdan Al-Eryani\textsuperscript{1,2}, Sandra O'Toole\textsuperscript{1} and Elgene Lim\textsuperscript{1,2}. \textsuperscript{1}Garvan Institute, Sydney, New South Wales, Australia and \textsuperscript{2}St Vincents Clinical School, UNSW Sydney, Sydney, New South Wales, Australia.

Breast cancers are a complex 'ecosystem' of diverse cell types, whose heterotypic interactions play central roles in defining the aetiology of disease and its response to therapy. The next generation of therapies will likely be based upon an integrated understanding of the malignant, microenvironmental and immune states that define the tumour and inform treatment response. However, our poor understanding of the tumour microenvironment (TME) of breast cancers has limited the development and implementation of new drugs that target stromal and immune cells.

Single cell genomics (SCG) is a remarkable new platform to examine the compositional, gene expression and other parameters of thousands of cells, rapidly and at scale. We have used a multi-dimensional SCG approach to characterise the TME in a unique cohort of early and metastatic breast cancers with rich clinico-pathological annotation. We have conducted single cell RNA-Sequencing on more than 125,000 cells collected from 22 patients.

Malignant cells showed remarkable intra-tumoural heterogeneity for canonical breast cancer features, such as intrinsic subtype, hormone receptor expression and activity, drug targets, drug resistance signatures and transcriptional drivers.

Cancer Associated Fibroblasts (CAFs), which are classically studied as a single cell type, were heterogeneous across primary and metastatic sites. Interestingly we identified a myofibroblast-like subset and an inflammatory-mediator subset and propose multi-faceted roles in regulating malignancy and tumour immunity. Distinct transcription factor networks regulated these polarised states.

We applied a new method known as CITE-Seq to measure cell surface immune markers and checkpoint proteins simultaneous to RNA-Sequencing. We resolve the tumour-immune milieu with high precision and generate new transcriptional signatures of breast tumour-infiltrating leukocytes.

To track lymphocyte clonal dynamics through space and time, we developed a novel method known as RAGE-Seq to permit simultaneous full length lymphocyte receptor- and RNA-sequencing at single cell resolution. We observe clonal expansion and trafficking of CD4+ and CD8+ T lymphocytes between the lymph nodes, blood and tumor of patients. In comparison, B cells were polyclonal, suggesting an absence of antigen-dependent clonal expansion.

This data provides by far the most extensive insights into the cellular landscape of breast cancer and will reveal new biomarkers and opportunities for stromal- and immune-based therapy.
Towards a human breast cell atlas

Tapsi K Seth¹, Shanshan Bai¹, Min Hu¹, Emi Sei¹, Anita Wood¹, Jie Wiley¹, Hui Chen¹, Alejandro Contreras¹, Mediget Teshome¹, Bora Lim¹ and Nicholas E Navin¹. ¹The University of Texas MD Anderson Cancer Center, Houston, TX.

The human breast tissue consists of lobules connected to a complex network of ducts that are evolutionarily designed to produce and transport milk to nourish offspring. Histopathology has identified 10 major cell types based on morphological features but have provided limited information on cell states - the transcriptional programs of cell types that reflect different biological functions. In this study, we have generated an unbiased 'cell atlas' of the normal human breast to define the cell types and cell states using single cell RNA sequencing methods. We performed 3’ microdroplet based single cell RNA sequencing of 31,442 stromal cells from 11 women with pathologically normal breast tissues that were collected from mastectomies. Unbiased expression analysis identified three major cell types: epithelial cells (luminal and basal), fibroblasts and endothelial cells, in addition to several minor cell types: macrophages, T-cells, natural killer cells, pericytes and smooth muscle cells. Analysis of cell states of these cell types revealed different transcriptional programs in luminal epithelial cells (hormone receptor positive and secretory), basal epithelial cells (myoepithelial or basement-like), endothelial cells (lymphatic or vascular), macrophages (M1 or M2) and fibroblasts (three subgroups) and provided insight into progenitors of each cell types. These data provide a valuable reference for the research community and will provide new insights into how normal cell types are transformed in the tumor microenvironment to promote or inhibit the progression of breast cancer.
Crosstalk between osteoblasts and breast cancer cells alters breast cancer proliferation through multiple mechanisms

Karen M Bussard¹, Alison B Shupp¹, Alexus D Kolb¹ and Dimpi Mukhopdhyay¹. ¹Thomas Jefferson University, Philadelphia, PA.

BrCa preferentially metastasizes to bone, where the 5-year relative survival rate is <10%. While the mechanism for preferred metastasis is unknown, bone likely provides a hospitable environment that attracts BrCa cells (BCCs) and allows them to colonize and grow.

In a cancer-free environment in the adult, the skeleton continuously undergoes remodeling. Osteoclasts excavate erosion cavities and osteoblasts (OB) synthesize bone matrix, with no net bone gain or loss. However, when metastatic BCC invade bone, this balance is disrupted to favor bone loss. Bisphosphonate treatments are not curative. OBs do not deposit new bone. This result suggests that OBs may be altered or experience a loss-of-function in the tumor niche.

We have new, late-breaking evidence to suggest that communication between OBs and BCCs ‘educates’ OBs to produce factors that suppress BCC proliferation in bone. We have in-vitro and in-vivo mouse-model evidence that ‘educated’ osteoblasts (EOs) have a unique secretory protein profile compared to ‘uneducated’ OBs. We also identified EOs as being present in the bone tissue samples of human patients with bone metastatic BrCa via multi-plex immunofluorescence. When we treated BCCs with EO conditioned media (CM), BCC proliferation was reduced in both triple negative and ER+ metastatic BCCs, while CM from ‘uneducated’ OBs did not affect BCC proliferation. This effect was mediated through alterations in EO production of decorin and NOV.

We identified EO CM as a rich source of exosomes (exo) and confirmed the presence of an exo population via iodixanol density gradient and western blotting for specific exo protein markers. We found that EO-derived exo, but not ‘uneducated’ OB-derived exo, decreased proliferation of ER+ and triple negative BCC. Also, treatment with EO-derived exosomes increased the number of Ki67 negative metastatic BCC. Moreover, we labeled EO exo with RFP-conjugated CD63 to visually confirm exo transfer from EO cells to BCCs using confocal microscopy. And, co-culture with EOs increased triple negative and ER+ metastatic BrCa expression of p21 compared to co-cultures with ‘uneducated’ OBs. Our data suggest that EOs use multiple mechanisms of cellular communication to regulate BCC proliferation in bone.

Impact: Our late-breaking data suggest that OBs produce factors that suppress metastatic BCC growth. Much less attention has been given to OB interactions with tumor cells at sites of bone metastasis due to observations that OB populations are reduced at sites of advanced osteolysis. However, we propose that OBs may be valuable endogenous targets to aid in restoration of bone deposition and suppression of metastatic BrCa growth in the niche in concert with therapeutic drugs to kill the cancer cells. Our data suggest there is a population of OBs that demonstrate a functional role in retarding metastatic BCC growth; a property capable of exploitation. Moreover, restoration of the OBs' ability to deposit new bone would lead to better quality of life and increased time of survival for bone metastatic BrCa patients where bone loss is found. For these reasons, OBs and EOs are suitable candidates for therapeutic targeting and will open new avenues for retarding the growth of BrCa bone metastases.
IMpassion130: Efficacy in immune biomarker subgroups from the global, randomized, double-blind, placebo-controlled, phase III study of atezolizumab + nab-paclitaxel in patients with treatment-naive, locally advanced or metastatic triple-negative breast cancer

Background: The Phase III IMpassion130 study (NCT02425891) evaluated atezolizumab (anti-PD-L1) + nab-paclitaxel (nabPx) vs placebo + nabPx as first-line treatment for pts with metastatic triple-negative breast cancer (TNBC). The study met its co-primary PFS endpoint in ITT pts and in pts with PD-L1 ≥1% on tumor-infiltrating immune cells (IC+). Clinically meaningful OS benefit was seen at interim OS analysis, notably in pts with PD-L1 IC+ tumors (Table). Here we report exploratory efficacy data in immunologically and clinically relevant, biomarker-defined subgroups.

Methods: Pts had histologically documented metastatic or unresectable locally advanced TNBC (evaluated locally per ASCO-CAP). Pts were randomized 1:1 to nabPx 100 mg/m² IV (d1, 8 and 15 of a 28-d cycle) + atezolizumab 840 mg IV q2w or placebo (A-nabPx or P-nabPx) until progression or toxicity. Exploratory biomarkers were centrally analyzed: PD-L1 on tumor cells (TC) by VENTANA SP142 IHC assay, intratumoral CD8 by IHC, stromal tumor-infiltrating lymphocytes (sTILs), BRCA1/2 mutational status and ER/PR/HER2 status.

Results: PD-L1 IC+ is highly predictive of A-nabPx efficacy (Table). The majority of PD-L1 TC+ tumors were also PD-L1 IC+. Intratumoral CD8, but not sTILs, were well correlated with PD-L1 IC. Consequently, CD8 was predictive of A-nabPx efficacy for PFS/OS, while sTILs only predicted PFS benefit. Local vs central TNBC assessment was concordant in most pts. Local vs central lab-defined TNBC populations derived similar benefit from A-nabPx. Efficacy by BRCA status will be presented to evaluate the benefits of immunotherapy for this subgroup.

Conclusions: Exploratory efficacy analyses from IMpassion130 suggest consistency between local and central ER/PR/HER2 testing and that PD-L1 IC+ is the most robust predictive biomarker for selecting untreated mTNBC pts who benefit from A-nabPx.

ApoBec3 induced mutagenesis sensitizes murine models of triple negative breast cancer to immunotherapy by activating B-cells and CD4+ T-cells

Daniel P Hollern, Nuo Xu, Kevin R Mott, Xiaping He, Kelly Carey-Ewend, David S Marron, John Ford, Joel S Parker, Benjamin G Vincent, Jonathan S Serody, and Charles M Perou. 1University of North Carolina, Chapel Hill, NC.

Immune checkpoint inhibitor (ICI) therapies have led to remarkable clinical responses in cancers such as melanoma and non-small cell lung cancer. In breast cancer, current immunotherapy trials have placed an emphasis on triple negative breast cancers (TNBC), where early results suggest response rates of 10-20%. Thus, it is critical to identify predictive biomarkers to enhance patient selection for immunotherapy. With this goal in mind, we simulated a clinical trial employing anti-PD1 and anti-CTLA therapies in immune-intact genetically engineered mouse models (GEMMs) of TNBC. Testing of ICI therapies on 8 different GEMMs demonstrated that each model was resistant. Whole exome sequencing showed that each model also harbored a low mutation burden. Given that mutation load is predictive of immunotherapy response in other cancer types, and that Apobec3B activity is associated with higher tumor mutation burden (TMB) in breast cancer, we created two different tumor lines with overexpression of murine Apobec3.

In contrast to the parental lines, the Apobec3 overexpressing lines showed an elevated tumor mutation burden and new mutations were consistent with the Apobec mutation signature. These TNBC lines with new mutations resulting from Apobec3 activity were exquisitely sensitive to anti-PD1/anti-CTLA4 combination therapy; as assessed by reduction in tumor volume and extended overall survival. To identify features that predict response, we examined resistant and sensitive tumors at pretreatment, at 1 week of treatment, and at end stage by flow cytometry and mRNA-seq. Gene expression profiling identified multiple immune signatures as predictive of response to ICI therapy; specifically CD8+ T-effector memory cells, CD4+ T-cells, and activated B-Cells. Similarly, gene expression analysis showed that these cell types increased at 1 week of therapy in sensitive models but not in resistant models. Flow cytometry confirmed these predictions.

Next, we used an antibody based approach to separately deplete CD4+ T-Cells, CD8+ T-cells, or B-cells in Apobec3 mutagenized murine tumors receiving aPD1/aCTLA4 combination therapy. In each case, depletion of these populations significantly reduced the therapeutic response. However, mice receiving combination immunotherapy and depleted for CD8+ T-cells still exhibited a significant extension in overall survival compared to non-treated controls. In contrast, the CD4+ T-cell depleted mice and B-cell depleted mice exhibited no ICI therapeutic benefit. Together, these data point to key immune biomarkers of response to anti-PD1/anti-CTLA4 therapy; we have further developed a genomic predictor of ICI response using our murine models and will test this on a human TNBC data set. Lastly, this GEMM system provides a rich RNA-seq resource, and new immune-activated models for TNBC, which uncovered a key role for B-cells and CD4+ T-cells in response to ICI therapies.
Unraveling lobular breast cancer progression and endocrine resistance mechanisms through genomic and immune characterization of matched primary and metastatic samples

Christine Desmedt¹, François Richard¹, Samira Majjaj¹, Julien Pingitore¹, David Brown², Françoise Rothé¹, Caterina Marchio³, Florian Clatot⁴, Odette Mariani⁶, Bram Boeckx⁶, Ghizlane Rouas¹, François Bertucci⁷, Christine Galant⁸, Gert Van den Eynden⁹, Roberto Salgado⁶, Diether Lambrechts⁶, Anne Vincent-Salomon⁸, Martine Piccart¹, Giancarlo Pruneri¹⁰, Denis Larsimont¹ and Christos Sotiriou¹.
¹Institut Jules Bordet-Université Libre de Bruxelles, Brussels, Belgium; ²MSKCC, New York; ³University of Turin, Candiolo, Italy; ⁴Centre Henri-Becquerel, Rouen, France; ⁵Institut Curie, Paris, France; ⁶VIB-KU Leuven Center for Cancer Biology, Leuven, Belgium; ⁷Institut Paoli-Calmettes, Marseilles, France; ⁸Cliniques Universitaires Saint Luc, Brussels, Belgium; ⁹Sint Augustinus, Wilrijk, Belgium and ¹⁰Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy.

Background:
Invasive lobular breast cancer (ILC) represents the second most common histology of breast cancer, accounts for 10-15% of all invasive cases and generally expresses the estrogen receptor (ER, coded by the ESR1 gene). Little is known about the genomic alterations associated with tumor progression and endocrine resistance in ILC. Here, we therefore molecularly characterized a unique series of matched primary and metastatic ILC.

Patients and methods:
We retrospectively identified 129 metastatic ER-positive ILC patients from 6 institutions. Following central pathology review and available DNA from the primary tumor (P), the metastasis(es) (M), as well as from normal tissue, 80 patients (279 samples) were eligible for this study. All but 6 patients (7.5%) received endocrine treatment before metastatic sampling. Low pass whole genome and targeted gene screen (N=20 genes) sequencing was conducted to detect copy number aberrations (CNAs) and mutations associated with ILC metastatic progression respectively. ESR1 mutations were further assessed using droplet digital PCR (ddPCR). Publicly available data from IJB (n=413 ILC Ps), TCGA (n=172 ILC Ps), and MSKCC-IMPACT (n=116 ILC Ms) were used to compare and validate the frequencies of the detected alterations in ILC. Stromal tumor infiltrating lymphocytes (TILs) were assessed by two experienced pathologists.

Results:
The overall matched CNA comparison revealed a significant positive association between relapse-free survival and the P/M genomic distance defined by the number of CNAs private to P or M (r²= 0.52, p<.001), suggesting that the longer the disease evolution, the more M differs from P. Regarding CNA changes in cancer genes, we observed the acquisition in M of MYC, CCND1, FGFR1/ZNF703, and ZNF217 amplifications in 17, 9, 6 and 6% of the patients, as well as RB1, PTEN, and TP53 deletions in 9, 11, and 6% of the patients, respectively. The matched P/M comparison of the mutations highlighted the acquisition in M of mutations in 11% of the patients for CDH1, in 10% for ESR1, in 8% for ARID1A, in 5% for ERBB2, GATA3, IGF1R, MAP3K1, and PIK3CA, and in 3% for AKT1 and TBX3. Of interest, when comparing the overall CNA frequencies of our Ms to publicly available data from ILC Ps, we observed a higher frequency of CCND1 and MYC amplification, of PTEN, RB1 and TP53 deletions, as well of AKT1, ERBB2, ESR1 and IGF1R mutations in our ILC Ms. Of note, we did not detect any significant difference in CNA or mutational frequency when comparing our ILC Ms to those from MSKCC-IMPACT.

Regarding the immune infiltration, higher TILs in Ps were significantly associated with younger age at diagnosis, high grade tumors, and with mixed non-classic and trabecular histology. A paired analysis revealed no significant difference in TIL levels between P and M. TIL levels in the P or M were not associated with survival.

Conclusion:
This is to our knowledge the largest metastatic ILC series in which matched P and M samples were interrogated, revealing several genomic alterations, some of which potentially targetable, driving disease progression and endocrine resistance.
The genomic landscape of 501 metastatic breast cancer patients

Lindsay Angus1, Saskia M Wilting1, Job van Riel1,2, Marcel Smid1, Tessa G Steenbruggen2, Vivianne CG Tjan-Heijnen2, Mariette Labots4, Johanna MGH van Riel6, Haiko J Bloemendal7, Neeltje Steeghs3, Harmen JG van de Werken7, Martijn P Lolkema1,8, Emile E Voest3,8, Agnes Jager1, Edwin Cuppen9,10, Stefan Sleijfer1,8 and John WM Martens1,8. 1Erasmus MC Cancer Institute, Erasmus University, Rotterdam, Netherlands; 2Cancer Computational Biology Center, Erasmus MC Cancer Institute, Erasmus University, Rotterdam, Netherlands; 3The Netherlands Cancer Institute, Antoni van Leeuwenhoek, Amsterdam, Netherlands; 4GROW-School for Oncology and Developmental Biology, Maastricht University Medical Center, Maastricht, Netherlands; 5Cancer Center Amsterdam, VU University Medical Center, Amsterdam, Netherlands; 6Elisabeth-TweeSteden Hospital, Tilburg, Netherlands; 7Meander Medical Center, Amersfoort, Netherlands; 8Center for Personalized Cancer Treatment, Rotterdam, Netherlands; 9Center for Molecular Medicine and Oncode Institute, University Medical Center Utrecht, Utrecht, Netherlands and 10Hartwig Medical Foundation, Amsterdam, Netherlands.

Background: In depth sequencing of primary breast cancer (BC) has identified a heterogeneous repertoire of disease drivers, evidence of clonal evolution and underlying mutational processes. As cancer evolves over time and under treatment pressure, whole genome sequencing (WGS) of metastatic BC (MBC) tissue is crucial to gain further insight into its genetic make-up and driving forces, thereby allowing improved patient management.

Methods: Metastatic tissue and matched germline DNA of patients with MBC (N=501) were prospectively recruited under the biopsy protocol of the Center of Personalized Cancer Treatment (CPCT-02; NCT01855477) and analyzed by WGS. Sequence reads were mapped to the reference genome to call somatic single nucleotide variants (SNV), small insertions and deletions (InDels) and copy number variations from which mutational signatures and tumor mutational burden (TMB; the number of SNV and InDels relative to the genome) were derived. The incidence of called aberrations in our cohort was compared to previously reported WGS data of 560 primary BC (BASIS cohort, Nik-Zainal et al. Nature 2016) (Table 1).

Results: According to routine diagnostics 303 patients (60.5%) were ER+/HER2-, 70 (14%) triple negative (TNBC), 95 (19%) HER2+ and the remaining 33 (6.6%) had as of yet an unknown subtype. Top 5 recurrently affected genes were TP53 (47%), ATM (33%), MAP2K4 (32%), NCOR1 (31%), ERBB2 (30%). In the metastatic lesions, median TMB was 2.9 per million base pairs (IQR: 1.7-5.3). Interestingly, 53 (11%) patients had a high TMB (≥10).

Compared to primary BC (BASIS cohort), we found (subtype-specific) enrichment of alterations in multiple genes such as ATM (0.4% to 33%), GPS2 (1.3% to 29%), MAP2K4 (6.4% to 32%), CBFB (2.7% to 25%), and, as previously reported, ESR1 (1.3% to 20%). APOBEC signature mutations appeared to be enriched in MBC while HRD signature mutations seemed less prevalent. Analyses to reveal additional genomic features is ongoing as well as the association of genomic alterations with uniquely collected information on prior treatments and response to treatment received directly after biopsy (i.e. endocrine therapy alone or combined with CDK4/6 inhibitors and chemotherapy). Also, to exclude methodological bias the raw data of the BASIS cohort will be processed through our pipeline.

**Conclusion:** WGS of this unique cohort of patients with MBC shows a genetic make-up roughly similar to primary BC, but does show subtype-specific enrichment of selected driver mutations in metastatic disease. This study provides better insight into the tumor biology of MBC potentially improving management of these patients.
Genomic characterisation of metastatic breast cancer

Fabrice Andre¹, Thomas Filleron², Charlotte Ng³, Francois Bertucci⁴, Christophe Letourneau⁵, Alexandra Jacquet⁶, Salvatore Piscuoglio⁷, Marta Jimenez⁸ and Thomas Bachelot⁷. ¹Institut Gustave Roussy, Villejuif, France; ²Centre Claudius Regaut, Toulouse, France; ³University of Basel, Basel, Switzerland; ⁴Institut Curie, Paris, France; ⁵Institut Paoli Calmette, Marseille, France; ⁶UNICANCER, Paris, France and ⁷Centre Leon Berard, Lyon, France.

Rationale: while large efforts have been done to characterize early breast cancer, little is known about the genomic landscape of metastatic breast cancer. In the present study, we performed whole exome sequencing of 800 metastatic breast cancers, in order to identify new candidate targets and better stratify patients eligible for innovative therapies.

Patients and Methods: Patients were selected to present a metastatic breast cancer and to have received a biopsy in the context of precision medicine trials (SAFIR01, SAFIR02, PERMED, MOSCATO, SHIVA). Samples with >30% cancer cells, and normal DNA, were sequenced using Hiseq and Novaseq. Drivers were identified using MutSigCV. Actionability of somatic genetic alterations was determined based on OncoKB. Decomposition of mutational signatures was performed using deconstructSigs. Prognostic value was assessed using a cox model. TCGA database was used as comparator to identify gene alterations enriched in metastatic samples.

Results: results presented in the current abstract are based on the first 629 patients analyzed. Sequencing was performed in 387 patients with HR+/Her2- breast cancer, 186 triple negative breast cancers, and 32 Her2-overexpressing breast cancers. only 9 patients received a pretreatment with a CDK4 inhibitor. 24 driver genes were significantly mutated. In patients with HR+/Her2-breast cancer, 11 genes were found more frequently mutated in the metastatic setting as compared to early stage breast cancer. This includes TP53 (29%), KMT2C (13%), NCOR1 (8%), NF1 (7%), RB1 (4%), C16orf3 (2%), FRG1 (6%), ESR1 (21%), RIC8A (4%), AKT1 (7%), PLSCR5 (2%). In addition, in the whole population, KRAS was found mutated in 3% of samples (G12A/C/R/V) while its frequency of mutation in early breast cancer is <1%. No gene alteration was found enriched in metastatic Her2+++ and TNBC. Copy number alterations were compared between metastatic and early breast cancer. 18 amplicons were found more frequently in HR+/Her2- metastatic breast cancers as compared to eBC. Among the genes enriched in metastatic samples, mutations in RB1 or NF1 were associated with a poor outcome (median OS 9 and 13 months respectively, p=0.0038 and 0.01 respectively). 73% of patients presenting HR+/Her2- mBC had an actionable alteration, as compared to 55% of patients presenting HR+/Her2- eBC (p<0.01). Patients with HR+/Her2- mBC presented an enrichment of gene alterations in the MAPK/ERK pathway (37% vs 22%) and in the HRD pathway (22% vs 10%). When the analysis focuses on mTNBC; the proportion of patient presenting an actionable alteration was comparable to the eTNBC. 11 (6%) and 16 (9%) patients presented a somatic mutation or homozygous gene deletion on BRCA1 and PTEN respectively.

We further assessed the mutational signatures in order to better understand which mutational processes could drive cancer progression. Metastatic HR+/Her2- mBC presented an increase in APOBEC, S3 (HRD), S10 (POLE-associated signature), S17 signatures as compared to early HR+/Her2- BC.

Conclusion: the present study, based on 629 patients, identifies 11 driver gene alterations and four mutational processes enriched in HR+/Her2- metastatic breast cancers. Final results on 800 patients will be presented.
Age-related breast cancer risk estimates for the general population based on sequencing of cancer predisposition genes in 19,228 breast cancer patients and 20,211 matched unaffected controls from US based cohorts in the CARRIERS study

Fergus J Couch¹, Chunling Hu¹, Steven N Hart¹, Rohan D Gnanaolivu¹, Jenna Lilyquist¹, Kun Y Lee¹, Chi Gao², Bruce Eckloff¹, Raed Samara³, Josh Klebba³, Paul Auer⁴, Leslie Bernstein⁵, Mia Gaudet⁶, Christopher Haiman⁷, Julie R Palmer⁸, Song Yao⁹, Susan M Domchek¹⁰, Jeffrey N Weitzel⁵, David E Goldgar¹¹, Katherine L Nathanson¹⁰, Peter Kraft² and Eric C Polley¹. ¹Mayo Clinic, Rochester, MN; ²Harvard University, Cambridge, MA; ³Qiagen Inc., Washington, DC; ⁴University of Wisconsin-Milwaukee, Milwaukee, WI; ⁵City of Hope Cancer Institute, Duarte, CA; ⁶American Cancer Society, Atlanta, GA; ⁷University of Southern California, Los Angeles, CA; ⁸Boston University, Boston, MA; ⁹Roswell Park Cancer Center, Buffalo, NY; ¹⁰University of Pennsylvania, Philadelphia, PA and ¹¹University of Utah, Salt Lake City, UT.

Background: Clinical germline genetic testing of cancer predisposition gene panels is used to identify women at increased risk for breast cancer. The identification of pathogenic mutations in established high and moderate predisposition genes may result in improved risk management of breast cancer for tested patients and their family members through tailored screening, prophylactic surgeries, or chemoprevention. However, the risks of breast cancer associated with mutations in these genes have likely been overestimated for many women in the general population because previous studies have focused on individuals with a family history of breast and/or ovarian cancer, early onset disease, or triple negative breast cancer. The goal of the “CAnceR RIsk Estimates Related to Susceptibility” (CARRIERS) study is to estimate breast cancer risks associated with mutations in hereditary cancer panel genes in the general population.

Methods: Germline DNA samples from blood or saliva were obtained from 39,439 breast cancer patients and matched unaffected controls from six US-based cohorts (BWHS, CPSII, CTS, MEC, NHS1, NHS2, WHI). DNA was subjected to dual bar-coded QIAseq multiplex PCR-based amplification of 1733 target regions covering all coding regions of 37 cancer predisposition genes and sequenced. Mutation calling was conducted with Haplotype Caller and Vardict.

Results: High quality sequence data was obtained for 38,990 of 39,439 samples (98.9%) and for 99.3% of target regions. Pathogenic mutations in 12 known breast cancer predisposition genes were identified 4.5% of all breast cancer cases and 2.1% of controls; and in 6.7% of African American breast cancer cases and 1.8% of controls. Differences in mutation frequencies were observed by age with mutations in 7.8% of cases diagnosed £50 years of age and 4.0% of cases diagnosed over age 50. Mutations in ATM, BRCA1, BRCA2, and PALB2 were enriched 2 to 3-fold in cases diagnosed under age 50 relative to older cases. No change in frequency of CHEK2 mutations by age was observed. In case-control analyses mutations in BRCA1, BRCA2 and PALB2 were significantly associated with a high risk of breast cancer (odds ratio (OR)>4.0). Of these, BRCA1 and BRCA2 displayed ORs of 13.5 and 16.6 in the £50 age group, but only 5.7 and 3.2 in the >50 age group. Only minor age-specific effects were observed for PALB2. Mutations in ATM and CHEK2 were associated with moderate risks of breast cancer (OR=2.0 to 4.0) in the younger age group, but not in the older age group.

Conclusions: Results from the CARRIERS cohort-based study establish that mutations in known breast cancer predisposition genes are associated with only moderate risks of breast cancer in the general population. However, risks are substantially increased for BRCA1 and BRCA2 but not ATM, CHEK2 or PALB2 mutations in those £50 years of age. The age-related estimates of breast cancer risk for each of the hereditary cancer panel genes in this study may inform selection of individuals in the general population who may benefit from genetic testing and associated risk management strategies.
Efficacy and utilization trends of adjuvant chemotherapy for stage I, II, and III breast cancer in the elderly population: A National Cancer Database (NCDB) analysis

Shreya Sinha¹, Lauren Panebianco¹, Xiancheng Wu¹, Dongliang Wang¹, Danning Huang¹ and Abirami Sivapiragasam¹. ¹SUNY Upstate Medical University, Syracuse, NY.

Background: The role of adjuvant chemotherapy in early stage breast cancer is well established with survival benefit seen in long term follow up studies, but only a small minority of patients in these studies were >65 years old. Dose and schedule can be tailored according to the special requirements of an elderly patient, as stated by the International Society of Geriatric Oncology (SIOG). However the magnitude of the benefit and trends in utilization of adjuvant chemotherapy has not been well studied in this population.

Methods: Female patients above 65 years age with stage I to III breast cancer were identified from the NCDB database from 2004-2015. Factors predicting utility of chemotherapy were assessed with multivariate analysis. Kaplan Meier curves were constructed for calculation of overall survival (OS) with hazard ratio (HR) estimated from cox model. Log rank test and pearson chi square was used for comparison between groups. Groups were compared for OS benefit at 5 and 10 years.

Results: Of a total of 2,445,730 patients analyzed, 160,676 met our inclusion criteria. Of them, 21,743 were >80 years old. Factors predicting use of adjuvant chemotherapy were shown in table 1.

Table 1-Factors predicting utilization of adjuvant chemotherapy

OS benefit was seen in patients who received adjuvant chemotherapy regardless of their age, ER, PR, HER-2 status or stage. Patients with TNBC had an HR of 0.547. More benefit was seen in the higher stages. HR for stages I, II, and III were 0.801, 0.608, and 0.666 respectively.

Conclusions: Adjuvant chemotherapy is considered standard of care for patients with early stage breast cancer. Elderly patients are more likely to get adjuvant chemotherapy based on histology, age<80, grade, stage, and hormone receptor status. In this study, we also learn that the OS benefit with adjuvant chemotherapy is significant in all subgroups analyzed for the elderly population.
PHARE randomized trial final results comparing 6 to 12 months of trastuzumab in adjuvant early breast cancer

Xavier Pivot1, Gilles Romieu2, Marc Debled3, Jean-Yves Pierga4, Pierre Kerbrat19, Thomas Bachelot5, Marc Espie6, Alain Lortholary7, Pierre Fumoleau4, Daniel Serin8, Jean-Philippe Jacquin9, Christelle Jouannaud10, Maria Rios11, Sophie Abadie-Lacourtosie12, Laurence Venat-Bouvet13, Laurent Cany14, Stephanie Catala15, David Khayat16, Laetitia Gambotti17, Iris Pauprote18, Celine Faure Mercier17, Sophie Paget-Bailly20, Julie Henriques20 and Jean-Marie Grouin21. 1Paul Strauss Cancer Center, Strasbourg, France; 2Val d’Aurelle Cancer Center, Montpellier, France; 3Bergonie Cancer Center, Bordeaux, France; 4Curie Institut, Paris, France; 5Leon Berard Cancer Center, Lyon, France; 6Saint Louis University Hospital, Paris, France; 7Centre Catherine de Sienne, Nantes, France; 8Sainte Catherine Institut, Avignon, France; 9Lucien Neuwirth Cancer Institut, Saint Priest en Jarez, France; 10Jean Godinot Cancer Center, Reims, France; 11Alexis Vautrin Cancer Center, Nancy, France; 12Loire Cancer Institut, Anger, France; 13Limoges University Hospital, Limoges, France; 14Clinique Francheville, Perigueux, France; 15Clinique Saint Pierre, Perpignan, France; 16Clinique Bizet, Paris, France; 17French National Cancer Institut, Boulogne, France; 18Ligue Contre le Cancer, Paris, France; 19Eugene Marquis Cancer Center, Rennes, France; 20University Hospital J Minjoz, Besancon, France and 21University of Rouen, Rouen, France.

Since 2005, 12 months of trastuzumab added to chemotherapy alone is the standard of care in patients with HER2-positive breast cancer. PHARE (‘Protocol for Herceptin® as Adjuvant therapy with Reduced Exposure’) is the first trial comparing a reduction of adjuvant trastuzumab versus the standard 12 months. In 2012, the first analysis failed to prove that 6-months was non-inferior to 12-months of adjuvant trastuzumab (NCT00381901). The current presentation reports the final analysis.

Methods: The trial was sponsored by the French National Cancer Institute (INCa) (www.e-cancer.fr), and approved by central Ethical Committee on May 15th 2006. Patients with HER2-positive early breast cancer were randomly assigned between 12 and 6 months of adjuvant trastuzumab duration. The randomization was stratified by concomitant or sequential trastuzumab administration with chemotherapy, estrogen receptor (ER) status and center. The primary objective was non-inferiority of 6-versus 12-months arms in the intent to treat population, in terms of disease-free survival (DFS) with a pre-specified hazard margin of 1.15. Overall Survival (OS) and metastasis free survival (MFS) were secondary endpoints.

Results: A total of 3380 patients were randomized, their median age was 54 years (21-86). Patients with HER2-positive early breast cancer were randomly assigned between 12 and 6 months of adjuvant trastuzumab duration. The randomization was stratified by concomitant or sequential trastuzumab administration with chemotherapy, estrogen receptor (ER) status and center. The primary objective was non-inferiority of 6-versus 12-months arms in the intent to treat population, in terms of disease-free survival (DFS) with a pre-specified hazard margin of 1.15. Overall Survival (OS) and metastasis free survival (MFS) were secondary endpoints.

Conclusion: The choice of the non-inferiority margin will remain inherently a subject of controversy especially in the context of oncology trials where the primary outcome is survival and the least additional death could be considered unacceptable questioning the very feasibility of such trials. Nevertheless, PHARE failed to show that 6 months of adjuvant trastuzumab was non-inferior to 12 months. The standard of care should remain 12 months of adjuvant trastuzumab.
A clinical model for assessing the individual breast cancer risk in mammography screening

Mikael Eriksson¹, Kamila Czene¹, Yudi Pawitan¹ and Per Hall¹. ¹Karolinska Institute, Stockholm, Sweden.

**Background.** Mammography screening reduces breast cancer mortality, but is suboptimal for the breast cancers that are not detected by the screening. These women are identified as symptomatic interval cancers with more aggressive tumors and worse prognosis. To efficiently screen for breast cancer the individual breast cancer risk should be determined. We describe a model that is suited for bi-annual screening programs and estimates the 2-year risk of breast cancer. The risk model could be used at most mammography screening units without adding substantial cost.

**Methods.** The study was based on the population based prospective KARMA cohort including 70,877 participants. Mammograms were collected up to five years following baseline mammogram. A prediction model was developed using mammographic features (density, microcalcifications and masses), use of hormone replacement therapy (HRT), family history of breast cancer, menopausal status, and body mass index. Relative risks were calculated using conditional logistic regression and 2-year absolute risks were calculated.

**Results.** Comparing women at highest and lowest mammographic density yielded a 5-fold higher risk of breast cancer for women at highest density. When adding microcalcifications and masses to the model, high-risk women had a nearly 9-fold higher risk of breast cancer compared to those at lowest risk. In the full model, taking HRT use, family history of breast cancer and menopausal status into consideration, area under the curve (AUC) reached 0.73. We calculated the absolute 2-year risk of breast cancer based on national incidence and mortality rates. We also stratified women into risk groups using the NICE guidelines adapted to 2-year risks. The 20% women with moderate or high breast cancer risk were 7.6 times more likely to develop breast cancer compared to the general risk. Also 18% of the women showed 4 times reduced risk compared to the average population.

**Conclusions.** This risk model can improve mammography screening by identifying women that are in need of additional examination procedures. There is also a substantial proportion of women with low breast cancer risk who will have little benefit from screening.
PALLET: A neoadjuvant study to compare the clinical and antiproliferative effects of letrozole with and without palbociclib

Mitch Dowsett1,2, Samuel Jacobs3, Stephen Johnston2, Judith Bliss1, Duncan Wheatley5, Chris Holcombe6, Rob Stein7, Stuart McIntosh8, Peter Barry9, David Dolling1, Claire Snowdon1, Sophie Perry1, Leona Batten1, Andrew Dodson1,2, Vera Martins1, Arjun Modi1, Chester Cormesan1, Shannon Puhalla16, Norman Wolmark3, Thomas Julian14, Katherine Pogue-Geile3, Andre Robidoux16, Louise Provencher12, Jean François Boileau11, Ibrahim Shalaby13, Michael Thirlwell17, Kate Fisher16, Cynthia Huang Bartlett4, Maria Koehler4, Kent Osborne9 and Mothaffar Rimawi9. 1The Institute of Cancer Research, London, United Kingdom; 2The Royal Marsden Hospital NHS Foundation Trust, London, United Kingdom; 3National Surgical Adjuvant Breast and Bowel Project (NSABP), Pittsburgh; 4Pfizer Inc, New York; 5Royal Cornwall Hospitals NHS Foundation Trust, Treliske, United Kingdom; 6Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, United Kingdom; 7University College London Hospitals NHS Foundation Trust, London, United Kingdom; 8Belfast Health and Social Care Trust, Belfast, United Kingdom; 9Baylor College of Medicine, Houston; 10International Drug Development Institute, Brussels, Belgium; 11Montreal Jewish General Hospital Segal Cancer Centre, Montreal, Canada; 12CHU de Quebec-Universite Laval, Quebec, Canada; 13Joe Arrington Cancer Research & Treatment Center, Lubbock, TX; 14Allegheny Health Network Cancer Institute, Pittsburgh; 15UPMC Cancer Center, Pittsburgh; 16Centre Hospitalier Université de Montréal, Montreal, Canada and 17McGill University Health Centre, Montreal, Canada.

Background: CDK4/6 inhibitors, such as palbociclib, are used to treat ER+ metastatic breast cancer in combination with endocrine therapy with trials ongoing in patients with primary disease. No biomarkers exist to identify those who do/do not benefit from added CDK4/6 inhibition. PALLE is an investigator-initiated/led phase II randomized trial collaboration between UK and NSABP investigators evaluating the biological and clinical effects of palbociclib with letrozole combination as neoadjuvant therapy.

Methods: Postmenopausal women with ER+ primary breast cancer and tumors >2.0cm (ultrasound) were randomized to one of 4 treatment groups (3:2:2:2 ratio): Group A: letrozole (2.5mg/d) for 14 weeks; Group B: letrozole for 2 weeks followed by letrozole + palbociclib to 14 weeks; Group C: palbociclib for 2 weeks followed by letrozole + palbociclib to 14 weeks; Group D: letrozole + palbociclib for 14 weeks. Palbociclib was given 125mg/d PO on a 21 days on, 7 days off schedule. Post-14 week treatment was at the discretion of the treating clinician including letrozole until surgery. Core-cut biopsies were taken at baseline, 2 weeks and 14 weeks. Co-primary endpoints for letrozole alone vs palbociclib groups (Group A vs Groups B+C+D) were: (i) change in Ki67 (IHC) between baseline and 14 weeks (log-fold change, Mann-Whitney test); (ii) clinical response (ultrasound) after 14 weeks (4 group, ordinal, Mann-Whitney test). Complete cell-cycle arrest (CCCA) (Ki67 ≤2.7%) was analyzed using a logistic regression model adjusting for recruitment region. Pre-specified exploratory biomarkers included c-PARP (apoptosis).

Results: 307 patients were recruited between 27 Feb 2015 and 08 Mar 2018; 103 were randomized to letrozole alone and 204 to letrozole + palbociclib. 279 (90.9%) patients were evaluable for 14 week clinical response. Clinical response was not significantly different between letrozole vs letrozole + palbociclib groups ([p=0.20; CR+PR 49.5% (46/93) vs 54.3% (101/186) and PD 5.4% (5/93) vs 3.2% (6/186)]) nor was the small proportion of patients with pathological CR (1/87, 1.1% vs 6/180, 3.3%; p=0.43). 190 (61.9%) patients were evaluable for 14 week change in Ki67. The median log-fold change in Ki67 was greater with letrozole + palbociclib vs letrozole alone (-4.1 vs -2.2; p≤0.001) corresponding to a geometric mean change of -97.4% vs -88.5%. Similarly, a greater proportion of patients who received letrozole + palbociclib achieved CCCA (90% vs 59%, p<0.001). 146 (47.6%) patients were evaluable for c-PARP and the log-fold change (suppression) was greater with letrozole + palbociclib vs letrozole alone (-0.80 vs -0.42; p=0.003) corresponding to a geometric mean change of -56.8% vs -31.4%. Other biomarkers of response / resistance are being evaluated. A higher proportion of patients had a grade ≥3 toxicity on letrozole + palbociclib than letrozole alone (49.8% vs 17.0%; p<0.001) mainly due to asymptomatic neutropenia.

Conclusion: Adding palbociclib to letrozole markedly enhanced the suppression of malignant cell proliferation as assessed by Ki67 but did not substantially increase the clinical response of primary ER+ breast cancer over a 14-week period. Concurrent reductions in cell death may have reduced the speed of tumor shrinkage.
Effects of prolonging adjuvant aromatase inhibitor therapy beyond five years on recurrence and cause-specific mortality: An EBCTCG meta-analysis of individual patient data from 12 randomised trials including 24,912 women

Richard Gray¹ and Early Breast Cancer Trialists' Collaborative Group¹. ¹University of Oxford, Oxford, United Kingdom.

Effects of prolonging adjuvant aromatase inhibitor therapy beyond five years on recurrence and cause-specific mortality: an EBCTCG meta-analysis of individual patient data from 12 randomised trials including 24,912 women

Background: Five years of endocrine therapy with tamoxifen and/or an aromatase inhibitor is highly effective in reducing the risk of recurrence but a substantial risk remains after treatment discontinuation. Continuing treatment with an aromatase inhibitor may mitigate this risk.

Methods: We sought individual patient data for meta-analysis from 12 randomised trials that compared 3-5 years of aromatase inhibitor versus no further treatment after five or more years of endocrine therapy. Primary outcomes were recurrence, and breast cancer mortality. Predefined subgroup comparisons were or prior endocrine therapy (tamoxifen alone, tamoxifen then AI, AI alone), site of recurrence (distant, local, contralateral), age, nodal status, tumour size, grade, and period of follow-up (yrs 0-1, 2-5, 5-9, 10+). Five trials randomised 2-3 years prior to treatment divergence and the primary analyses included only women who were recurrence and second primary cancer free and still alive at the point of treatment divergence.

Results: Data have so far been received on 7,488 women (100% of those randomised) in trials of extended AI following tamoxifen alone, 10,796 women (82% of 13,192 randomised) following prior tamoxifen then AI, and 959 (23% of 4,229 randomised) following AI alone. Preliminary analyses including 1,617 breast cancer recurrences and 854 breast cancer deaths confirm a 35% reduction in recurrence with extended AI following tamoxifen alone but suggest a more moderate reduction after prior AI therapy. Data from two trials (NSABP B-42 & N-SAS BC 05) contributing ~5666 women should be available before SABCS to allow definitive analyses.

Conclusion: This meta-analysis will provide the most reliable possible summary of the available evidence to inform clinicians on the efficacy of extending AI therapy compared to stopping AI after about 5 years of endocrine therapy in preventing disease recurrence and death from breast cancer, both overall and in different categories of women.
A prospective randomized multi-center open-label phase III trial of extending aromatase-inhibitor adjuvant therapy to 10 years - Results from 1697 postmenopausal women in the N-SAS BC 05 trial: Arimidex extended adjuvant randomized study (AERAS)

Background: Treatment with an aromatase inhibitor for 5 years as up-front monotherapy or after tamoxifen therapy for 2-3 years is the treatment of choice for hormone-receptor-positive breast cancer in postmenopausal women. Extending treatment with an aromatase inhibitor to 10 years may reduce the risk of breast cancer recurrence.

Methods: We conducted a prospective randomized multi-center open-label phase III trial to assess the effect of the extended use of anastrozole for an additional 5 years. Postmenopausal patients with stage-I-III, hormone-receptor-positive breast cancer, disease-free after 5 years of either anastrozole alone or tamoxifen 2-3 years followed by anastrozole 3-2 years were randomized to continual group with anastrozole for an additional 5 years or stop group without an additional anastrozole. Our primary end point was disease-free survival.

Results: We enrolled 1697 women. After a median follow up of 4.9 years, there were 149 events involving disease recurrence or the occurrence of contralateral breast cancer (51 in continual group and 98 in stop group) and 7 deaths (3 in continual group and 4 in stop group). The 5-year disease-free survival rate was 91.9% (95% confidence interval [CI], 89.4 to 93.8) in continual group and 84.4% (95% CI: 80.0 to 88.0) in stop group (hazard ratio for disease-free survival, 0.548; P=0.0004). by a two-sided log-rank test stratified according to nodal status, prior adjuvant chemotherapy, institution, and choice of anastrozole or tamoxifen). The rate of 5-year overall survival was 99.5% in continual group and 99.6% in stop group. (hazard ratio,1.389 ;P=0.665). The rate of 5-year distant disease-free survival was 97.2% in continual group and 94.3% in stop group (hazard ratio, 0.514 ;P=0.0077). Bone-related adverse events were observed more frequently among patients in continual group than among patients in stop group, including a higher incidence of bone pain, stiff joints, bone fractures, and new-onset osteoporosis.

Conclusion: The extension of treatment with an adjuvant aromatase inhibitor (anastrozole) to 10 years resulted in significantly higher rates of disease-free survival and distant disease-free survival than those with no additional anastrozole, but the rate of overall survival was not different between two groups. Our study shows that it is safe and beneficial for postmenopausal patients with hormone-receptor-positive breast cancer to take an anastrozole as adjuvant therapy for an additional 5 years after initial treatment. (UMIN:000000818)
Prospective optimization of estrogen receptor degradation yields ER ligands with variable capacities for ER transcriptional suppression

Ciara Metcalfe¹, Wei Zhou¹, Jane Guan¹, Anneleen Daemen¹, Marc Hafner¹, Robert A Blake¹, Ellen Ingalla¹, Amy Young¹, Jason Oeh¹, Tom De Bruyn¹, Savita Ubhayakar¹, Irene Chen², Jennifer M Giltnane¹, Jun Li¹, Xiaojing Wang¹, Deepak Sampath¹, Jeffrey H Hager³ and Lori S Friedman¹. ¹Genentech, South San Francisco; ²University of California San Francisco, San Francisco and ³Ideaya Biosciences, San Diego.

ER+ breast cancers can depend on ER signaling throughout disease progression, including after acquired resistance to existing endocrine agents, providing a rationale for further optimization and development of ER-targeting agents. Fulvestrant is unique amongst currently approved ER ligand therapeutics due to classification as a full ER antagonist, which is thought to be achieved through degradation of ER protein. However, the full clinical potential of fulvestrant is believed to be limited by poor bioavailability, spurring attempts to generate ligands capable of driving ER degradation but with improved drug-like properties.

Here, we evaluate three ER ligand clinical candidates that recently emerged from prospective optimization of ER degradation – GDC-0810, AZD9496 and GDC-0927 - and show that they display distinct mechanistic features. GDC-0810 and AZD9496 are more limited in their ER degradation capacity relative to GDC-0927 and fulvestrant, display evidence of weak transcriptional activation of ER in breast cancer cells (i.e. partial agonist activity), and do not achieve the same degree of in vitro anti-proliferative activity as GDC-0927 and fulvestrant. In the HCI-013 (ER.Y537S) and HCI-011 (ER.WT) ER+ patient-derived xenograft models, GDC-0927 drives greater transcriptional suppression of ER, and greater anti-tumor activity relative to GDC-0810.

We found that despite their full antagonist phenotype, GDC-0927 and fulvestrant promote association of ER with DNA, including at canonical ERE motifs, prior to ER degradation. Interestingly however, integration of ER ChIP-Seq and ATAC-Seq data revealed that ER complexed with fulvestrant or GDC-0927 fails to increase chromatin accessibility at DNA binding sites, in contrast to partial agonists which result in increased chromatin accessibility at ER binding sites. Thus, although ER contacts DNA when engaged with fulvestrant and GDC-0927, it is functionally inert. To further explore mechanistic features that might account for the differential activity of full antagonists and partial agonists that occurs prior to ER degradation, we used cell-based fluorescence recovery after photobleaching (FRAP) to measure the kinetics of ER diffusion within the nucleus. We demonstrate that while ER is generally highly mobile, including after engagement with GDC-0810 and AZD9496, GDC-0927 and fulvestrant immobilize intra-nuclear ER. A site saturating mutagenesis screen revealed a series of novel ER mutations that prevent ER immobilization by fulvestrant and GDC-0927. This class of “always mobile” ER variants promotes an antagonist-to-agonist transcriptional switch for fulvestrant and GDC-0927, and simultaneously prevents ER degradation by these molecules, implying that ER immobilization is a key functional determinant of robust transcriptional suppression.

We thus propose that ER degradation is not a driver of full ER antagonism, but rather a downstream consequence of ER immobilization, occurring after a suppressive phenotype has been established at chromatin. We additionally argue that evaluating the transcriptional output of candidate ER therapeutics, both pre-clinically and clinically, will be critical for the identification of ER ligands with best-in-class potential.
Dynamics of breast cancer relapse reveal molecularly defined late recurring ER-positive subgroups: Results from the METABRIC study

Christina Curtis¹, Oscar M Rueda², Stephen-John Sammut³, Suet-Feung Chin², Jennifer L Caswell-Jin¹, Jose A Seoane¹, Maurizio Callari², Rajbir Batra², Bernard Pereira², Alejandra Bruna², H Raza Ali², Elena Provenzano³, Bin Liu², Michelle Parisien⁴, Cheryl Gillett⁵, Steven McKinney⁶, Andrew Green⁷, Leigh Murphy⁷, Arnie Purushotham⁸, Ian Ellis⁷, Paul Pharoah⁸, Cristina Rueda⁹, Samuel Aparicio⁶ and Carlos Caldas²,³. ¹Stanford University School of Medicine, Stanford, CA; ²Cancer Research UK Cambridge Institute, Cambridge, United Kingdom; ³Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; ⁴Research Institute in Oncology and Hematology, Winnipeg, MB, Canada; ⁵Guy’s and St Thomas’ NHS Foundation Trust, King’s College London, London, United Kingdom; ⁶British Columbia Cancer Research Centre, Vancouver, BC, Canada; ⁷University of Nottingham and Nottingham University Hospital NHS Trust, Nottingham, United Kingdom; ⁸University of Cambridge Strangeways Research Laboratory, Cambridge, United Kingdom and ⁹Universidad de Valladolid Facultad de Ciencias, Valladolid, Spain.

Background: Recent studies have demonstrated that women with early stage ER-positive (ER+) and HER2-negative (HER2-) breast cancer have a persistent risk of recurrence and cancer related death up to 20 years post diagnosis, highlighting the chronic nature of ER+ breast cancer and critical need to identify tumor characteristics that are more predictive of risk of recurrence than standard clinical covariates. However, progress in delineating the dynamics of breast cancer relapse and biomarkers of late recurrence has been hindered by the lack of large cohorts with long-term clinical follow-up and molecular information.

Methods: We report the results of a cohort of 3,240 breast cancer patients from the United Kingdom and Canada with 20 years of follow-up (median 9.75 years), including 1,980 with accompanying molecular data from the primary breast tumor. Information for each patient on loco-regional recurrence (LR), distant recurrence (DR), and site(s) of metastases was collected. We developed a non-homogenous Markov chain model that accounted for different clinical endpoints and timescales, as well as competing risks of mortality and the distinct baseline hazards that characterize different molecular subgroups. This approach enabled robust analysis of the spatio-temporal dynamics of breast cancer recurrence across the clinical subgroups, PAM50 subgroups and the integrative clusters, while also enabling individual risk of relapse predictions.

Results: We employed our multistate model to compute the probability of experiencing a LR or DR, as well as the baseline transition probabilities from surgery, LR or DR at various time intervals for average individuals in each of the clinical/molecular subgroups. These analyses reveal four late-recurring ER+ (predominantly HER2-) subgroups, together accounting for 26% of all ER+ tumors, with high (median 42-55%) risk of recurrence up to 20 years post-diagnosis. Each of these four subgroups maps to one of the Integrative Clusters, defined based on genomic copy number alterations and gene expression, and is enriched for a characteristic copy number amplification events: 11q13 (CCND1, RSF1), 8p12 (FGFR1, ZNF703), 17q23 (RPS6KB1) and 8q24 (MYC). These four molecular subgroups are superior in predicting late DR than standard clinical variables.

Conclusions: A detailed understanding of the rates and routes of metastasis and their variability across the distinct molecular subtypes is essential for devising personalized approaches to breast cancer care. We describe a molecularly characterized breast cancer cohort with long-term clinical follow-up and a statistical modeling framework, enabling delineation of the dynamics of breast cancer recurrence at unprecedented resolution. These analyses reveal four late recurring ER+ subgroups and accompanying biomarkers that collectively define the quarter of ER+ cases at highest risk of recurrence. Our findings highlight opportunities for improved patient stratification and biomarker-driven clinical trials directed at the subset of breast cancer patients with persistent risk of recurrence.
Regional lymph node irradiation in early stage breast cancer: An EBCTCG meta-analysis of 13,000 women in 14 trials

Background There is uncertainty as to which lymph node regions should be irradiated following breast cancer surgery. Systematic review of radiation dosimetry indicates that in randomised trials of nodal radiation therapy (RT) versus not, radiation delivery was qualitatively better in modern trials compared to older trials.

Methods We undertook an individual patient data meta-analysis of randomised trials assessing the benefits and risks of RT to different lymph node regions including the axilla, supraclavicular fossa (SCF) and internal mammary chain (IMC). Eligible studies started before 2009, and included a randomisation, or pseudo-randomisation (by left-versus-right sided tumours), in which the only difference between treatment groups was the use, or extent, of nodal irradiation. Surgery/RT to the breast was the same in both arms. Analyses used standard log-rank methods, and were stratified by study, age, nodal status and year of follow-up. – Studies were categorised according to estimated mean heart dose in the nodal RT arm and whether regimens were likely to have delivered $\geq 85\%$ of prescribed dose to target nodal regions.

Results Information was available on 13,132 women in 14 comparisons of nodal RT versus not. There were 3260 recurrences, 2545 deaths from breast cancer and 4147 deaths overall. Eight trials starting 1961–1978, with median follow-up 9.2 (interquartile [IQR] range 3.4–17.5) years, had estimated $>8$ Gy mean heart dose and likely nodal dose $<85\%$ in the nodal RT arm. In these older trials, including 2178 women, nodal RT had no effect on breast cancer recurrence (Rate ratio (RR)=0.98, 95% CI 0.85–1.13, p=0.83) or breast cancer mortality (RR=1.05, 0.91–1.21, p=0.54), but increased non-breast cancer mortality (RR=1.44, 1.20–1.73, p<0.0001), leading to a net increase in any death (RR=1.18, 1.06–1.32, p=0.004). Six studies starting 1989–2003, with a mean follow-up 9.1 [IQR 7.0–11.0] years, had likely nodal dose $\geq 85\%$, and estimated mean heart dose $<8$ Gy in the nodal RT arm. In these more recent studies, including 10,954 women, nodal RT reduced breast cancer recurrence (RR=0.86, 95% CI 0.79–0.94, p=0.0006), breast cancer mortality (RR=0.81, 0.74–0.90, p<0.0001) and overall mortality (RR=0.86, 0.80–0.93, p=0.0002). No excess of non-breast cancer mortality was apparent (RR=0.96, 0.79–1.18, p=0.71). Recurrence rate ratios did not vary significantly according to nodal region(s) irradiated (axilla/SCF/IMC), or the use of adjuvant chemotherapy.

Conclusions RT to regional lymph nodes in older (1961–78) studies increased the overall risk of death, probably explained by radiation exposure of the lungs and heart. Nodal RT in more recent (1989–2003) studies reduced breast cancer recurrence, breast cancer mortality and overall mortality without increasing non-breast cancer mortality. The proportional benefits from today’s RT may be larger. Absolute benefits for individual women will depend on their absolute recurrence and breast cancer mortality risks.
RAPID: A randomized trial of accelerated partial breast irradiation using 3-dimensional conformal radiotherapy (3D-CRT)

Timothy Whelan¹, Jim Julian¹, Mark Levine¹, Tanya Berrang², Do-Hoon Kim¹, Chu Shu Gu¹, Isabelle Germain³, Alan Nichol⁴, Mohamed Akra⁵, Sophie Lavertu⁶, Francois Germain⁷, Anthony Fyles⁸, Theresa Trotter⁹, Francisco Perera¹⁰, Susan Balkwill¹¹, Susan Chafe¹², Tom McGowan⁸, Thierry Muanza¹³, Wayne Beckham⁷, Boon Chua¹⁴ and Ivo Olivotto⁹. ¹McMaster University, Hamilton, ON, Canada; ²University of British Columbia, Victoria, BC, Canada; ³Université de Québec, Quebec, QC, Canada; ⁴University of British Columbia, Vancouver, BC, Canada; ⁵University of Manitoba, Winnipeg, MB, Canada; ⁶University of Montreal, Montreal, QC, Canada; ⁷University of British Columbia, Kelowna, BC, Canada; ⁸University of Toronto, Toronto, ON, Canada; ⁹University of Calgary, Calgary, AB, Canada; ¹⁰University of Western Ontario, London, ON, Canada; ¹¹University of British Columbia, Surrey, BC, Canada; ¹²University of Alberta, Edmonton, AB, Canada; ¹³McGill University, Montreal, QC, Canada and ¹⁴University of New South Wales, Sydney, Australia.

Background
Whole breast irradiation (WBI) after lumpectomy reduces the risk of local recurrence, thereby avoiding subsequent mastectomy. It is a key component of breast conserving therapy. WBI is usually given in daily fractions over 3-6 weeks. With accelerated partial breast irradiation (APBI), radiation is delivered over a week or less to the surgical cavity with a margin of normal tissue. It was introduced to provide treatment in a shorter more convenient form. 3D-CRT is an attractive approach as it is non-invasive and uses standard techniques for external beam RT that are widely available. The objective of the RAPID trial was to determine if APBI using 3D-CRT was not inferior to WBI following breast conserving surgery (BCS).

Methods
Women ≥40 years of age with axillary node-negative invasive ductal carcinoma, or ductal carcinoma in situ (DCIS) ≤3cm treated by BCS with clear margins of excision were eligible. Randomization was stratified for age (< or ≥50y), histology (DCIS alone or invasive breast cancer), tumor size (< or ≥1.5cm), ER status (+/-) if invasive disease, and treatment center. Patients were allocated to APBI using 3D-CRT (38.5Gy in 10 fractions delivered twice daily) or WBI (42.5Gy in 16 daily fractions or 50Gy in 25 daily fractions; boost radiation was permitted). The primary outcome was ipsilateral breast tumor recurrence (IBTR). Important secondary outcomes included radiation toxicity and nurse assessed adverse cosmesis (fair or poor on global assessment). The trial was designed to show that the 5-year IBTR rate in the APBI arm was not inferior to the WBI arm by more than 1.5% (hazard ratio [HR] ≤2.02) with 85% power and a one-sided alpha of 5%.

Results
From February 2006 to July 2011, 2135 patients from sites in Canada, Australia, and New Zealand were randomly assigned: 1070 to APBI and 1065 to WBI. The median follow-up was 8.6 years. The mean age of the study population was 61 years; 82% of patients had invasive breast cancer and 18% had DCIS only. For invasive cancers: 60% were < 1.5cm and 90% were ER positive. For DCIS tumors: 68% were < 1.5cm. A total of 65 IBTRs were observed. For the APBI patients, the 5-year and 8-year cumulative rates of IBTR were 2.3% and 3.0%, respectively. For the WBI patients, the 5-year and 8-year cumulative rates of IBTR were 1.7% and 2.8%, respectively. The corresponding data for the WBI patients were 1.7% and 2.8%. The HR for APBI versus WBI was 1.27, 90% confidence interval, 0.84 to 1.91. Acute radiation toxicity (occurring within 3 months of treatment start) e.g. radiation dermatitis and breast swelling was less in patients treated with APBI compared with WBI (≥ Grade 2, 28% vs 45%, p<0.001). Late radiation toxicity (beyond 3 months) e.g. breast induration and telangiectasia was greater in patients treated with APBI (≥ Grade 2, 32% vs 13%, p<0.001 and Grade 3, 4.5% vs 1.0%, p<0.001). Adverse cosmesis was higher in patients treated with APBI compared with WBI at 3 years (29% vs 17%, p<0.001) and at 5 years (32% vs 16%, p<0.001).

Conclusions
The APBI regimen used in our trial was non-inferior to WBI in preventing local recurrence. Although it was associated with less acute toxicity, an increase in late normal tissue toxicity and adverse cosmesis was observed with APBI.
Dose escalated simultaneous integrated boost radiotherapy for women treated by breast conservation surgery for early breast cancer: 3-year adverse effects in the IMPORT HIGH trial (CRUK/06/003)

Background
IMPORT HIGH is a randomised, multi-centre phase III trial testing dose escalated simultaneous integrated boost (SIB) against sequential boost each delivered by intensity modulated radiotherapy (IMRT) for early stage breast cancer with higher risk of local relapse. The primary endpoint was initially breast induration at 3 years, requiring 840 patients; accrual was extended (target 2568) with the new primary endpoint of local relapse. We report adverse effects (AE) at 3 years.

Methods
Women age ≥18 after breast conservation surgery for pT1-3 pN0-pN3a M0 invasive carcinoma were eligible. Randomisation was 1:1:1:1 between 40Gy/15F to whole breast (WB) + 16Gy/8F sequential photon boost to tumour bed (40+/16Gy), 36Gy/15F to WB, 40Gy to partial breast + 48Gy (48Gy) or + 53Gy (53Gy) in 15F SIB to tumour bed. AEs were assessed annually by clinicians in all patients and in a planned sub-set (840) of patients by photographs at 3 years and by patients at 6 months, 1 and 3 years. AE scores were dichotomised as none/mild vs marked for photographs and none/mild vs moderate/marked for patients and clinicians. Fisher's exact tests compared groups; principal comparison (protocol-specified) between 53Gy and 48Gy (p<0.01 defined as statistical significance).

Results
2617 women consented between 03/2009 and 09/2015 from 39 UK radiotherapy centres. Median follow-up was 49.1 (IQR 36.8-63.2) months. Median age was 49 (IQR 44-56); 9%, 38% & 53% were tumour grade 1, 2 & 3 respectively; 30% were node positive. 66% received chemotherapy and 73% endocrine therapy. 3-year AE data were available for 2017 clinician assessments, 641 photographs and 842 patient assessments. Proportions of patients with marked AEs were low overall. Rates of moderate/marked AEs at 3 years were broadly similar between the randomised groups; with a suggestion of a slightly increased risk for breast induration in 53Gy compared with control (borderline significance).

AE at 3 years

**Conclusions**

These results represent the largest and most mature reported AE outcomes of breast SIB within a clinical trial. At 3 years, rates of moderate-marked AEs were similar between SIB IMRT and WB + sequential boost IMRT delivered over 3 and 4.5 weeks respectively.

A randomized community-based trial of an angiotensin converting enzyme inhibitor, lisinopril or a beta blocker, carvedilol for the prevention of cardiotoxicity in patients with early stage HER2-positive breast cancer receiving adjuvant trastuzumab

Pamela Munster¹, Jeffrey Krischer², Roy Tamura², Angelina Fink², Lauren Bello-Matricaria³ and Maya Guilin³. ¹University of California, San Francisco, CA; ²University of South Florida, Tampa, FL and ³University of Kentucky, Lexington, KY.

Background:
Exposure to trastuzumab for one year is an integral part of therapy for patients with early stage HER2-positive breast cancer. Yet, cardiac side effects, particularly in patients who also receive anthracyclines require frequent monitoring and result in dose interruptions and discontinuation of trastuzumab. Prophylactic use of angiotensin converting enzyme (ACE) inhibitors or beta blockers (BB) may prevent cardiotoxicity associated with chemotherapy and trastuzumab.

Methods
A large community-based prospective double-blind, placebo-controlled trial, evaluated the rates of pre-specified cardiotoxicity in patients with early stage breast cancer treated with one year of trastuzumab. Cardiac events were followed for two years. Patients were randomized to simultaneously receive either the ACE inhibitor, lisinopril, or the BB, carvedilol, or placebo and were further stratified by anthracycline use to determine whether ACE inhibitors or BB can prevent trastuzumab-induced decrease in left ventricular ejection fraction (LVEF) and trastuzumab interruptions.

Results:
The study included 468 eligible patients (median age:51, BMI:27 kg/m², baseline systolic BP: 126mmHg and LVEF :63 ± 6.29%) from 127 community-based practices, 189 patients received an anthracycline. For the entire study population and the non-anthracycline group, no difference in number of trastuzumab interruptions were seen. For patients receiving an anthracycline, cardiac event rates were higher in the placebo group (47%), and reduced in both the lisinopril (37%), and the carvedilol (31%) groups. Interruptions of trastuzumab were required in 23% patients on lisinopril and 20% on carvedilol compared to 40% on placebo (p=0.007). Changes in LVEF from baseline (least square means, SE) were significantly reduced with both carvedilol (-4.5 (0.8), p=0.008, and lisinopril (-4.0 (0.8), p=0.002) than placebo, (-7.7 (0.8). Cardiotoxicity-free survival was longer on both carvedilol (hazard ratio 0.49, 95% confidence intervals 0.27, 0.89, p=0.009) or lisinopril (HR 0.53, CI 0.30, 0.94, p=0.015).

Conclusions
In patients with HER2-positive breast cancer receiving trastuzumab and an anthracycline, both lisinopril and carvedilol during treatment reduced cardiotoxicity in patients, but not in those with non-anthracycline containing regimens. The use of lisinopril or carvedilol may allow the use of an anthracycline without compromising trastuzumab treatment in those who might benefit from an anthracycline.
Resistance to neoadjuvant chemotherapy in triple negative breast cancer mediated by a reversible drug-tolerant state

Gloria V Echeverria1, Zhongqi Ge1, Sahil Seth1, Sabrina L Jeter-Jones1, Xiaomei Zhang1, Xinhui Zhou1, Shirong Cai1, Yizheng Tu1, Aaron McCoy1, Michael Peoples1, Rosanna Lau1, Jiansu Shao1, Yuting Sun1, Christopher Bristow1, Alessandro Carugo1, Xiaoyan Ma1, Angela Harris1, Yun Wu1, Stacy Moulder1, William F Symmans1, Joseph R Marszalek1, Timothy P Heffernan1, Jeffrey T Chang2 and Helen Piwnica-Worms1. 1The University of Texas MD Anderson Cancer Center, Houston, TX and 2The University of Texas Health Science Center, Houston, TX.

Approximately 50% of patients with localized triple negative breast cancer (TNBC) have substantial residual cancer burden following treatment with neoadjuvant chemotherapy (NACT), resulting in distant metastasis and death for most of these patients. While genomic and phenotypic intra-tumor heterogeneity are pervasive features of TNBCs at the time of diagnosis, the functional contributions of heterogeneous tumor cell populations to chemoresistance have not been elucidated.

To investigate tumor evolution accompanying NACT, we employed orthotopic patient-derived xenograft (PDX) models of treatment-naïve TNBC, which retain intra-tumor heterogeneity characteristic of human TNBC. We discovered that some PDX models initially exhibited partial sensitivity to standard front-line NACT (Adriamycin plus Cytoxan, AC). Following AC, residual tumors were resistant to chemotherapy but repopulated tumors with chemo-sensitive cells if left untreated, indicating that tumor cells possessed inherent plasticity. To identify the tumor cell subpopulation(s) conferring chemoresistance, we conducted barcode-mediated clonal tracking in three independent PDX models by introducing a high-complexity pooled lentiviral barcode library into PDX tumor cells which were then orthotopically engrafted into recipient mice. Strikingly, residual tumors maintained the same heterogeneous clonal architecture as naïve tumors. Concordantly, whole-exome sequencing revealed conservation of genomic subclonal architecture throughout treatment. These results were corroborated by genomic sequencing of serial biopsies pre- and post-AC obtained directly from TNBC patients enrolled on an ongoing clinical trial at MD Anderson (ARTEMIS; NCT02276443). Together, these studies revealed that genomically distinct pre-treatment subclones were equally capable of surviving AC to reconstitute tumors after treatment.

To identify functional addictions of residual tumor cells, we conducted histologic and transcriptomic profiling. Residual tumors following AC-treatment exhibited extensive fibrotic desmoplasia and tumor cell pleomorphism in both PDX models and in serial biopsies obtained from TNBC patients enrolled on the ARTEMIS trial. Strikingly, these AC-induced features were reverted upon regrowth of residual tumors in PDXs and in patients' tumors. Similarly, residual tumors exhibited unique transcriptomic features, many of which are also de-regulated in cohorts of human TNBCs undergoing chemotherapy treatment. These features were nearly completely reverted after tumors regrew, suggesting that the residual tumor state may be a unique and transient therapeutic window. Gene set enrichment analyses revealed that residual tumors had increased activation of oxidative phosphorylation and decreased glycolytic signaling. Pharmacologic targeting of oxidative phosphorylation with a small-molecule inhibitor of mitochondrial electron transport chain complex I (IACS-010759) significantly delayed the regrowth of AC-treated residual tumors in three independent PDX models. Collectively, these studies reveal that a reversible phenotypic state can confer chemoresistance in the absence of genomic selection and that the residual tumor state is a novel therapeutic window for chemo-refractory TNBC.
No survival benefit of chemotherapy escalation in patients with pCR and “high-immune” triple-negative early breast cancer in the neoadjuvant WSG-ADAPT-TN trial

Background: Immune markers such as tumor infiltrating lymphocytes (TILs), CD8, PD1, PD1 and other protein or mRNA-based genomic markers have been identified as prognostic / predictive in TNBC regarding survival / chemotherapy (CTX) efficacy. In the adjuvant WSG-PlanB trial, patients with high TILs and/or CD8 by mRNA had excellent outcome, irrespective of anthracycline use; in the neoadjuvant ADAPT-TN trial, high PD1, PD1 and CD8 and/or TILs were predictive for pCR. Still, optimal markers for potential treatment de-escalation have yet to be determined. Here, we analyse for the first time impact of immune mRNA-based markers and TIL’s as prognostic and predictive survival markers.

Methods: TNBC patients (ER/PR<1%, HER2-) were randomized to neoadjuvant 4x nab-paclitaxel 125 mg/m² gemcitabine 1000 mg/m² d1/8 q3w (gem arm) or 4x nab-paclitaxel 125 mg/m²/carboplatin AUC2 day 1/8 3-weekly (q3w) (carbo arm). Primary endpoint of WSG-ADAPT-TN was pCR (ypT0/is/ypN0); secondary endpoints included translational analyses, e.g., TILs or expression of 119 genes by nCounter platform. Standard adjuvant chemotherapy (4xEC) was optional (not randomized) in patients achieving pCR after 12 weeks. According to protocol, 1st safety survival analysis was performed after 3y median follow-up.

Results: Present translational analysis included 306 of 336 TNBC patients (36 months median FU). pCR was associated with significantly better survival (3y EFS: 92% vs. 71%, p<.001), but despite substantially higher pCR in the carbo arm (46% vs. 29%), no significant EFS advantage was seen (p=.6) (gem: 78%; carbo: 80%; 3y-EFS). Bivariate Spearman correlations among CD8, PD1, and PDL1 were strongly positive; their correlations with TILs were moderately positive. Preliminary Cox analysis of EFS was performed with clinical variables (cN, cT, menopausal status); neoadjuvant study arm; pCR; TILs; proliferation markers (baseline Ki67 by IHC, scores derived from PAM50); baseline immune markers; risk scores; and individual gene expression scores previously identified as prognostic for pCR in one or both neoadjuvant arms. Independent prognostic factors included pCR, cN, Ki67, PD1, and CD8; these were entered into (prognostic) interaction analysis. The resulting model contained cN, high Ki67 and low TILs as (unfavorable) main effects and the interaction of (higher) PD1*pCR (favorable). Among pCR patients, the groups with/without additional adjuvant CTX were similar with respect to explanatory factors. Baseline TILs, Ki67, cN, and PD1 were entered into exploratory predictive analysis; the model retained only the interaction [adjuvant CTx * (fractionally ranked) PD1]. In patients with pCR, those with low PD1 benefited from standard anthracycline-containing adjuvant CTx, whereas patients high PD1 did not with an 98% 3y-EFS.

Conclusions: Our exploratory results suggest independent prognostic impact of mRNA markers and TIL’s in early TNBC. Patients with both pCR (after 12 weeks) and “high-immune” signature (defined here by PD1) had excellent 3y-EFS and may be candidates for treatment de-escalation (e.g. omission of anthracyclines), whereas “low-immune” pCR patients may benefit from standard adjuvant poly-chemotherapy.
International pooled analysis of the prognostic impact of disseminated tumor cells from the bone marrow in early breast cancer: Results from the PADDY study

Introduction
As early breast cancer might relapse even after complete removal of breast and lymphnodes, the disease must persist in secondary sites. The detection of disseminated tumor cells (DTC) in the bone marrow (BM) has been described as a surrogate of residual disease. Various trials showed an impaired prognosis of DTC positive early breast cancer (EBC) patients. The PADDY (Pooled Analysis of DTC Detection in Early Breast Cancer) study is a large international pooled analysis that aimed to assess the prognostic impact of DTC detection in patients with EBC.

Methods
A pre-specified protocol was followed, and centers known to practice BM sampling for DTC detection were contacted for individual patient data. Patients with EBC, with available follow-up data and BM sampling before any anti-cancer treatment were eligible. BM aspirates were collected at the time of primary surgery. DTC were identified by antibody (A45-B/B3, AE1/AE3, 2E11 and E29) staining against cytokeratin. The DTC status was compared to other prognostic factors using the chi-squared test. Univariate log-rank test and multivariate cox regression were used to compare survival of DTC positive versus DTC negative patients.

Results
Individual data from 10,320 patients (11 centers from Europe and USA) were included with a median follow-up of 91 months. Of all patients, 2,823 (27.4 %) were DTC positive. DTC detection was associated with higher tumor grade, higher T stage, nodal positivity, ER and PR negativity, and HER2 positivity (all p<0.001). In univariate analyses, overall, breast cancer specific, disease-free and distant disease-free survival (OS, BCSS, DFS, DDFS) were significantly shorter in DTC positive patients with p-values of <0.001. Multivariate analyses showed the DTC status to be an independent prognostic marker for OS, BCSS, DFS and DDFS with hazard ratios (HR) and 95%-confidence intervals (CI) of 1.23 (95%-CI: 1.06-1.42, p=0.007), 1.38 (95%-CI: 1.11-1.72, p=0.004), 1.29 (95%-CI: 1.10-1.50, p=0.001) and 1.32 (95%-CI: 1.10-1.58, p=0.003), respectively.

Conclusions
Detection of DTC in the bone marrow is an independent prognostic marker in patients with non-metastatic breast cancer. Further studies should investigate the impact of DTC on metastatic cancer progression and their role for clinical decision making.
Surgical treatment after neoadjuvant systemic therapy in young women with breast cancer: Results from a prospective cohort study

Hee Jeong Kim¹, Laura Dominici¹,², Shoshana Rosenberg¹, Linda Ma Pak¹,², Phillip D Poorvu¹, Kathryn Ruddy³, Rulla Tamimi², Lidia Schapira⁴, Steven Come⁵, Jeffrey Peppercorn⁶, Virginia Borges⁷, Ellen Warner⁸, Hilde Vardeh⁹, Laura Collins⁵, Tari King¹,² and Ann Partridge¹. ¹Dana-Farber Cancer Institute, Boston, MA; ²Brigham and Women's Hospital, Boston, MA; ³Mayo Clinic, Rochester, MN; ⁴Stanford University, Palo Alto, CA; ⁵Beth Israel Deaconess Medical Center, Boston, MA; ⁶Massachusetts General Hospital, Boston; ⁷University of Colorado Cancer Center, Aurora, CO and ⁸Sunnybrook Health Science Center, Toronto, Canada.

Background

Young women are more likely than older women to present with higher stage breast cancer (BC) and may benefit to a greater extent from downstaging with neoadjuvant systemic treatment (NST). Young age is also associated with greater likelihood of pathologic complete response (pCR). Using a large prospective cohort of young women with BC, we investigated response to neoadjuvant therapy, eligibility for breast conserving surgery (BCS) pre- and post-NST, and surgical treatment.

Methods

The Young Women's Breast Cancer Study (YWS) is a multi-center cohort of women diagnosed with BC at age ≤ 40, that enrolled 1302 patients from 2006 to 2016. Disease characteristics and treatment information were obtained through medical record and central pathology review. Surgical recommendation before and after NST, conversion from BCS borderline/ineligible to BCS eligible, surgery, documented reasons for choosing mastectomy (MTX) among BCS eligible women, and final pathologic response were independently reviewed.

Results

Among 1302 women enrolled in YWS, 801 (62%) presented with unilateral stage I-III breast cancer and 317 (40%) received NST. Median age was 36 years old (22-40). Pre-NST, 85/317 (27%) were BCS eligible, 49 (15%) were borderline, and 169 (53%) were not eligible (16 inflammatory breast cancer (IBC), 88 large tumor size /cosmetic, 48 diffuse calcifications, and 83 multicentricity). Among the 218 patients who were BCS ineligible/borderline pre-NST, 82 (38%) became eligible for BCS after NST. 4 patients who were BCS eligible pre-NST became ineligible. Of all patients eligible for BCS post-NST (n=163), 80 (49%) attempted BCS, 74 (93%) of whom were successful, and 83 (51%) chose MTX. Reasons for choosing MTX included: patient preference (38/83 (46%)), BRCA or TP53 mutation (31 (37%)), family history (3 (4%)), unknown (11 (13%)). On final pathology, 75 (24%) patients had pCR. Among patients who achieved a pCR, 48 (64%) underwent MTX, fewer than half (21/48 (44%)) were for anatomic indications (IBC, large tumor at diagnosis, diffuse calcifications, multicentric disease).

Conclusion

While NST doubled the proportion of young women eligible for BCS, nearly half chose MTX regardless of response to NST, mostly for personal preference or high-risk preventative reasons. These data highlight that surgical decision making among young women with breast cancer is often driven by factors beyond extent of disease and clinical response to therapy.

Symptoms and health-related quality of life on endocrine therapy alone (E) versus chemoendocrine therapy (C+E): TAILORx patient-reported outcomes results

Lynne I Wagner1, Robert J Gray2, Sofia Garcia3, Timothy J Whelan4, Amye Tevarweerk2, Betina Yanez3, Ruth Carlos6, Ilana Gareen7, Worta McCaskill-Stevens8, David Cella3, Joseph A Sparano9, George W Sledge, Jr.10 and On behalf of the TAILORx Study Team.

Background: TAILORx patient-reported outcomes (PRO) quantify symptoms and health-related quality of life (HRQL) from C+E beyond E alone from the patient's perspective, thus can inform decision-making for women in the intermediate risk group for whom chemotherapy may still be considered.

Methods: TAILORx participants with OncoType DX Recurrence Scores 11-25 were randomly assigned to E or C+E. All TAILORx participants enrolled 1/2010-10/2010 (N=612) completed PROs measuring fatigue, endocrine symptoms, cognitive impairments (PCI), and fear of recurrence at baseline, 3, 6, 12, 24 and 36 months. HRQL was assessed at baseline, 12, and 36 months. Linear regression (LR) examined PRO scores among the per-protocol sample.

Results: Overall, participants reported significantly more fatigue, endocrine symptoms and PCI at 3, 6, 12, 24 and 36 months compared to baseline and those randomized to C+E reported a greater magnitude of change baseline-3 months compared to those randomized to E alone (Table 1). Overall, by 12 months symptoms were comparable between groups. Pre-menopausal women had comparable symptoms at 24 and 36 months. Post-menopausal women randomized to C+E had greater endocrine symptoms at 24 and 36 months and greater fatigue at 6 and 24 months. Fear of recurrence was comparable between arms during treatment and follow-up. Multiple linear regression identified increased fatigue (LR slope \( \beta = 0.67 \)), endocrine symptoms (\( \beta = 0.14 \)), and PCI (\( \beta = 0.11 \)) as significant predictors of decreased HRQL across arms (\( p < 0.001 \)). HRQL was comparable between E and C+E at 12- and 36-months.

Significance between mean change scores *p<0.05;**p<0.01;***p<0.001. LMED=estimated tx difference using linear model regressing score on baseline value and tx

Conclusions: TAILORx is the first trial to examine patient-reported fatigue, endocrine symptoms, PCI and HRQL among breast cancer patients randomized to endocrine therapy alone vs chemoendocrine therapy, thus allowing us to quantify acute and long-term symptoms uniquely attributable to chemotherapy. As expected, chemotherapy is associated with greater fatigue, endocrine symptoms and PCI acutely during treatment, and for post-menopausal women with greater long-term endocrine symptoms. Increased symptoms were associated with poorer HRQL. Long-term HRQL was comparable between groups.
Development and validation of a chemotherapy toxicity (Chemo Tox) risk score for older patients (Pts) with breast cancer (BC) receiving adjuvant/neoadjuvant treatment (Adjuvant Tx): A R01 and BCRF funded prospective multicenter study

Background: Older pts with BC receiving adjuvant tx are at increased risk of chemo tox; however, no BC-specific tool exists to quantify this risk. The Cancer and Aging Research Group (CARG) developed/validated a chemo tox score for older pts with all stages of solid tumor. The goals of this study were to: 1) build upon the CARG score by developing/validating CARG-BC (a BC specific adjuvant chemo tox score for older pts) and 2) evaluate its association with dose modifications, reduced relative dose intensity (RDI) and hospitalizations.

Methods: 501 pts age $\geq$ 65 with stage I-III BC from 16 sites were accrued (300 development; 201 validation cohort). A pre-chemo assessment captured: CARG chemo tox score, BC tumor/tx variables, and additional geriatric assessment (GA) items. Grade 3-5 chemo tox by NCI CTCAE v 4.0 was captured. Univariate analysis identified chemo tox risk factors (p<0.10) in addition to the CARG score which were used to develop a predictive model by best subset method; each risk factor was assigned a score, and summed to yield a total score (CARG-BC). Model performance was assessed by area under the ROC curves (AUC) of the development cohort, 10-fold internal validation, external validation, and goodness of fit.

Results: Among 501 pts, 28 received non-standard regimens and were excluded, leaving 473 evaluable pts: 283 development and 190 validation cohort. The development cohort (median age 70; range 65-85) had Stage I (39%), II (41%), & III (20%) BC with 65% hormone positive, 24% triple negative, 27% Her2 positive; and 37% received an anthracycline. Grade 3-5 tox occurred in 46% (36% grade 3, 10% grade 4, 0.4% grade 5). The CARG score was significantly associated with grade 3-5 tox (p<0.001; AUC 0.64). The addition of BC tumor/tx & GA variables (CARG-BC: see table) improved the AUC to 0.76 (95% CI, 0.70-0.82; goodness of fit $p=0.28$). The score ranged from 0-19, (low risk 0-5, mid risk 6-9, high risk 10+) and was significantly associated with grade 3-5 tox (p<0.001) while KPS was not (p=0.20). The 10-fold internal validation AUC was 0.78. The external validation AUC (0.69) was not statistically different (p=0.15) from the development AUC. A higher CARG-BC score was associated with dose delay/reduction, chemo discontinuation, hospitalization, and RDI<85% (all p-value <0.001).

Conclusions: We developed and validated a risk score (CARG-BC) which identifies an older pt's risk for adjuvant BC chemo tox and is associated with dose reduction, delay, reduced RDI, and hospitalization. This tool could be considered as a part of adjuvant tx decision-making.

The impact of breast cancer surgery on quality of life: Long term results from E5103

Shoshana M Rosenberg¹, Anne O'Neill², Karen Sepucha³, Kathy D Miller⁴, Chau T Dang⁵, Donald W Northfelt⁶, George W Sledge⁴,⁷, Bryan P Schneider⁴ and Ann H Partridge¹. ¹Dana-Farber Cancer Institute, Boston, MA; ²ECOG-ACRIN Biostatistics Center, Boston, MA; ³Massachusetts General Hospital, Boston, MA; ⁴Indiana University, Indianapolis, IN; ⁵Memorial Sloan-Kettering Cancer Center, New York, NY; ⁶Mayo Clinic, Rochester, MN and ⁷Stanford University, Stanford, CA.

Background: Breast cancer (BC) treatment, including surgery, can impact not only short-term health outcomes but may also affect longer term health-related and psychosocial quality of life (QOL). We sought to describe the impact of BC surgery on QOL among breast cancer survivors followed in a large randomized trial.

Methods: The ECOG-ACRIN protocol E5103 was a phase III trial that randomized BC patients (pts) who had undergone definitive BC surgery to receive adjuvant doxorubicin, cyclophosphamide, and paclitaxel with either bevacizumab (bev) or placebo. Telephone based surveys were administered to all pts enrolled between 01/Jan/10 and 08/Jun/10 as part of a Decision-Making/QOL component until 18 mos post enrollment. Functional/psychosocial QOL domains were assessed by the EQ-5D-3L and the FACT B+G. Fisher’s exact test compared categorical and Wilcoxon rank sum test compared continuous variables between subgroups. Multivariable regression was used to evaluate factors in addition to primary surgery at enrollment (age, race, ER/PgR status, tumor size, nodal status) associated with overall FACT score at 18 mos.

Results: Patient reported outcomes at 18 mos were available from 89.6% (465/519) pts. At enrollment, 57% (266/465) had a mastectomy; 43% (199/465) breast conserving surgery (BCS). Median age at enrollment was 52 (range: 25-76) years. There were no differences in QOL between bev vs placebo treatment arms (EQ-5D-3L Index Score p=0.65; FACT B+G Score p=0.23) at 18 mos so groups were combined. Using EQ-5D-3L, over half of the pts (58%) reported at least some pain/discomfort; 38% symptoms of anxiety/depression. A higher proportion of mastectomy pts reported problems with usual activities compared to BCS pts (Table). Compared to BCS pts, mastectomy pts had lower average EQ5D-3L scores 0.80 vs. 0.84, p=0.04 and FACT B+G scores 109 vs. 114, p=0.01, indicating worse QOL. In univariate analyses, non-white race (p=0.03), ER/PgR+ status (p=0.04) and mastectomy as primary surgery (p=0.01) were significantly associated with worse QOL (lower FACT B+G scores). In multivariable analyses, non-white race (p=0.02) and ER/PgR+ status (p=0.05) remained associated with worse QOL; mastectomy was borderline significant (p=0.06).

Conclusions: Among women participating in a contemporary adjuvant BC chemotherapy trial, a substantial proportion of survivors experience symptoms that may be amenable to intervention, including referral to physical rehabilitation, especially among pts undergoing more extensive surgery. Attention to psychosocial health is also essential both during and after completion of active treatment to optimize QOL outcomes.

Systemic imaging fails to detect metastasis in early stage breast cancer

Anu G Gaba¹, Robert Kraft², Britta K Stjern³, Minnu Monu⁴, Melissa A Gunderson⁵, Christine Hanish⁶, Afrah Samreen⁶ and Gopikrishna Paladugu⁷. ¹Sanford Roger Maris Cancer Center, Fargo, ND; ²University of North Dakota School of Medicine, Grand Forks, ND and ³Sanford Health, Fargo, ND.

Background: Current NCCN guidelines for early stage breast cancer (Stage I and II) do not recommend routine systemic imaging in the absence of symptoms or abnormal labs suggestive of distant metastasis. This study aims to determine the frequency and appropriateness of these imaging studies performed, its impact on staging and the factors that influence physicians in ordering these imaging studies.

Methods: Patients with stage I and II breast cancer at initial presentation were retrospectively identified between years 2011-2015 from the tumor registry. Charts were reviewed to determine patients who got systemic imaging (CT scan, non-breast MRI, bone scan or PET scan) within 6 months of diagnosis. Provider notes and laboratory data were analyzed to establish the appropriateness of ordered imaging studies and if the imaging altered the stage. For each patient in the study, age at diagnosis, the grade of the breast tumor, hormonal receptor status and HER-2 status was documented. Statistical analysis was done using appropriate tests.

Results: A total of 1067 patient charts were screened, of which 882 were identified for inclusion in the study (544 stage I, 338 stage II). Amongst the cohort, 18.57% (101) of patients with stage I and 50.89% (172) of patients with stage II cancer received imaging studies within the first 6 months of diagnosis. Only 12.68% (69) of stage I patients and 18.24% (62) of stage II patients were judged appropriate for imaging based on symptoms and lab results suggesting metastasis. In the imaged cohort of Stage I patients, only 4.35% (3) of the appropriately imaged group and 13.33% (4) of the inappropriately imaged group had a change in stage. Similarly, in the Stage II cohort, only 4.84% (3) of the appropriately imaged group and 8.18% (9) of the inappropriately imaged group saw a change in state. The difference in stage change in the appropriately and inappropriately imaged groups was not statistically significant. (p = 0.11 for Stage I, p=0.41 for Stage II). Only 5.9% of Stage I and 2.9% of Stage II imaged patients changed to stage IV. Grade 1 patients were less likely to receive systemic imaging than grade 2 and 3 patients ((p <0.001). Similarly, the difference in imaging rates ordered in patients with ER and/or PR negative status versus ER and PR positive status was significant (p=0.0004). Triple negative (p <0.001) status and age≤ 50 years were statistically significant predictors of patients receiving imaging (p = 0.014). HER-2 status alone was not a significant predictor of getting imaged (p = 0.527).

Conclusions: We performed the first ever study to investigate a correlation between the appropriateness of ordered imaging studies in early stage breast cancer and its ability to detect a change in stage. Distant metastasis identification among stage I & II patients was extremely rare among both appropriately and inappropriately imaged groups. Our findings suggest a wide prevalence of inappropriately ordered imaging studies in Stage I and II breast cancer as well as limited utility for even appropriately ordered ones. Further, other factors such as grade of the tumor, ER/PR/HER2 status and age were found to be statistically significant predictors of whether patients received imaging studies.
Quantitative breast MRI to predict response to neoadjuvant therapy in community imaging centers: Preliminary results

Anna G Sorace\textsuperscript{1}, Jack Virostko\textsuperscript{1}, Chengyue Wu\textsuperscript{1}, Angela M Jarrett\textsuperscript{1}, Stephanie L Barnes\textsuperscript{1}, David Ekrut\textsuperscript{1}, Debra Patt\textsuperscript{2}, Boone Goodgame\textsuperscript{3}, Sarah Avery\textsuperscript{4} and Thomas E Yankeelov\textsuperscript{1}. \textsuperscript{1}University of Texas at Austin, Austin, TX; \textsuperscript{2}Texas Oncology, Austin, TX; \textsuperscript{3}Seton Healthcare, Austin, TX and \textsuperscript{4}Austin Radiological Association, Austin, TX.

Introduction: Early response assessment to neoadjuvant therapy (NAT) for locally advanced breast cancer would allow for more accurate prognosis and provide the opportunity to replace an ineffective treatment with an alternative regimen. This could potentially increase systemic treatment efficacy and avoid unnecessary side effects from ineffective therapies. Quantitative MRI has been shown to be beneficial in predicting breast tumor response to treatment early during the course of NAT within many academic environments. Importantly, integrating quantitative imaging techniques into the community-based setting has the potential to reach a large percentage of breast cancer patients, as most patients receive their care at private practice or community hospitals. This study evaluated the ability to implement quantitative dynamic contrast enhanced MRI (DCE-MRI) and diffusion-weighted MRI (DW-MRI) data in the community setting to predict the eventual response of breast tumors to NAT.

Experimental Design: Women undergoing NAT for breast cancer (N=16) were scanned with DCE-MRI and DW-MRI at baseline (prior to beginning therapy, \(t_1\)) and three longitudinal time points during the course of NAT to evaluate early response to therapy (\(t_2, t_3, t_4\)). MRI was performed at two community imaging centers using a 3T Siemens Skyra scanners equipped with 8- or 16-channel breast coils. DW-MRI was acquired with a spin echo sequence with TR/TE = 3000/52 ms, \(b\)-values of 200, 800 s/mm\(^2\) and used to compute the apparent diffusion coefficient (ADC) values for every voxel. DCE-MRI data was collected (following a pre-contrast T\(_1\) map) with TR/TE/\(\alpha\) = 7.02 ms/4.60 ms/6\(^\circ\), and a temporal resolution of 7.27 sec for eight minutes. A catheter placed within an antecubital vein delivered gadolinium-based contrast agent (0.1 mmol/kg of Multihance or 10 mL of Gadovist) at 2 mL/sec via a power injector after the acquisition of the first minute of dynamic scans (baseline). Quantitative measures of ADC (evaluating cellularity from DW-MRI) and \(K_{\text{trans}}\) (evaluating vascular perfusion and permeability from DCE-MRI) were calculated for the segmented tumor volume. Imaging was compared to pathology reports at the conclusion of NAT.

Results: The patients (\(n = 6\)) achieving a pathological complete response (pCR) revealed a 12.9\% ± 19.1\% increase in the mean ADC values of the tumor from \(t_1\) and \(t_2\). Conversely, patients (\(n = 10\)) that had residual disease burden after NAT (i.e., a non-pCR) had a decreased ADC, revealing a -8.0\% ± 19.2\% change between \(t_1\) and \(t_2\) (\(p = 0.06\)). The mean \(K_{\text{trans}}\) values of the tumor decreased showing a change of -61.4\% ± 18.2\% from \(t_1\) to \(t_2\) in the pCR patients. Conversely, non-pCR patients had a 10.2\% ± 80.4\% increase in \(K_{\text{trans}}\) between \(t_1\) and \(t_2\) (\(p = 0.14\)).

Conclusion: Preliminary evidence reveals that quantitative DCE-MRI and DW-MRI can be implemented in community-based imaging settings to predict the response of breast tumors to NAT. Thus, our results provide evidence that quantitative DW-MRI and DCE-MRI can be disseminated across community imaging facilities, thereby dramatically increasing the patient population for which these techniques can serve.

We acknowledge the support of CPRIT RR160005.
Improvement of breast cancer screening access and quality in an underserved population through system interventions

Deborah J Manst1, Denisse Gil1, Elizabeth A Marcus1, Paul Mullarkey1 and Pamela S Ganschow1. 1Cook County Health & Hospitals System, Chicago, IL.

Background: Differences in access to and quality of screening and treatment are proposed to contribute to racial disparities in breast cancer outcomes. Interventions designed to improve mammography access and quality encompass strategies at the individual patient, healthcare provider, and system levels. In 2016, an urban safety net healthcare system based in Chicago implemented several changes in response to collected data showing variations in quality at institutions performing mammography. These changes included the installation of digital machines at one of four sites, centralizing reading of images from all four sites to a single site with radiologists specialized in mammography and increasing care coordination including enhanced patient outreach efforts. We examined the impact of these systems-based interventions on the access to and quality of mammography services.

Methods: Data was obtained on 15,918 screening mammograms performed across four mammography centers within the Cook County Health & Hospitals System from the six months prior to and one year after implementation of changes. Manual chart abstraction was performed for each study that was assessed as BIRADS 0 (Breast Imaging and Reporting Data System), meaning an incomplete study requiring additional imaging evaluation, or mammograms that appeared suspicious or highly suspicious and categorized as BIRADS 4 or 5. Screening mammogram volume at each site was recorded and compared. Quality of screening mammograms was assessed using eleven metrics reflecting radiologist performance and efficiency of facility care processes. These metrics included the rate of recall, cancer detection rate, proportion of cancers that were early stage or minimal in size, proportion of women with timely follow-up imaging and biopsy, and rates of loss to follow-up.

Results: The volume of screening mammograms completed at each of the four sites increased from the six months prior to intervention to the six months after (range of 61-322% increase). At one-year post intervention, there were smaller, but sustained increases in volume (range of 12-70% increase). Improvements were seen in at least one quality metric at each site in the post-intervention period (range 1-8). The proportion of women with timely follow-up after abnormal mammogram also improved across all four sites: from 38% getting follow-up imaging within 30 days pre-intervention to 68% after, and from 62% to 75% of women with biopsy completion within 60 days. Rate of cancer detection improved at two of the sites with the lowest pre-intervention values, from 1.7 to 3.1 and 2.8 to 5.7 per 1,000 mammograms (quality benchmark: 3-10/1,000 screening tests).

Conclusion: Improvements in access to and quality of screening mammography demonstrate the value of implementing system level changes in enhancing breast cancer care and may translate to better outcomes for all women.

Ru Yao¹, Bo Pan¹, Ying Xu¹, Yidong Zhou¹, Jing Zhang¹, Huanwen Wu¹, Feng Mao¹, Yan Lin¹, Songjie Shen¹ and Qiang Sun¹. ¹Peking Union Medical College Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, China.

Background: Ultrasound (US) is an effective initial screening test for breast cancer both in Caucasian and Chinese women [PMID: 26712110, 26715161, and 25668012]. The real-world modality of breast cancer screening in the China is hospital-based screening among asymptomatic self-referred women. In our previous study, we showed that US and mammography (MG) detected non-palpable breast cancer (NPBC) had similar long-term survival and that US detected more invasive NPBC with positive lymph node [2016 SABCS P5-02-05, PMID: 27689334]. This study was to investigate whether these findings would be still true with more NPBC cases included and longer follow-up in the consecutive hospital cohort.

Methods: From 2001 to 2017, 5,264 asymptomatic women with positive (BI-RADS 4 and 5) initial screening US underwent biopsies in PUMC Hospital, and 914 US-NPBC in 883 women were diagnosed. Meanwhile, women without dense breasts (defined as BI-RADS category C and D) also received screening MG after physical examination and US. There were 1,159 patients with positive (BI-RADS 4 and 5) MG and normal US (BI-RADS 1, 2 and 3) underwent MG-guided biopsies and 216 MG-NPBC were diagnosed in 214 women. The clinicopathological characteristics and 10-year disease-free survival (DFS) and overall survival (OS) were reviewed and compared between the US-NPBC and MG-NPBC. Prognostic factors of NPBC were identified by univariate and multivariate Cox analysis.

Result: Compared to MG, US could detect more invasive (81.2% vs 48.6%, p<0.001), lymph node positive (18.3% vs 10.2%, p<0.001), stage II+III (21.7% vs 12.5%, p<0.001) and low grade cancer (p=0.001).Between invasive US-NPBC and MG-NPBC, no significant difference was identified for lymph node status, TNM stage or subtype.US-NPBC received more breast conserving surgery (32.6% vs 24.1%, p<0.001) and chemotherapy (37.5% vs 23.6%, p<0.001). There was no significant difference in DFS or OS between US- vs MG-NPBC among ductal carcinoma in situ (DCIS), invasive and all NPBC.

§ Kaplan-Meier survival curves between each two subgroups would be displayed in the poster.

Conclusion: Overall, US could detect more invasive NPBC patients with positive lymph node and advanced stage compared to MG, and screen invasive NPBC at similar TNM stage and subtype distribution as MG. US-NPBC patients received more breast conserving surgery and chemotherapy, and could achieve comparable 10-year DFS and OS as MG-detected NPBC. Hence US is justified in the real-world as the initial imaging modality in hospital-based screening Chinese women.
Defining a breast screening “bundle”: Provider reimbursement and patient cost-share

Kemi Omotoso1, Mark Fredrick1, Vanessa Dalton1, Sarah Bell1, Paniz Charkhchi1, Neil Kamdar1 and Ruth Carlos1. 1University of Michigan, Ann Arbor.

Introduction: Alternative payment models encourage “bundling” of imaging services, where a bundle aggregates all services used by a population of patients for a clinical indication and estimating the per patient cost. We assess provider cost and patient cost-share for screening mammography as a bundle, or episode of care.

Methods: We used patient-level analytic files between 2004 and 2014 from Optum Clininformatics Data Mart including women 40-64 years without a history of breast cancer or mastectomy and at least one year of continuous enrollment in a given plan, examining standardized costs as a proxy for provider cost and patient cost-share, summing copayments, coinsurance and deductibles. In the episode of care, we included screening mammography (SM) and all downstream diagnostic tests up to but not including biopsy. Definition of the diagnostic pathway or episode of care aggregated any subsequent testing after the initial SM independent of test order. Bureau of Labor Statistics Medical Consumer Price Index (CPI) adjusted costs to 2014 dollars.

Results: We identified an average of 530,844 commercially insured women ages 40-64 years with at least 12 months of continuous enrollment in a given plan per year. We identified 8 order-independent diagnostic pathways that women can experience during the episode: 1) SM only; 2) SM+ diagnostic mammography (DM); 3) SM + DM + MRI 4) SM + DM + ultrasound (US); 5) SM+DM+US+MRI; 6) SM+MRI; 7) SM+US; 8) SM+US+MRI. Across the whole population, patient cost-share fell from $9.83 (CI of $9.68-9.98) in 2004 to $7.31 (CI of $7.18-7.45) in 2014, largely due to cost-share elimination for screening mammography after the ACA. However, evaluating the individual diagnostic pathways, patient cost-share increased over time for all pathways except for those who had a negative screening mammogram and required no further diagnostic work-up prior. Among those requiring diagnostic work-up, rate of cost-share increase was steeper for any diagnostic pathway that included breast MRI. In contrast, provider cost held steady or declined, particularly for those pathways that included MRI. Across the whole population, provider cost for the breast screening episode fell from $176.54 (CI $175.92-177.16) in 2004 to $141.16 (CI $140.83-141.49) in 2014.

Implications for Practice: Although provider cost and patient cost-share for the breast cancer screening bundle declined over time, patients experience an uneven burden of cost-sharing dependent on the diagnostic pathway. Patient cost-share bundles need to be created in conjunction with provider cost bundles for the breast cancer screening episode of care.

Is asymptomatic surveillance after standard treatment beneficial? : A 10yr-survival analysis of recurrent breast cancer patients by detection method of recurrence

Youngjoo Lee¹, Han Shin Lee¹, Sei Hyun Ahn¹, Byung Ho Son¹, Jisun Kim¹ and Sae Byul Lee¹. ¹Asan Medical Center, Seoul, Republic of Korea.

Surveillance of recurrence after standard treatment of breast cancer (BC) for early detection and it's impact on overall survival are known to differ depending on recurrent site. Current guideline recommends asymptomatic surveillance to only detect loco-regional recurrences. As the evidences depend on historical randomized clinical trials we aimed to address questions whether earlier detection might have impact on survival, now that plenty of new treatment strategies can be offered. Also to give answers to heterogeneous surveillance strategy in real-world practice, we performed a retrospective 10yr-survival analysis of a large cohort of recurrent BC patients according to their detection method.

From 4188 operable breast cancer patients who completed standard treatment Asan Medical Center from 2006 to 2008, 469 patients with recurrent BC were analyzed. Median disease free interval was 35.3 months (range 2.8-97.6) and overall survival (OS) was analyzed as time from initial diagnosis/surgery to death. Among 469 patients who developed recurrence, 23.7% were local (ipsilateral breast, skin, chest wall), 22.6% were regional (ipsilateral axillary, internal mammary lymph nodes) and 53.7% developed distant metastasis. 10yr-overall survival was analyzed according to recurrent site and it's detection method. Detection of recurrence were categorized as 'asymptomatic surveillance (N=162, 34.5%)' and 'symptom-guided (N=307, 65.5%)'. Asymptomatic screening method included mammography, breast-ultrasound, serum tumor marker (CA15-3) and systemic images (eg. chest X-ray, bone scan, PET scans). Symptom-guided detection rate for local, regional and distant metastasis was 14.9%, 5.5% and 15.1% respectively. Overall, asymptomatic vs symptomatic 10yr-OS did not differ (81.3 vs 78.8 months, p=0.778).

Among patients with distant metastasis, 10ys-OS was not significantly different (70.3 vs 66.7 months, p=0.846) and was similar according to stage/subtype. Among patients with local recurrence only, 10yr-OS was 95.1 months ('symptomatic' vs 'asymptomatic, 94.4 vs 94.5, p=0.809), which may be insufficient number of events to show significant difference. Among regional recurrent BCs, longer OS was observed in asymptotically detected patients than symptom-guided group (86.1 vs 63.4, p=0.004). In Cox regression analyses, asymptomatic detection showed significant better survival (HR=3.9, 95%CI:1.6-9.5) and this observation was more evident in patients with hormone receptor(HR) negative primary BCs (69.9 vs 47.9, p=0.029). Intriguingly, only 8.6% (7/80) of regional recurrence were diagnosed by mammography.

We observed survival benefit with asymptomatic screening in detecting regional recurrence especially in HR-negative primary BC patients. And role of systemic radiology even in advanced high risk breast cancer patients were limited. Although with limitation that surveillance method varied widely, we emphasize the role of asymptomatic surveillance of regional nodal evaluation including breast-ultrasound. These findings are to be validated from a prospective clinical study along with using cutting edge modalities other than radiology which enable detection of micro-metastasis.
Who drops out of breast cancer screening? Results from the EDIFICE 6 survey

Jean-François Morère1, François Eisinger2, Sébastien Couraud3, Laurent Greillier4, Chantal Touboul5, Christine Lhomel6, Morgan Rouprêt7, Jérôme Viguier8 and Thibault De la Motte Rouge9. 1Hôpital Paul Brousse, Villejuif, France; 2Institut Paoli-Calmettes, Marseille, France; 3Centre Hospitalier Lyon Sud, Pierre Bénite, France; 4Assistance Publique - Hopitaux de Marseille, Marseille, France; 5Kanta Health, Paris, France; 6Roche, Boulogne-Billancourt, France; 7Hôpital Pitié-Salpêtrière, Paris, France; 8Hôpital Bretonneau, Tours, France and 9Centre Eugène-Marquis, Rennes, France.

Background Breast cancer (BC) screening has been part of a nationally organized program in France since 2004. Women aged 50-74 years are invited for a mammography every two years. After stabilization of up-take figures over the period 2008-2014, the latest data from the French health authorities confirm a declining trend which began in 2015-2016. This fall has been observed in all age groups, with the exception of women aged 70-74 years. It therefore appeared important to gain clearer insight into the characteristics of women who have had at least one screening examination but have not returned after the recommended two-year interval for a repeat mammography.

Methodology The French nationwide observational survey EDIFICE 6 was conducted online from 26 June to 28 July 2017 on 12,046 individuals (age, 18-69 years). Representativeness was ensured by quota sampling on age, gender, profession, and stratification by geographical area and type of urban district. Multivariate stepwise logistic regression analysis was conducted to identify factors likely to explain the non-uptake of subsequent BC screening. The present analysis included 1954 women (50-69 years) with no history of cancer.

Results Of those who were in the target age range for BC screening, 26% (N=380) did not return for the repeat examination within the recommended 2 years. Compared to those who were compliant with the recommendations, the population of non-compliant women was characterized by higher proportions of unmarried women (23% vs 19%, P<0.05), socially vulnerable individuals (53% vs 38%, P<0.05), and smokers (33% vs 20%, P<0.05). No differences were observed between compliant and non-compliant women in terms of mean age (59.3 SD 5.8, years) or socioprofessional categories. In multivariate analysis, the items associated with non-compliance included: current smoking (OR=1.81 [CI=1.40 – 2.34]), individuals who would not encourage someone close to enroll in a clinical trial (OR=1.55 [1.17-2.04]), considering that protection provided by a prevention program is ineffective (OR=1.48 [1.11-1.97]), and social vulnerability (OR=1.38 [1.09-1.74]). The most frequently cited reasons for non-uptake of subsequent screening were “I don't feel concerned” (45%), “individual negligence/not a priority” (29%), fear of the examination/results (25%), “I have not received a screening invitation” (18%), and self-examination (15%).

Conclusion Indicators of non-uptake of repeat BC screening show various patterns: behavioral (currently smoking), social (vulnerability), and those related to information/education. In our analysis, this latter appeared concurrently with medical skepticism. The two main underlying reasons for not pursuing with breast cancer screening were “not feeling concerned” and “individual negligence”. Our findings highlight the need for novel awareness campaigns that specifically target this population.
Breast cancer screening in the Republic of Belarus: Advantages and learning perspective

Olga Trusova¹, Vitaly Osharin¹, Vitaly Smelov², Louis Wilkinson³ and Rosalind Given-Wilson³. ¹N.N.Alexandrov National Cancer Centre, Lesnoy, 2, Minsk District, Belarus; ²International Agency for Research on Cancer, Lyon, France and ³St George's Hospital National Training Centre, London, United Kingdom.

**Background:**
Breast cancer (BC) is the most common cancer among women in the Republic of Belarus. To reduce BC-related mortality, the implementation of organized pilot BC screening programmes using digital mammography has been supported by the European Union as part of the BELMED project. During recent years Belarus has developed its own digital mammographs and software that allows storing and processing images in the DICOM format. To assure digital mammographic performance in the local context, the first external clinical image quality assessment (QA) of Belarus mammograms was performed by a leading UK radiologist.

**Methods:**
The reviewed mammograms from 88 (out of 2,267) Belarus women (mean age: 59.5 years; SD:5.7) attending the a breast screening pilot in Minsk were examined as 81 with positive and 7 with negative findings, according to Belarus readers. This included all 10 histologically confirmed BCs. Within the framework of BELMED project, a total of 400 mammographic images were selected for evaluation by a leading expert radiologist from the UK Public Health England Breast Screening Programme. Evaluated mammographic images were classified according to the Belarus (non-BIRADS) and BIRADS (the UK radiologist) categories, associated with a follow-up plan. Gradings were compared across categories (the Cohen's Kappa) and according to the proportion of cases referred for further tests (the Wilcoxon signed rank test).

**Results:**
The reviewer concluded that approximately 50% of the positive mammograms didn't require further assessment in screening according to the UK radiologist. All histologically confirmed BCs were not among those downgraded. Substantial agreement was found in the gradings for BC (Kappa: 0.66, p<0.001). The study has resulted in adopting the BIRADS classification in the country and launching additional training of radiologists (e.d. in biopsy) and radiographers (in positioning).

**Conclusions:**
To minimize additional tests on women, comprehensive QA (audit and regular check of mammographic technique, the opinion of physicists, etc.) is essential. Applying the implementation research may result in further improvement of the national BC programme. Improved practice can be promoted by continuous image review and training for individual staff (i.e., through BELMED, in collaboration with UK training centres) to further improve the skills of Belarus specialists and increase the quality of BC screening programme in Belarus.
Adherence to breast cancer screening recommendations among underserved participants in an urban safety net mammography clinic

Matthew M McClennathan¹, Jiachen Lu¹, Bridget A Oppong², Lucile L Adams-Campbell¹ and Chiranjeev Dash¹. ¹Georgetown Lombardi Comprehensive Cancer Center, Washington, DC and ²Reston Hospital Center, HCA Virginia Health System, Reston, VA.

Background: The Georgetown Lombardi Comprehensive Cancer Center's Capital Breast Care Center (CBCC) is a safety net mammography screening center that uses a community-based patient navigation program to provide underserved minority women guidelines-concordant mammography screening. Given that screening navigation is designed to eliminate some established barriers such as, access, transportation, and cost, we retrospectively examined patient adherence rates to regular (annual/biennial) mammography screening. We also investigated whether patient demographics are associated with adherence to breast cancer screening.

Methods: Data were derived from medical records of patients that received a baseline mammogram at CBCC in 2011 (n = 1,637) and were followed up for 4 years. Within the study time period of 2011-2015, patients were of age 40-74 and had not received a prior breast cancer diagnosis. 10 definitive cases of breast cancer were newly diagnosed in this population during the follow-up period and were excluded from the analysis. Adherence was then calculated based on the American College of Radiology (annual screening starting at 40) and the United States Preventive Services Task Force guidelines (biennial screening starting at 50).

Results: In 2011, the mean age of women screened at CBCC was 51.25 years with 45% being 40-50 years of age. CBCC has a predominantly minority population with 48% of the women identifying as Black/African American (AA) and 41% identifying as Hispanic in 2011. Over the 4 year follow up period, 41.11% of the patients screened in 2011 did not return for another screen. The adherence rate for annual screening in the 40-74 age group was 3.3% (3.0% in Black/AA; 4.2% in Hispanic) over the 4-year follow-up. The adherence rate for biennial screening among the 50-74-year-old age group was 21% overall (20% among Black/AA; 26% among Hispanics). Approximately 40% of the participants with baseline screenings in 2011 received at least one additional screening over the 4 year follow up but their mammography schedules were not guidelines concordant and they were labeled as "partially adherent" for this analysis.

Conclusion: While the number of partially adherent patients was consistent with previous population-based adherence studies, the proportion of non-adherent patients was higher compared with other population-based studies in primarily Non-Hispanic White populations. Our analysis highlights the importance of focusing on adherence to guidelines and not just mammography initiation in underserved minority populations through educational interventions targeted to patients and providers.
CDA screening technology for multi-ethnic group, early stage breast cancer screening

HongMei Tao¹, Yue Lin¹, ChaoQian Liu², Juan Dou², Yuan Sheng², JunJie Wu², Wei Hu², YuTao Li³, Xing Tang¹, Chris Yu¹ and XueDong Du¹. ¹Anpac Bio-Medical Science Co., Ltd, Shanghai, China; ²Changhai Hospital, Naval Medical University, Shanghai, China; ³Ministry of Education Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China and ⁴Anpac Technology USA Co., Ltd., San Jose, CA.

Background: Breast cancer is the second leading cause of death from cancer in American women. Current breast cancer screening technologies have issues with poor sensitivity for early stage breast cancer, high false positives, radiation side effects, etc. Cancer Differentiation Analysis (CDA) technology is a blood-sample based, multi-level, multi-parameter diagnostic method which detects signals from both proteins, cells, and to some extent, molecular level, in which multiple aspects of information are collected to improve diagnostic accuracy. CDA technology has been investigated as a viable clinical utility in breast cancer screening, particularly for early stage breast screening with clear advantages (both whole blood and serum can be used, ability to detect early, easy, simple, no side effects, and high degree of sensitivity and specificity).

Methods: In this study, the human subjects involved are Caucasians, with serum samples of 44 pathologically confirmed breast cancer patients and 34 healthy individuals from 3 blood bank centers in the USA, of which 40 cases were stage I breast cancer, 2 cases were stage II, and the other 2 cases were stage III breast cancer. CDA data of 44 breast cancer patients and 34 healthy individuals were collected in US lab and analyzed using SPSS, and the results were shown in the table below. Results from the above study was compared with a clinical study on Asian group with data collected in lab in China using CDA technology.

Results: The average CDA value of all breast cancer and stage I breast cancer samples, and controls were 45.99, 45.76 and 42.36 (rel. units) respectively (see Table 1). Both breast cancer and stage I breast cancer could be significantly distinguished from the control group (p < 0.001) (Table 2). For stage I breast cancer vs. control group, Area under ROC curve was 0.727, sensitivity and specificity were 62.5% and 82.4% respectively, which is higher than a typical mammogram. To compare with different ethnic groups, data collected on an Asian group is also shown in Table 2, which showed that overall, AUC, sensitivity and specificity are comparable (some difference may be attributed to sample type difference (whole blood vs. serum)) for early stage breast cancer patients for those two ethnic groups, demonstrating that CDA technology can be extended to multiple ethnic groups.

Conclusions: CDA screening can be extended to different ethnic group including Caucasian and Asian with good sensitivity and specificity for stage I breast cancer.

We thank Ugur Basmaci, Sunsil Pandit and Sharon Vorse-Yu for their support.

# Whole blood samples. 10 stage I breast cancer samples and 25 control samples
Early stage breast cancer screening using an emerging novel liquid biopsy screening technology

ChaoQian Liu¹, Juan Dou¹, Yuan Sheng¹, JunJie Wu¹, Wei Hu¹, YuTao Li², Yue Lin³, HongMei Tao³, Xing Tang³, XueDong Du³ and Chris Yu⁵. ¹Changhai Hospital, Naval Medical University, Shanghai, China; ²Ministry of Education Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China; ³Anpac Bio-Medical Science Co., Ltd., Shanghai, China and ⁴Anpac Technology USA Co., Ltd., San Jose, CA.

Background: An emerging novel liquid biopsy technology called Cancer Differentiation Analysis (CDA) has been evaluated as a viable early stage breast cancer screening tool. CDA technology is a blood-sample based, multi-level, multi-parameter diagnostic method which detects signals from both protein, cellular, and to some extent, molecular levels, in which multiple aspects of information can be collected to improve diagnostic accuracy, even for early stage of cancer. Improving capability to screen breast cancer is an important on-going research effort, as breast cancer represents a leading cancer with high incidence rate.

Methods: In this single-blind study, 22 breast cancer patients and 25 healthy individuals were recruited at Changhai Hospital of Shanghai. Histopathological examination results of breast cancer patients were collected, 22 cases were diagnosed as infiltrating ductal carcinoma of breast, of which 10 patients were stage I breast cancer. 25 individuals were confirmed healthy after physical examinations. Peripheral blood was drawn in EDTA tubes for CDA tests. CDA data of 22 breast cancer patients and 25 healthy individuals were conducted using SPSS, and the results were shown in the table below.

Results: The average CDA of breast cancer, stage I breast cancer, and controls were 43.20, 44.17 and 36.17 (rel. units) respectively as shown in Table 1. Both breast cancer and stage I breast cancer could be significantly distinguished from the control (p = 0.000, p = 0.001, respectively). For stage I breast cancer vs. control group, Area under ROC curve was 0.876, sensitivity and specificity were both 80.0% (Table 2). In contrast to traditional breast cancer screening methodologies which have relatively low sensitivity and high false positives for stage I detection, often with radiation side effects and high costs, advantages of CDA technology include ability to detect early stage cancer with relatively high sensitivity and specificity, and it is also highly cost effective without side effects.

Conclusions: Initial results showed that CDA technology could effectively distinguish stage I breast cancer from healthy individuals, CDA could be a potential candidate for breast cancer screening.

Differential distant disease-free intervals for mammography detected vs. clinical presentation invasive breast cancer: Early detection or lead time bias?

Henry G Kaplan¹, Judith A Malmgren² and Mary K Atwood¹. ¹Swedish Cancer Institute, Seattle, WA and ²HealthStat Consulting, Inc, Seattle, WA.

Background: Distant recurrence metastatic breast cancer (rMBC) incidence has declined with coincident improved breast cancer (BC) survival over time. Lead time is time from screening diagnosis to diagnosis that would have been made without screening. The purpose of screening is to detect disease at an early more treatable stage. Lead time bias would indicate early detection led only to a perceived increase in survival time without affecting the course of BC progression. Our objective was to evaluate detection method and treatment changes to distant recurrence and survival over time.

Methods: In a longitudinal institutional cohort 1990-2011, we reviewed primary invasive stage I-III BC patients (n = 7991) for initial BC detection method by mammography (MamD) or patient/physician (ClinP), distant recurrence (rMBC), time from initial diagnosis to distant recurrence (DDFI) and distant disease specific survival (DDSS), follow up through 2016 updated annually. 856 patients with distant recurrence were identified and confirmed by imaging, biopsy or both. Diagnosis year time periods were set to coincide with significant treatment changes over time (1990-98, 1999-2004, 2005-2011). Chi square, mean ANOVA, DDSS and Cox proportional hazards analysis were conducted.

Results: 48% of the cohort were ClinP and 52% MamD with MamD BC increasing over time [1990-98 45%, 2005-2011 54%, p<.001]. 72% of rMBC patients were ClinP BC. ClinP BC had shorter distant recurrence time, 4.99 years vs. 6.05 MamD BC (p = .001). Mean time from rMBC diagnosis to death was 2.88 years with no significant difference by detection method. In a Cox proportional hazards model adjusted for race, reduced risk of rMBC was observed for stage I/II, recent diagnostic years, hormone receptor positive, MamD, and low histologic grade [TNM I HzR .11, 95% CI .09, .14; TNM II HzR = .36, 95% CI = .31, .43; 1990-2004 HzR = .63, 95% CI = .53, .75; 2005-2011 HzR = .49, 95% CI = .41, .58; HR+ HzR = .70, 95% CI = .59, .82; MamD HzR = .68, 95% CI = .58, .81; low histologic grade HzR = .80, 95% CI = .67, .96; age >40 HzR = .79, 95% CI = .65, .96]. No difference was observed for DDSS by detection method [5-year DDSS: ClinP = 22%, MamD = 21%; log rank test = .019, p = .892].

Conclusion: At initial diagnosis, the majority of rMBC cases are symptomatic, have shorter DDFI but DDSS equal to MamD BC. MamD BC cases have lower rMBC incidence and longer DDFI possibly due to more responsive earlier diagnosed initial disease, slower progression disease or as yet unidentified biologic/genomic differences. Lead time bias may partially explain lower rMBC incidence given the benefits owed to treatment of MamD invasive BC which preclude disease progression to clinically evident BC. Mammography detected/non-symptomatic and clinically detected/symptomatic BC have differential incidence of and time to distant recurrence but no difference in DDSS. Mammography detection appears to confer a distant disease risk reduction advantage independent of other known prognostic factors but the disease has the same virulence once it becomes metastatic. Our results indicate treatment changes by diagnosis year proxy and mammography detection are both associated with decreased rMBC risk.
ASCO/CAP human epidermal growth factor receptor-2 (HER2) in situ hybridization (ISH) categories evaluated by quantitative HER2 protein diagnostic methodologies: A comparative analysis

Brandon Buscaglia, Bradley Turner, Hideki Goda, Weidong Huang, Kim Leitzel, Takako Natori, Yasushi Nakano, Hisatake Okada, Jeff Sperinde, Monali Vasekar, Marcus D’Aguiar, Loralee McMahon, Jill Henry, Allan Lipton and David Hicks.

1University of Rochester Medical Center, Rochester, NY; 2Konica Minolta, Hino-shi, Tokyo, Japan; 3Monogram Biosciences, South San Francisco, CA; 4Penn State Hershey Medical Center, Hershey, PA and 5Lebanon VA Medical Center, Lebanon, PA.

Background: In 2013, the ASCO/CAP consensus panel published updated guidelines for HER2 testing in breast cancer that modified the definition of HER2 amplification by in situ hybridization (ISH), creating five new prognostic categories (group 1: classic amplified, group 2: monosomy, group 3: co-amplified (polysomy), group 4: equivocal, and group 5: classic non-amplified). Patients determined to be ISH amplified, were considered eligible for HER2-directed therapy. Concern over whether patients from non-classic groups 2-4 would benefit from treatment has led to the recent publication of the 2018 HER2 focused update. This update has modified the criteria for interpreting these ISH categories, recommending that the final diagnosis take into consideration a combination of HER2 immunohistochemistry (IHC) and ISH results. With increased emphasis on the HER2 protein assessment, it has prompted us to quantitatively examine HER2 protein expression in the ISH categories, using two different novel technologies. Materials & Methods: A cohort of 170 cases (URMC) and 102 cases (PSHMC) of invasive breast cancers, which had previously undergone HER2 IHC and ISH testing, were selected for this study. Cases were sorted and categorized into the HER2 ISH categories defined by ASCO/CAP. HER2 protein expression was quantitatively measured in the URMC and PSHMC cohorts using a novel immunodetection methodology (streptavidin-coated Phosphor-Integrated Dot (PID) fluorescent nanoparticles), and a novel dual-antibody, proximity-binding immunoassay (HERmark Breast Cancer Assay, Monogram Biosciences, South San Francisco, California), respectively. HER2 protein expression was compared to the HER2 FISH and IHC results by ASCO/CAP category.

Results: Cases in group 1 had a significantly (p < 0.01) higher average PID/cell and HERmark compared to cases in groups 2-5 (Table 1). Cases in groups 2-4 showed lower quantitative levels of HER2 protein expression, similar to the classic non-amplified cases (group 5). Group 1 was further divided into three subgroups (Table 2): Group A - ISH high-level amplified (ratio ≥ 2, HER2 ≥ 6, CEP17 < 2.7), Group B - amplified with elevated CEP17 (ratio ≥ 2, CEP17 > 2.7), and Group C - low-level amplified (ratio ≥ 2, HER2 > 4 and < 6). Group A and B had a significantly (p < 0.01) higher average PID/cell and HERmark compared to Group C. Group C was more comparable to cases in groups 2-5 (Table 1).

Conclusion: Our results suggest that quantitative assessment of HER2 protein expression may help to further classify cases for HER2 status for targeted therapy, supporting the 2018 ASCO/CAP recommendation that non-classic ISH results might be resolved by evaluating protein expression. Follow up studies with a larger patient cohort and dual quantitative assessment are warranted.

Comparing staging assignments based on the 7th and 8th editions of the American Joint Committee on Cancer staging system for breast cancer

Riley Brian¹, Jennifer Tseng², Jean Bao² and Nora Jaskowiak². ¹University of Chicago Pritzker School of Medicine, Chicago, IL and ²University of Chicago, Chicago, IL.

Background: The 8th edition of the American Joint Committee on Cancer (AJCC) staging system for breast cancer has redefined breast cancer staging to better represent the heterogeneity of the disease. The previously established TNM system reflected only tumor size (T), nodal status (N), and distant metastasis (M). The updated staging system introduces new clinical and pathological prognostic staging systems by incorporating tumor grade, tumor markers, and genomic assays. Prospective comparisons of staging assignment between AJCC 7th and 8th edition staging systems have not been performed in the United States. The objective of this study was to compare subjects' assigned stage between the AJCC 7th and 8th edition staging systems.

Methods: Data were collected from patients with non-metastatic breast carcinoma who presented to the University of Chicago between January 1, 2018 and May 31, 2018. Upstaging or downstaging was defined as an increase or decrease by one or more letter or number stages (i.e. from IIA to IIB or IB). Descriptive data were generated for all collected data. Analysis was performed in Stata 14.0.

Results: Clinical anatomic and prognostic stages were assigned to 246 patients while pathologic anatomic and prognostic stages were assigned to 142 patients. Forty-seven patients underwent neoadjuvant therapy and were not assigned a pathologic prognostic stage, while 57 patients had not undergone surgery at our institution by the end of the study period and were not assigned a pathologic stage. Two patients had lobular carcinoma in situ and were no longer considered to have a malignancy by the 8th edition staging system; anatomic staging was otherwise unchanged from 7th edition to 8th edition staging in this cohort. Of the 246 patients assigned clinical anatomic and prognostic stages, 48 patients were upstaged (19.5%), 37 were downstaged (15.0%), and 161 were not affected (65.5%) by prognostic staging. Of the 142 patients assigned pathologic anatomic and prognostic staging, nine patients were upstaged (6.3%), 32 were downstaged (22.5%), and 101 were not affected (71.1%) by prognostic staging.

### Stage Changes with the AJCC 8th Edition

<table>
<thead>
<tr>

<td>15.0 (37)</td>
<td>65.5 (161)</td>
</tr>
<tr>
<td>Pathologic Stage</td>
<td>6.3 (9)</td>
<td>22.5 (32)</td>
<td>71.1 (101)</td>
</tr>
</tbody>
</table>

Four patients were eligible to be downstaged in pathologic prognostic staging by genomic assays such as Oncotype (consisting of Stage 1B or higher patients with T1N0M0 HER2 - ER + PR - Grade 3 disease or T2N0M0 HER2 - ER + disease). Of these patients, three had genomic assays performed by the end of the study period. Results from genomic assays did not affect the staging of these three patients.

Conclusions: Approximately one third of breast cancer patients were assigned new clinical or pathologic stages with the AJCC 8th edition staging system. These findings confirm that implementation of the new criteria for staging will be important to many patients in discussions of treatment and prognosis.
Molecular subtyping of androgen receptor-positive patients using gene expression profiles

Kevin J Thompson¹, Tejaswi Alaparthi¹, Jason P Sinnwell¹, Erin E Carlson¹, Xiaojia Tang¹, Matthew Bockol¹, Peter T Vedell¹, James N Ingle¹, Vera Suman¹, Richard M Weinshilboum¹, Liewei Wang¹, Judy C Boughey¹, Krishna R Kalari¹ and Matthew P Goetz¹. ¹Mayo Clinic, Rochester, MN.

Breast cancer is a heterogeneous disease, and unsupervised clustering approaches using gene expression data have identified 3-6 distinct subtypes of triple negative breast cancer (TNBC). A genomics and clinically distinct subtype of TNBC is referred to as LAR (Luminal Androgen Receptor). Tumors with this subtype typically express high levels of the AR and exhibit alterations within genes involved in the PI3K pathway (e.g. PIK3CA mutations). Prospective studies are underway using drugs that target the AR alone or in combination with PI3K and CDK 4/6 inhibitors. Given the importance of accurately identifying this subtype, we sought to develop an online tool that uses submitted gene expression data to confidently characterize LAR samples by corroborating the classification with previously published clustering approaches.

Methods: We have investigated TNBC RNA-Seq data from The Cancer Genome Atlas (TCGA) breast cancer study (N=123 samples) by cluster analysis. Analysis of the average silhouette width in both biased and unbiased K-means clustering approaches demonstrated LAR and basal as two distinct and significant clusters. A shrunken centroid model of 426 differentially expressed genes, named as CABAL (Clustering Among Basal and Luminal androgen receptor), was constructed by comparing LAR and basal subtypes.

Results: We applied the CABAL model to classify the four TNBC microarray datasets that were previously used in clustering experiments as well as an independent RNA-Seq data cohort. Non-negative matrix factorization (NMF) and fuzzy clustering were applied to the samples (N=1046). Clustering similarity among the methods was assessed with the adjusted rand index, and CABAL demonstrated significant similarity with both fuzzy and NMF clustering methods. Similarly, hierarchical clustering analysis performed on the pooled cohort of 1046 samples recapitulated the CABAL classification with an area under the receiver operating curve of 0.91.

Conclusions: Confident and robust identification of samples with the LAR phenotype is paramount in the assessment of clinical associations and therapeutic efficacy. To facilitate LAR identification, we have provided a web-based prediction tool of the CABAL classification, integrated with the NMF and fuzzy clustering results to identify candidate LAR samples. The end user is provided with the pair-wise adjusted rand indexes, thus reinforcing in the clustering characterizations. Further, our online LAR depiction tool provides a set of graphical and tabular summaries, which will be illustrated, while providing additional molecular characterizations of the PAM50 and Metabric classifications. The availability of this tool could advance the genomic research and treatment of TNBC patients.
Long term survival and tumor biology of screen-detected small non-palpable breast cancer in Chinese women: The smaller, the better?

Ying Xu¹, Bo Pan¹, Ru Yao¹, Yi-Dong Zhou¹, Feng Mao¹, Qing-Li Zhu¹, Huan-Wen Wu¹, Yan Lin¹, Song-jie Shen¹ and Qiang Sun¹.
¹Peking Union Medical College Hospital, Beijing, China.

**Background:** Tumor biology would reflect the prognosis and potentially the lead time and over-diagnosis rate of screen-detected small breast cancer [PMID: 28591529, 21452022 and 24888816]. Chinese women had earlier peak age of breast cancer incidence and used ultrasound as the primary screening imaging test on a hospital-basis [2016 SABCS P5-02-05, PMID: 27689334]. In our previous work, we showed that US detected non-palpable breast cancer (NPBC) had higher percentage of invasive and lymph node positive cancer, yet still could be regarded as low-risk cancer [PMID:27689334, 28412736]. This study was performed to investigate the prognostic impact of immunohistochemical subtypes and tumor size: the smaller the NPBC, the better the tumor biology and prognosis?

**Methods:** From January 2001 to December 2017, 6,423 consecutive asymptomatic women underwent mammography (MG) or ultrasound (US) guided biopsy in Peking Union Medical College Hospital. Among them, 159 T1a, 239 T1b, 377 T1c and 72 T2 NPBC were diagnosed and treated. The clinicopathological features, treatment choice, 10-year disease-free survival (DFS) and overall survival (OS) of the small NPBC (defined as ≤1.0cm, T1a+b) were reviewed and compared with T1c and T2 NPBC. Prognostic factors of these subgroups of invasive NPBC were identified.

**Results:** Compared to big NPBC, the T1a+b small NPBC showed more lymph node negative (p<0.001) and low Ki67 (<14%, p<0.001) cancers with earlier TNM stage (p<0.001), more luminal A subtype (p=0.003) and significantly improved 10-year DFS and OS (p=0.004). T1c+T2 NPBC had more triple-negative subtype and received more chemotherapy (p<0.001) and targeted therapy (p=0.008). Breast conserving rate and the use of radiation and endocrine therapy showed no significant difference.

Conclusion: Small asymptomatic NPBCs were detected when small because they were good in terms of low Ki67 index, favorable subtype, tumor biology and long term prognosis. On the contrary, T1c and T2 NPBCs were screened when already big or even with positive nodes without clinical symptoms indicating that they might have larger chance of becoming interval cancers.
Risk stratification by ultrasound for screen-detected non-palpable breast cancer in Chinese women: Regular low risk versus ultra-low risk?

Ying Xu¹, Bo Pan¹, Ru Yao¹, Yi-dong Zhou¹, Feng Mao¹, Qing-Li Zhu¹, Jing Zhang¹, Yan Lin¹, Song-jie Shen¹ and Qiang Sun¹.
¹Peking Union Medical College Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, P.R., China.

Background: Mammography (MG) screen-detected breast cancer has been established as low-risk in the western world. However, ultrasound (US) is currently the 'real-world' initial imaging test for breast cancer in China. In our previous work, we firstly showed with a multi-center randomized controlled trial that US could detect breast cancer with improved sensitivity and accuracy in high risk Chinese women [PMID: 25668012]. Then we demonstrated on a hospital-screening basis that US and MG detected non-palpable breast cancer (NPBC) had similar survival [2016 SABCS P5-02-05, PMID: 27689334]. This study was performed to test the hypothesis [Hypothesis would be published in the journal of Medical Hypothesis, 118 (2018):9-12] whether MG+/US- NPBC could be taken as ultra-low risk cancer which had more favorable clinical characteristics and survival than the regular low-risk NPBC.

Methods: From 2015-2017, 1,478 consecutive patients received biopsy with initial positive screening US (BI-RADS 4 and 5) at Peking Union Medical College Hospital. Among them, 206 US+/MG- and 135 US+/MG+ NPBC were diagnosed. Meanwhile, 371 patients who had negative initial screening US (BI-RADS 1, 2 and 3) and positive additional MG (BI-RADS 4 and 5) underwent MG-guided biopsies, and 88 MG+/US- NPBC were diagnosed. Clinical characteristics, treatment and 3-year disease free survival (DFS) and overall survival (OS) were analyzed and compared. Prognostic factors were identified.

Results: There was no significant difference in age, lymph node status, hormone receptor status, endocrine therapy, chemotherapy, targeted-therapy among the three subgroups of NPBC. MG detected significantly more ductal carcinoma in situ (DCIS, 59.1% vs 22.8% and 28.1%, p<0.001) whereas ultrasound diagnosed more invasive cancers (77.2% and 71.9% vs 40.9%, p<0.001), multifocal cancer (p=0.020) and patients who received breast-conserving surgery (p<0.001) and needed radiotherapy (P=0.001). No significant difference was found for 3-year DFS and 3-year OS were all 100%, although MG+/US- NPBC showed a trend of better DFS.

Conclusion: MG+/US- NPBC had satisfactory prognosis, higher percentage of DCIS and might be taken as 'ultra-low risk' cancer. Hence US had the potential of stratifying the screen-detected NPBC into regular low risk (US+/MG+ and US+/MG-) and ultra-low risk (MG+/US-).
Breast cancer diagnosis is associated with relative left ventricular hypertrophy

Amy Kirkham¹, Lingyu Xu¹, Harris Wang¹, Kelvin Chow¹, Joseph J Pagano¹, James White², Mark J Haykowsky³, Jason RB Dyck¹, Justin A Ezekowitz¹, Gavin Y Oudit¹, John R Mackey¹, Richard B Thompson¹, Edith Pituskin¹ and Ian Paterson¹. ¹University of Alberta, Edmonton, AB, Canada; ²University of Calgary, Calgary, AB, Canada and ³The University of Texas Arlington, Arlington, TX.

Background: Cardiac dysfunction is a major concern for patients with breast cancer (BC) receiving adjuvant therapy. Retrospective, cross-sectional echocardiographic data suggests that patients with cancer have reduced myocardial strain prior to cancer therapy exposure. Cardiac magnetic resonance (CMR) is the gold standard imaging modality for cardiac structure and function and can also evaluate myocardial micro-architecture with T1 mapping. We hypothesized that treatment naïve patients with early-stage BC (ESBC) have abnormal myocardial tissue characteristics on CMR.

Methods: Women with newly diagnosed ESBC were prospectively recruited for CMR prior to cancer drug treatment. Those with hypertension, diabetes mellitus or prior cancer treatments were excluded. Age and sex matched healthy controls were identified from a prior prospective study. All participants underwent a non-contrast CMR scan on a 1.5T magnet. Image acquisition included cines for cardiac structure and function as well as T1 mapping using saturation recovery single-shot acquisitions. Global longitudinal strain (GLS) was derived from cine images. Demographics and imaging metrics for healthy controls and patients were compared using two-sample t-test.

Results: 106 patients with ESBC, mean age 51±9, were included along with 55 matched healthy controls. Body mass index and systolic blood pressure were similar between groups, however resting heart rate was elevated in patients compared to controls, 77±11 vs 67±11 /min respectively, p<0.001 (Table 1). On CMR there was no difference in left ventricular volume or ejection fraction however global longitudinal strain was higher in patients compared to controls, -20.9±2.3 vs -19.9±3.7%, p=0.04 (Table 2). Left ventricular mass was higher compared to controls, 52±6 and 47±6 g/m2 respectively, p<0.001. However myocardial T1 was similar between groups, T1=1198±27ms for controls vs 1206±46ms for patients, p=0.42.

Conclusions: The cardiac phenotype of patients with ESBC is characterized by relative left ventricular hypertrophy with normal myocardial tissue. Further understanding of the mechanisms involved may provide insight into the cardiovascular risk associated with BC diagnosis.

New diagnostic tools for bone health assessment: Perspectives in medical oncology

Francesca Cosmi1,2, Alessandro Del Conte2, Luisa Foltran2, Alessandra Nicolosi3 and Silvana Saracchini2. 1University of Trieste, Trieste, TS, Italy; 2IRCCS CRO, Aviano, PN, Italy and 3M2TEST srl, Trieste, TS, Italy.

Background
Pituitary down regulators, aromatase inhibitors tamoxifen and chemotherapeutic drugs, all have a negative impact on bone health in breast cancer patients. Although trabecular bone accounts for only 20% of skeleton mass, bone resistance depends also on the its micro-architecture, or quality, of, in addition to bone density. The BESTEST® is an innovative and inexpensive diagnostic method that gives an indication of the quality of the bone structure: it measures the weight-bearing capacity of the bone structure, evaluated from simulated application of loads on bone structure images acquired by radiograms in the proximal epiphysis of the hand. Results are expressed as BSI_T-score and BSI_Z-score (which refers the results to the average value for the same age) and provide precious add-on information to densitometry.

We discuss the preliminary results obtained in female patients undergoing breast cancer treatment.

Material and methods
100 Caucasian women, took BESTEST® as follow-up while undergoing oncological treatment. Femoral neck DXA T-score available in a subgroup of 60. 10 patients self-reported an osteoporotic fracture, DXA T-score available for 8. Control population: 200 women, accessing BESTEST® and DXA for screening purposes, 30 self-reporting an osteoporotic fracture.

Results

<tr>
<td>Control</td>
</tr>
</tbody>
</table>

The fractured subgroup exhibits significantly lower BSI T-score than the population (T-test p< 0.0100) and results are similar after BSI Z-score correction for age (T-test p = 0.0300). The BSI T-score of the DXA subgroup is representative of the oncological population undergoing treatment (T-test p=0.8668).

As expected, BSI T-score and DXA T-score are not correlated: $R^2 = 0.0917$ in the control and $R^2 = 0.0294$ in the population. The DXA subgroup exhibit significantly lower BSI T-score than the control (T-test p = 0.0002) and similar results are obtained after BSI Z-score correction for age. A lower significance (T-test p = 0.0281) is found for DXA T-score. The 8 fractured oncological patients exhibit significantly lower values of BSI T-score that the oncological population (T-test p = 0.038) and all patients have a BSI T-score indicative of a compromised trabecular structure. DXA T-score values cannot be considered statistically different (T-test p = 0.6744) and results span all possible diagnostic results from high risk to normal.

Conclusions
Statistical analyses show that bone micro-architecture is indeed affected by oncological treatment and that bone alterations due to oncological treatment are easily detected with BESTEST, especially when associated with fractures.

This preliminary study clearly provides a rational background for further, deeper investigations into the use of a new, rapid and
safe technique for monitoring the effect of breast and prostate cancers therapies on bone micro-architecture modifications.
The breast cancer care continuum in Tanzania: From accessing care for breast concerns to cancer diagnosis and treatment

Anne F Rositch¹, Christina A Chao¹, Nestory Masalu² and Kala Visvanathan¹. ¹Johns Hopkins Bloomberg School of Public Health, Baltimore, MD and ²Bugando Medical Centre, Mwanza, Tanzania, United Republic of.

Background: Tanzania, like many low to middle income countries, has developed their first ever national guidelines focusing on early diagnosis of breast cancer to combat the high fatality rates. Thus, one component of the “Time to A.C.T.” study sought to provide critical information on women presenting to a health facility who might need clinical breast examination per the new guidelines and ultimately how many of these women were diagnosed and treated for breast cancer.

Methods: In this retrospective cohort study, data were abstracted from 777 medical charts from three health facilities spanning the health system hierarchy (district n=103, regional n=64, and zonal n=610 hospitals) in Mwanza, Tanzania. Charts were identified from the departments of oncology, surgery, gynecology, obstetrics and emergency medicine, and focused on women aged 30 and older who were seeking or receiving care related to any “breast concern” from January 2015 to April 2018.

Results: The median age of women seeking care for breast concerns was 43 years (IQR: 34-54). Women most commonly presented with complaints of swelling (43%), a palpable lump (27%), or pain (24%) of the breast or nipple. Ultimately, 26% of these care-seeking women were diagnosed with breast cancer (including DCIS=2, invasive ductal or lobular cancer=121, and metastatic cancer =15), of whom 73% were pathologically confirmed. Treatment data were available for only 79 women with breast cancer: 24 had surgery only, 33 had chemotherapy only, 21 had surgery and chemotherapy, and 1 woman had surgery, chemotherapy and radiation.

Conclusions: This study increases our understanding of the health services needs associated with Tanzania’s commitment to down stage breast cancer through early detection and treatment. Almost a third of women who presented with a breast concern were diagnosed with breast cancer. Although this likely reflects the fact the majority of medical charts were identified at a zonal hospital that has the most capacity for cancer diagnosis and treatment, it also highlights the importance of getting women into care, proper referrals and ultimately diagnosis and treatment. This information on who seeks care, why, and where will help appropriately allocate and scale up capacity for breast cancer care.
The implementation of a patient referral service in a Brazilian cancer center

Fabiana B Makdissi1, Edson R Costa Filho2, Erica C Conti3 and Lucimara C Santos3. 1AC Camargo Cancer Center, Sao Paulo, Brazil; 2AC Camargo Cancer Center (Strategy And Innovation), Sao Paulo, Brazil and 3AC Camargo Cancer Center (Navigator Nurses), Sao Paulo, Brazil.

BACKGROUND: Healthcare systems face problems of cost increases and poor delivery organization. Integrated delivery may reduce costs and improve quality and health outcomes.

OBJECTIVE: To describe how the A.C. Camargo Cancer Center, aiming at greater integration, implemented a referral service for breast cancer patients.

METHODS AND RESULTS: The process was divided in three phases: 1) AS IS ANALYSIS, 2) BENCHMARKING, 3) PILOT & IMPLEMENTATION.

1) AS IS ANALYSIS
A.C. Camargo was responsible for treating 16% of all breast cancer cases that arose from 2000 to 2012 in São Paulo State. Prior to implementation of the program, there was no special patient classification at the initial appointments.

2) BENCHMARKING
As proposed by MD Anderson Cancer Center, we used the patient's classification at the time of an appointment request (regular screenings, undiagnosed or breast cancer patient).
As proposed by Memorial Sloan Kettering Cancer Center, we used a "Physician Referral Service" staffed by "Referral Specialists" and "Trained Oncology Nurses" to collect patient information prior to the first appointment.
As suggested by Princess Margaret Cancer Center, we collected patient care data (e.g., abnormal imaging, palpable lump).

3) PILOT & IMPLEMENTATION
Phase I: Feb. 13, 2017 to Dec. 28, 2017. We reached 7% of new patients in the Breast Surgery Department (BSD): 48% were in the Cancer Group, 45% in the Abnormal Imaging Group (Undiagnosed) and 7% in the Palpable Lump Group.
New patients were classified by the Call Center. Electable cases were referred to the Nurse Navigator, who proceeded with appointments according to protocol.
Root cause analysis of non-captured patients led to the following improvements: extension of participant Call Center cells, script review, and implementation of a training program.
The Phase I results led to the following improvements: 1) reclassification of a subgroup with highly suspicious images as the "Cancer Group"; 2) Transfer of the new referral and scheduling functions to the Call Center; and 3) Implementation of new "first appointment items", personalized for each patient group. This information was displayed to the physician and operations staff in advance of the consultation.

Phase II: Dec. 29, 2017 to June 28, 2018. We reached 100% of new patients in the BSD: 17% were in the Cancer Group, 23% in the Abnormal Imaging Group, 8% in the Palpable Lump Group, and 53% in the Regular Screening Group.
Phase II results led to the following improvement: 1.) Distribution of the cancer groups' first appointment items equally among surgeons.

Phase III: From June 29, 2018 to the operation. Implemented new appointment items for new clinical patients and for pre-treatment returns.

CONCLUSION: With implementation of the Referral Service, the BSD at A.C. Camargo is now able to identify the reason for each appointment before the first consultation. This practice promotes operational predictability and more effectively organizes the personalized journey of each patient, including care on the part of Nurse Navigators for the most critical cases.

Harnessing the distinctive properties of tumor-adjacent tissues to develop ethnicity-dependent biomarkers of breast cancer

Harikrishna Nakshatri¹, Brijesh Kumar¹, Heather Burney¹, Mary L Cox¹, Max Jacobson¹, George Sandusky¹, Crislyn D'Souza-Schorey² and Anna Maria Storniolo¹. ¹Indiana University School of Medicine, Indianapolis, IN and ²University of Notre Dame, Notre Dame, IN.

Recent data demonstrating a correlation between lymph node positivity at the time of detection, and the probability of disease recurrence even decades post detection only solidifies the principle that the detection of breast cancer prior to lymph node metastasis can appreciably better clinical outcomes. Although radiologic methods have greatly improved early detection and remain the mainstay for detection, molecular assays to complement existing strategies will reduce number of false positives as well as enhance detection in cases that preclude conclusive diagnosis with radiologic techniques. Normal breast biology is routinely studied using tissues from reduction mammoplasty or normal tissues adjacent to tumor (NATs). However, studies have shown histologic abnormalities in reduction mammoplasty samples and DNA methylation and gene expression abnormalities in NATs due to “field” effects of the tumor. To interrogate the differences between normal breast and NATs as potential early detection markers, we created a tissue microarray (TMA) comprising breast tissues of 100 age-matched healthy women from the Komen Tissue Bank (KTB) and tumor-NAT pairs from 100 women (a total of 300 samples). Approximately 50% of women in each set were of African American (AA) ancestry and the remaining was of European decent. The TMAs was curated as such, because of our recent findings on ethnicity-dependent differences in breast stem-luminal progenitor-mature cell hierarchy. TMA was analyzed for ZEB1, an oncogenic transcription factor that is central to cell fate and stemness, and estrogen receptor alpha (ERα) and FOXA1, which are expressed predominantly in hormone-responsive mature luminal cells. ZEB1 expressing cells were localized to surrounding ductal structures of the normal breast, whereas ERα+ and FOXA1+ cells were located within the ductal compartment. KTB-normal of AA women contained significantly higher levels of ZEB1+ cells compared to KTB-normal of Caucasian women (CA). We observed only marginal increases in ZEB1+ cells in NATs or tumors of AA women. By contrast, in CA women, both NATs and tumors compared to KTB-normal contained higher levels of ZEB1+ cells. The unique localization pattern external to the ductal structures, as well as intrinsically higher expression in AA women suggest that ZEB1+ cells serve not only as stem cells from which cancers may originate but could also contribute to the microenvironment conducive for ductal tumor progression leading to aggressive and early onset of breast cancer as observed in AA women. Conversely, KTB-normal of AA showed modestly higher FOXA1 expression compared to CA women, and further, FOXA1 levels were declined in NATs of AA but not CA women. ERα levels did not change in any of our analyses, pointing to the specificity of ethnicity-dependent changes in this TMA. We also noted ethnicity-dependent variations in the levels of CD8+ T cells, PD-1+ immune cells and PD-L1+ cells but not CD68+ macrophages in NATs, suggesting distinctive immune environment in NATs. This comprehensive approach will not only serve as a platform to develop tumor-adjacent “normal” tissues as molecular markers for early detection but also provides a molecular basis for aggressive breast tumor in AA women.
Estrogen receptor β agonists inhibits syngeneic mammary tumor growth through cell-cycle arrest by modulating cell-cycle regulators

Kumaraguruparan Ramasamy¹, Cathy Samayo¹, Naveen K Krishnegowda¹, Aswani Thurlapati¹, Ratna K Vadlamudi¹ and Rajeshwar R Tekmal¹. UT Health San Antonio, San Antonio, TX.

Breast Cancer is the main cause of cancer-associated mortality in women worldwide. The estrogen receptors (ER's) play an important role in normal mammary gland development, as well as in breast cancer. Estrogen Receptor α is expressed in 70% of breast cancers, where it contributes to increased cell proliferation and decreased cell death. Endocrine therapies such as anti-estrogens and aromatase inhibitors target ERα signaling and improve outcomes of these patients. Syngeneic, immunocompetent mouse models are essential for elucidating the mechanisms and for evaluating novel strategies for the treatment of breast cancer. In contrast to the tumor-inducing role of ERα, ERβ has been shown to have tumor suppressive activities in various cancer, including the breast cancer. Compounds that selectively activate ERβ hold promise because they could potentially avoid the unwanted effects of ERα activation, while exploiting the tumor-suppressive function of ERβ. In the present study, we assessed the antitumor effects of ERβ agonists using three different syngeneic mouse models; D2A1 (BALB/c) and MM51 (FVB) syngeneic models and ex-vivo culture of highly metastatic cell line E0771 (C57/B6). Effect on in vitro cancer cell growth was evaluated by cell proliferation and clonogenic assays. Cell cycle distribution was analysed by flow cytometry. Our results demonstrate that ERβ agonists LY500307 and S-Equol not only inhibited the growth of all three mouse mammary tumor cell lines, but also reduced the colony formation ability. ERβ agonists also induced the cell-cycle arrest in time and dose-dependent manner. In mechanistic studies, ERβ agonists LY500307 and S-Equol, modulated the protein levels of cyclin-dependent kinases (CDKs) (4, 6, and 2), cyclins (D1 and E), in a differential manner in these three cell lines. Our in vivo studies of D2A1 and MM51 cells demonstrates that ERβ agonist LY500307 inhibited the tumor growth and the effect was more pronounce in combination with aromatase inhibitor letrozole. Ex-vivo model of E0771 cells showed that LY500307 has potential to dramatically reduce the proliferation of mouse mammary tumor growth. Together, these results identify potential molecular targets and anticancer effects of ERβ agonists in mouse mammary tumors.
Consequences of FOXP1-mediated transcriptional repression of the mitotic checkpoint gene MAD2 in breast cancer

Cheng-Yu Lin¹, Mehlika Hazar-Rethinam¹, Pulari Thangavelu¹, Eloise Dray² and Pascal HG Duijf¹. ¹The University of Queensland Diamantina Institute, University of Queensland, Brisbane, Queensland, Australia and ²Institute of Health and Biomedical Innovation, Queensland University of Technology, Brisbane, Queensland, Australia.

Introduction:
The mitotic checkpoint, or spindle assembly checkpoint (SAC), is a safeguard mechanism that prevents chromosome missegregation during mitosis. It is well established that overexpression of the mitotic checkpoint component MAD2 leads to chromosome instability (CIN) and tumorigenesis. MAD2 expression is controlled by transcriptional activator and repressor E2Fs, as well as by cell cycle dependent element/cell cycle homology region (CDE/CHR) sequences in its promoter. However, precisely how MAD2 transcription is regulated has remained elusive. Focusing on breast cancer, we therefore aimed to identify novel MAD2 transcriptional regulators and to characterize how these might contribute to CIN and tumor formation.

Materials and Methods:
Potential MAD2 transcriptional regulators were identified using a DNA-protein pull-down assay and mass spectrometry. In-depth characterization of protein-DNA interactions and transcriptional effects were studied using chromatin immunoprecipitation, promoter mutagenesis and reporter assays. Cell lines in which identified repressors were stably knocked-down by shRNAs were used to investigate changes in MAD2 protein levels, cell cycle progression and chromosome segregation fidelity. In silico analyses and immunohistochemistry on tissue microarrays were used to study associations between expression of the regulators and MAD2 at the mRNA and protein levels in breast cancer. Repressor expression levels were also assessed in the context of breast cancer patient prognosis and survival.

Results and discussion:
We identified the forkhead box transcription factor FOXP1 as a main transcriptional repressor of MAD2 expression. FOXP1 reduces MAD2 promoter activity via direct binding to CDE/CHR elements. Furthermore, knockdown of FOXP1 expression decreases the proportion of cells in G2/M phase. In addition, low FOXP1 expression strongly correlates with high MAD2 expression at the mRNA and protein levels, and with poor patient prognosis in breast cancer, especially triple-negative breast cancer.

Conclusion:
We identified FOXP1 as a novel transcriptional repressor of MAD2 expression. Our results suggest that reduced FOXP1 levels in breast cancer affect both MAD2 expression and cell cycle progression. This may promote CIN and tumor formation via upregulation of MAD2. Our results may have important implications for breast cancer diagnostics and, potentially, therapeutic targeting.
Breast cancer cell-derived IL-1B drives metastasis and colonisation of the bone microenvironment

Penelope D Ottewell1, Diane V Lefley1, Katie Freeman1, Walter M Gregory2, Andrew M Hanby3, Amy R Spicer-Hadlington4, Xinming Liu1, Steven MJ Bradbury1, Lisa Hambley1, Gloria Allocca1, Victoria Cookson1, Marianna Kruithof de-Julio5, Robert E Coleman1, Janet E Brown1, Ingunn Holen1 and Claudia Tulotta1. 1University of Sheffield, Sheffield, South Yorkshire, United Kingdom; 2University of Leeds, Leeds, South Yorkshire, United Kingdom and 3University of Bern, Bern, Switzerland.

Background: Breast cancer bone metastases are incurable and new therapeutic targets needed. After homing and colonising bone, cancer cells remain dormant, until signals from the microenvironment stimulate their proliferation to form overt metastases. We have recently identified interleukin-1B (IL-1B) as a potential marker for predicting breast cancer patients at increased risk of skeletal relapse and established a role for IL-1 signalling in tumour dormancy in bone. Here we present novel data to support that tumour cell-derived IL-1B plays major roles in breast cancer metastasis and growth in bone.

Methods: Tumour/stromal IL-B and IL-1R1 expression was assessed in samples from the AZURE study following immunohistochemical staining. A humanised mouse model of MDA-MB-231 bone metastasis was used to assess effects of the IL-1R antagonist, Anakinra, on tumour growth and spontaneous metastasis. Effects of tumour cell-derived IL-1B on parameters associated with epithelial to mesenchymal transition and metastasis were measured by ELISA, QPCR, Western blot, transwell and scratch assays in MDA-MB-231, MCF7 and T47D cells transfected with IL-1B/control. Homing of breast cancer cells to bone was monitored in BALB/c nude mice intra venously injected with IL-1B overexpressing/control cells. To assess anti-tumour effects of IL-1 inhibition combined with standard of care, BALB/c or C57BL/6 mice were injected with 4T1 or E0771 cells (intra cardiac or intra ductal) 7-days prior to administration of Anakinra, doxorubicin, zoledronic acid (ZA) or placebo, alone or in combination for 14 days.

Results: In tissue samples from >1300 patients with stage II/III breast cancer, active IL-1B in tumour cells correlated with relapse in bone (hazard ratio 1.85; 95% CI 1.05-3.26; P=0.02) and other sites (hazard ratio 2.09; 95% CI 1.26-3.48; P=0.0016). In a model of spontaneous human breast cancer metastasis to human bone, Anakinra significantly reduced metastasis to bone (from 80% in control animals to, 20% in Anakinra treated mice) and reduced the number of tumour cells shed into the circulation. Genetic manipulation of breast cancer cells to overexpress IL-1B demonstrated that exogenous production of IL-1B promoted EMT (decreased E-Cadherin, N-Cadherin and G-Catenin), invasion, migration and organ-specific homing in ER-ve (MDA-MB-231) and ER+ve (T47D and MCF7) cells in vitro and in vivo. Contact between tumour cells and osteoblasts or bone marrow cells increased IL-1B secretion from all three cell types. Exposure of tumour cells to IL-1B in the absence of bone cells did not stimulate tumour cell proliferation. Instead, elevated concentrations of IL-1B caused expansion of the bone metastatic niche (increased osteoblasts and blood vessels) that in turn stimulated tumour proliferation.

Adding Anakinra to chemotherapy and ZA to mice injected with E0771 cells completely prevented bone metastasis formation and reduced extra-skeletal metastasis by 33%. In mice injected with 4T1 cells, the triple combination therapy reduced bone metastasis by 50% and extra-skeletal metastases by 65%.

Conclusion: Our novel data demonstrate that IL-1B/IL-1R1 signalling plays an important role in breast cancer metastasis to bone. Pharmacological inhibition of IL-1B has potential as a novel treatment.
Novel mechanisms of Rac1 activation by the Cullin-3/KCTD10 ubiquitin E3 complex in HER2-positive breast cancer

Akari Murakami¹, Masashi Maekawa²,³, Erina Kusakabe¹, Haruna Yamasawa¹, Reina Aoki¹, Saaya Komatsu¹, Kana Taguchi¹, Kanako Nishiyama¹, Michiko Yamashita¹, Wakana Sugimori¹, Katsuhisa Kawai⁴, Jun Nakayama⁵, Nobukazu Araki⁴, Kentaro Semba⁶, Tomohiko Taguchi⁶, Yoshiaki Kamei¹, Yasutsugu Takada¹ and Shigeki Higashiyama²,³. ¹Ehime University, Toon, Japan; ²Ehime University Graduate School of Medicine, Toon, Japan; ³Proteo-Science Center, Ehime University, Toon, Japan; ⁴School of Medicine, Kagawa University, Kita-gun, Japan; ⁵School of Advanced Science and Engineering, Waseda University, Shinjuku-ku, Japan and ⁶Graduate School of Life Sciences, Tohoku University, Sendai, Japan.

Overexpression of HER2 in breast cancer is correlated with poor prognosis. HER2-targeted drugs, such as trastuzumab and lapatinib, have been successful to treat HER2-positive breast cancers, however, the acquisition of the drug resistance of the cells is recognized. Here we suggest the novel molecular targets to cure HER2-positive breast cancers.

The oncogenic roles of Rac1, a Rho family small GTPase, in a variety of cancers have been demonstrated. For example, the elevated expression or hyperactivation of Rac1 is frequently observed in human cancers, correlating with their aggressiveness and poor prognosis. In breast cancers, upregulation of Rac1 GEF (GTP exchange factor) and downregulation of Rac1 GAP (GTPase activating protein) have been reported. Moreover, activation of Rac1 contributed to trastuzumab resistance, which poses a serious problem during chemotherapy.

In the present study, we first investigated in detail in which subtypes of breast cancers mRNA expression of Rac1 is correlated with their poor prognosis. Using the METABRIC database, we found that high mRNA expression of Rac1 significantly correlated with the poor prognosis of HER2-positive breast cancer (p=0.0012, High: n=49, Low: n=171). On the other hands, other three types (basal, claudin-low, or luminal-B type) did not show significant correlation between the expression levels of Rac1 mRNA and their prognosis (p=0.15, High: n=97, Low: n=102; p=0.052, High: n=110, Low: n=89; p=0.17, High: n=70, Low: n=391; respectively). In luminal-A type breast cancer, low mRNA expression of Rac1 significantly correlated with poor prognosis (p=0.0046, High: n=492, Low: n=187).

We next investigated the molecular mechanism underlying Rac1 activation in HER2-positive breast cancer cells, SKBR-3 cells. We found that Cullin-3 (CUL3, a subunit of a RING ubiquitin E3 ligase complex) and its adaptor protein KCTD10 are essential for Rac1 activation. Mechanistically, CUL3/KCTD10 ubiquitinate RhoB, a Rho family small GTPase that suppresses the activation of Rac1, leading to the degradation RhoB. We also found that HER2 signaling is essential for the activation of Rac1.

Conclusions: This study reveals that the novel molecular axis CUL3/KCTD10/RhoB regulates the Rac1 activation in HER2-positive breast cancer cells. The interference of CUL3/KCTD10 complex formation may be a new strategy to the treatment of HER2- and Rac1-positive breast cancers.
Isoform specific targeting of insulin receptor

Kelly LaPara¹, Jie Ying Chan¹, Alina Zdechlik², Koby Ljunggren¹, Daniel Schmidt², Benjamin Hackel² and Douglas Yee¹².
¹University of Minnesota Cancer Center, Minneapolis, MN and ²University of Minnesota, Minneapolis, MN.

The insulin receptor (InsR) exists in both an A and B isoform. InsR-B differs from InsR-A by the inclusion of exon 11, which encodes 12 amino acid residues at the C-terminus of the InsR alpha-subunit. Increased InsR-A expression is associated with mitogenic signaling pathways while InsR-B is linked to insulin-mediated metabolic functions. Predominant InsR-A expression may therefore be important in growth and fetal development of embryos, whereas predominant InsR-B expression has a role in metabolic insulin action in adult life. Increased InsR-A expression is seen in breast cancer. In endocrine resistant breast cancer, InsR-A is expressed at high levels (Gradishar, et al. Clin Cancer Res 22:301 2016 PMID: 26324738). Thus, developing InsR-A specific inhibitors could be a useful therapy for breast cancer. We have previously published InsR specific binders using a T7 phage gene 2 protein (Gp2), a small protein scaffold (Chan, et al. Mol Cancer Ther 16:1324 2017 PMID: 28468775), with the long-term goal of creating effective InsR inhibitors and diagnostics. Using yeast display and directed evolution, we identified three Gp2 variants (Gp2 #1, #5, and #10) with low nanomolar affinity and specific binding to cell surface InsR. We have shown that these Gp2 variants inhibited insulin-mediated monolayer proliferation in both endocrine-sensitive and resistant breast cancer, but did not downregulate InsR expression. To further characterize the specificity of Gp2 variants, we used two techniques. HEK293T cells were infected with lentiviral vectors expressing either InsR-A tagged with mCherry or InsR-B tagged with eGFP. Using these cells, we performed “mock panning” and showed the Gp2 #5 variant bound both InsR-A and InsR-B, but had higher affinity for InsR-B. We also incorporated Gp2 #5 into the capsid of a tropism-null adeno-associated virus (AAV). Using this Gp2-AAV, we infected HEK293T-InsR-A or InsR-B cells at a number of different multiplicities of infection. These data were consistent with panning data and showed specific Gp2-AAV infection of cells expressing high levels of InsR-B, but not InsR-A. Thus, our data show that Gp2 variants we created have a higher affinity for InsR-B than InsR-A. Despite this preferred affinity, these Gp2 binders have sufficient binding to InsR-A to disrupt the biological effects of insulin in breast cancer cells. Thus, even relatively low affinity binding to InsR-A can disrupt its function. Further development of InsR-A Gp2 binders may be developed and provide more specific targeting of the breast cancer specific isoform of InsR.
Leptin modulates exosome biogenesis in breast cancer cells through an enhanced Hsp90/Tsg101 interaction

Luca Gelsomino¹, Cinzia Giordano¹, Ines Barone¹, Salvatore Panza¹, Giuseppina Augimeri¹, Daniela Bonfiglio¹, Stefania Catalano¹ and Sebastiano Andò¹. ¹University of Calabria, Arcavacata di Rende, CS, Italy.

Exosomes, small membrane vesicles secreted by both normal and malignant cells upon fusion of endosomal multivesicular bodies (MVBs) with the plasma membrane, play an important role in cell-to-cell communication. Several reports have highlighted the involvement of exosomes in many aspects of breast cancer (BC) development and progression, thus mounting interest in the potential exploitation of these vesicles and their cargoes as cancer biomarkers, drug delivery systems, and for the development of novel therapies. It has been extensively demonstrated the involvement of the obesity hormone leptin in all steps of breast tumorigenesis, but up to now its role in modulating breast cancer exosome generation has not been investigated. Here, we studied the effect of leptin on exosome biogenesis and secretion in estrogen receptor α (ERα)-positive MCF-7 and triple negative MDA-MB-231 BC cells. First, we revealed by Transmission Electron Microscopy (TEM) that the number of MVBs in the cytoplasm of leptin-treated MCF-7 and MDA-MB-231 BC cells was significantly increased compared to control untreated cells. Next, we characterized size distribution, particle number and protein cargo of exosomes, isolated by ultracentrifugation method, from conditioned media (CM) of cells treated or not with leptin. Nanoparticle Tracking Analysis revealed that the concentration of exosomes in the leptin treated MCF-7- and MDA-MB-231-CM was significantly higher compared to untreated samples. Furthermore, exosomes quantification by Acetylcholinesterase activity showed that the full leptin receptor antagonist, peptide LDFI, abrogated leptin-induced exosome secretion. Exosomes from leptin treated cells showed an increased expression of the leptin target gene Heat shock protein 90 (Hsp90) and its client protein HER2, along with activated leptin signaling effectors (pJAK2, pSTAT3, and pMAPK42/44) compared to exosomes from untreated cells. Mechanistically, our results demonstrated that, among proteins involved in exosome biogenesis, leptin significantly increased protein expression of the well-known exosomal luminal marker Tumor susceptibility gene 101 (Tsg101), without affecting its mRNA levels. Thus, we aimed to analyse specific Tsg101 protein-protein interaction as a possible mechanism able to modulate its stability or half-life within the cells. To answer this question, we performed, in MCF-7 BC cells, co-immunoprecipitation studies combined with mass spectrometry. Analysis of the spectra identified Hsp90 as a specific Tsg101 interacting protein, and concomitantly immunoblotting assays revealed a specific interaction between HSP90 and Tsg101 in basal condition that was further increased upon leptin exposure. Accordingly, leptin-induced Tsg101 protein levels were completely abrogated in the presence of specific Hsp90 inhibitor, 17-allylamino-17-demethoxygeldanamicin.

In conclusion, our results demonstrate for the first time that leptin was able to increase exosomes release in BC cells, through an up-regulation of Tsg101 expression at posttranslational level. These findings, providing additional insights into the molecular mechanism governing exosome generation in BC cells, might open new avenues for therapeutic intervention in BC.
eEF1A2 facilitates PTEN-GSK3β mediated Aurora-A protein degradation during S-G2 phase inactivated in PTEN-deficient breast cancer

Warapen Treekitkarnmongkol¹, Luisa Maren Solis¹, Kazuhiro Kai¹, Alastair M Thompson¹, Weihua Tian¹, Ignacio I Wistuba¹, Kaori Sasai², Yoshimi Jltsumori², Aysegul A Sahin¹, David H Hawke¹, Jonathan M Lee³, Lidong Qin⁴, Tasneem Bawa-Khalfe⁵, Roland Rad⁶, Kwong K Wong¹, Catherine M Abbott⁷, Hiroshi Katayama² and Subrata Sen¹. ¹The University of Texas M.D. Anderson Cancer Center, Houston, TX; ²Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan; ³University of Ottawa, Ottawa, ON, Canada; ⁴Houston Methodist Research Institute, Houston, TX; ⁵University of Houston, Houston, TX; ⁶Technische Universität München, München, BY, Germany and ⁷University of Edinburgh, Edinburgh, United Kingdom.

The AURKA gene, encoding Aurora kinase-A (Aurora-A), is frequently amplified and overexpressed across multiple cancer types correlating with poor prognosis. Although the AURKA gene is frequently amplified in human cancers, underlying mechanism(s) for Aurora-A protein stability through different phases of cell cycle are not well elucidated. Inhibiting the kinase activity and promoting protein degradation are two well-validated conceptual strategies for targeting protein kinases in cancers. Here, we demonstrate that Eukaryotic Elongation Factor 1 Alpha 2 (eEF1A2) facilitates PTEN-GSK3β mediated Aurora-A protein degradation through the SCF complex (SKP1-Cul1-FBXW7) during the S/G2 phase of proliferating cells. In contrast, this mechanism is inactivated in cancer cells accompanying PTEN-GSK3β pathway deficiency. Mechanistically, eEF1A2 interacts with Aurora-A, GSK3β, FBXW7 and Cul1-E3 ligase, as the SCF complex, to facilitate Aurora-A polyubiquitination for 26S proteasomal degradation. eEF1A2 promotes PTEN phosphorylation at T366 and stability, inactivates AKT and activates GSK3β which in turn phosphorylates Aurora-A at S283, S284 and S342. The phosphorylation of Aurora-A at S342 is detected during S/G2 phase of cell mitosis in parallel with eEF1A2-SCF complex formation with active form of GSK3β and neddylated Cul1. Conversely, genetic ablation of EEF1A2 and PTEN, activation of AKT, inhibition of GSK3β, expression of Aurora-A phosphodeficient-mutant attenuates the Aurora-A protein degradation which is corroborated in Aurora-A overexpressing mouse mammary carcinomas and human breast carcinomas. This study identifies a novel mechanism of Aurora-A protein degradation mediated eEF1A2-PTEN-GSK3β pathway and provides a framework for the discovery of Aurora-A therapeutic targets in breast cancer that harbors deficiency of PTEN tumor suppressor pathway.
Endothelial nitric oxide synthase gene intron4 VNTR polymorphism in patients with breast cancer

Meral Gunaldi¹, Nilgun Isiksacan², Sacide Pehlivan³ and Sinan Binboga². ¹Istanbul Aydin University Medical School, WM Medical Park Hospital, Istanbul, Turkey; ²Bakirkoy Training and Research Hospital, Istanbul, Turkey and ³Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey.

Background: Endothelial nitric oxide synthase (eNOS), also known as NOS3 is an enzyme that in humans is encoded by the NOS3 gene located in the 7q35-7q36 region of chromosome 7. Nitric oxide (NO) is synthesized from L-arginine by eNOS in the vascular endothelium and plays crucial roles in cellular proliferation. In the present study, it is hypothesized that polymorphisms of the Intron4b/a variable number of tandem repeat (VNTR) polymorphism Intron4b/a in the eNOS gene may be associated with an increased risk in the developing breast cancer.

Methods: We included 38 (38 F/Female) patients with breast cancer and 70 (44M/26F) healthy controls. The VNTR polymorphism in intron4 (intron4b/a) was analyzed by PCR. The results were statistically analyzed by calculating the odds ratios (OR) and 95% confidence intervals using the χ² test.

Results: The distributions of genotype and allele frequency was compared among the groups. The bb, ab and aa genotypes were observed in 29 [76.3%], 9 [23.7%], 0 [0%] patients with breast cancer and in 33 [47.1%], 15 [21.4%], 22 [31.5%] healthy controls respectively. The b and a alleles were observed in 67 [88.2%], 9 [11.8%] patients with breast cancer and in 81 [57.8%], 59 [42.2%] healthy controls respectively. The susceptibility to patients with breast cancer had significantly higher frequencies in bb genotype (p=0.004 OR=3.613). The patients with breast cancer had significantly lower frequencies in aa genotype (p=0.001, OR=1.458). The frequency of the a allele was significantly lower in the patients with breast cancer (p=0.001, OR=4.070).

* Fisher’s Exact Test a, comparison of genotype and allele frequencies between breast and healthy control groups.

Conclusion: We conclude that there was sensible correlation between eNOS gene intron 4b/a VNTR polymorphism and the risk of breast cancer and bb genotype frequency was significantly higher in these patients than healthy controls.
We are constantly exposed to a variety of both external and internal DNA damaging agents, such as UV light from the sun and reactive oxygen species created as by-products of aerobic respiration. As a result, our DNA accumulates thousands of instances of damage per cell per day. DNA damage response (DDR) pathways, which include DNA repair and cell-cycle checkpoints, are responsible for the repair of DNA damage and are critical for protecting against mutagenesis and maintaining genome integrity. DNA double-stranded breaks (DSBs) are the most deleterious type of DNA damage and are repaired by one of two pathways: Non-homologous end-joining (NHEJ), an error-prone mechanism of repair active throughout the entire cell cycle, or homologous recombination (HR), considered to be an 'error-free' method for DSB repair that occurs in the S and G2 phases of the cell cycle. Deficiencies in NHEJ or HR can result in genomic instability via genomic incorporation of chromosomal aberrations, which can ultimately lead to an increased risk of cancer. However, in many cases, the mechanisms by which defects in these pathways lead to an increased risk of developing cancer is unknown, making preventative care and treatment of resulting cancers more difficult.

Breast Cancer 1 (BRCA1), an established tumor suppressor, is a protein necessary for the proper repair of DNA DSBs through the HR pathway. Defects in BRCA1, whether genetically inherited or spontaneously developed, have been linked to different types of cancer in both men and women, including breast, ovarian, and pancreatic cancer. Yet, the regulation of BRCA1 in HR is not well understood and thus highlights a major a gap in our understanding of how deficiencies in HR contribute to the development of cancer. Our lab has discovered that SIRT2, a class III NAD+ dependent histone deacetylase and putative human tumor suppressor, plays a crucial role in the DDR and repair of DNA DSBs. We have shown that depletion of SIRT2 impairs HR and increases cell sensitivity to ionizing radiation in a deacetylase-dependent manner. A mass spectrometry analysis showed SIRT2 interacts with several proteins involved in DDR, including BRCA1. We validated the interaction between SIRT2 and BRCA1 and found SIRT2 deacylates BRCA1 both in vitro and in cells. Depletion of SIRT2 and subsequent deacetylation of BRCA1 decreases BRCA1 protein levels in cells, impairing HR. Our results show SIRT2 is a novel regulator of BRCA1 and is critical for the repair of DNA DSBs through HR. These findings provide invaluable insights into how to exploit the interplay between SIRT2 and BRCA1 as a novel therapeutic approach for the prevention and treatment of cancer.
Mismatch repair protein loss in breast cancer: Clinicopathological associations in a large British Columbia cohort

Angela S Cheng1, Samuel CY Leung1, Dongxia Gao1, Meenakshi Anurag2, Torsten Nielsen1 and Matthew J Ellis2. 1Genetic Pathology Evaluation Center, Vancouver, BC, Canada and 2Baylor College of Medicine, Houston, TX.

Background: Alterations to mismatched repair (MMR) pathways are a known cause of cancer (particularly colorectal and endometrial). Recently, the FDA approved pembrolizumab for use in MMR-deficient (MMRD) cancers of any type, and the diagnosis can be made by immunohistochemistry (IHC) or genomic methods. In breast cancer, mutational process analyses indicate MMRD occurs in about 2% of breast cancer (Cancer Res; 77; 4755-62, 2017) and recent functional studies have shown associations with resistance to endocrine therapy and sensitivity to CDK4/6 inhibitors (Cancer Discov; 7; 1168-83, 2017). To date, insufficient cases have been assembled to power meaningful associative or survival studies. Herein, the strong correlation between IHC-determined loss of MLH1, PMS2, MSH2 or MSH6 and genomic evidence allowed the assessment of MMRD on a large tissue microarray (TMA) series linked to detailed biomarkers and long-term outcome data.

Methods: IHC markers MLH1, PMS2, MSH2 and MSH6 were optimized on the Ventana automated stainer for application to breast cancer TMAs. The patient cohort consists of females from British Columbia diagnosed with primary invasive breast carcinoma in 1986-1992, referred to the British Columbia Cancer Agency for treatment and follow-up. TMA blocks were sectioned and stained. Slides were scored by a pathologist and only nuclear positivity was evaluated positive. Loss of nuclear positivity for any one of the four tested marker defined MMRD. Clinicopathological associations were tested by Chi-square, and survival by Kaplan-Meier plot with log rank test.

Result: 1635 cases were interpretable for all MMR markers. 31 cases (1.9%) met criteria for MMRD. 6 cases had paired losses (4 MLH1-PMS2 loss, 2 MSH2-MSH6 loss) and the remaining 25 cases had singular MMR loss (11 PMS2 loss, 10 MLH1 loss, 3 MSH6 loss, 1 MSH2 loss). Deficiency of the the MutL complex (MLH1/PMS2) predominated over the MutS complex (MSH2/MSH6).
Among the demographic and pathological variables assessed – age, grade, tumour size, lymphovascular invasion, nodal and menstrual status – high grade is associated with MMRD (p=0.014). In terms of biomarker, MMRD is significantly associated with PR negativity (p=0.003) and PD-L1 expression (p=0.049), but not with ER, Her2, Ki67, or basal breast cancer IHC markers, nor does MMRD significantly correlate with any of the established major intrinsic subtypes of breast cancer. Tumor infiltrating lymphocyte (TIL) counts are higher in MMRD cases (p=0.009). Although statistically not significant (small numbers), Kaplan-Meier plots of survival analysis demonstrated a trend for MMR loss to be associated with decreased breast cancer disease-specific and overall survival.

Conclusion: This large series assessed by IHC corroborates findings from smaller genomic series that MMRD is present in about 2% of breast cancers. MMRD tumors are more likely to be high grade, low PR and immunologically active (higher PD-L1 expression and TIL counts). MMR deficiency is present across all major molecular subtypes (luminal, HER2, basal). Given the efficacy of PD1/PDL1 targeting agents in MMR deficient tumors of other types, evidence for the activity of these agents in MMR deficient breast cancers should be actively sought.
A selective Cdk12/13 non-covalent inhibitor with potent anti-breast cancer activity

Victor Quereda¹, Simon Bayle¹, Vena Francesca¹, Monastyrsyi Andrii¹, Roush William¹ and Duckett Derek¹. ¹Scripps Florida, Jupiter, FL.

Cyclin-dependent kinases 12 and 13 (CDK12 and CDK13) are Ser/Thr protein kinase members of the CDK family. CDKs are regulated by cyclins and members of the family are key regulators of the cell cycle. Other members of this family—CDK7, CDK8, CDK9, CDK12 and CDK13—have been described as transcription-regulating kinases. CDK12 and CDK13 phosphorylate the C-terminal domain (CTD) of rpb1 the largest subunit of RNA polymerase II and interact with RNA processing factors, playing pivotal roles controlling transcription initiation and elongation, as well as posttranscriptional RNA processing. Specifically, CDK12 acts as the limiting factor for the transcription of a small subset of genes that are involved in the DNA damage response pathway and CDK13 affects expression of genes involved in growth signaling pathways. Importantly, like their cell cycle family members CDK12 and CDK13 have also been shown to be promising therapeutic targets for several cancer types. We have generated a novel, selective, and orally bioavailable, small molecule inhibitor of CDK12 and CDK13. Our lead molecule downregulates key DNA damage repair proteins including ATM, ATR, Brca1 and Rad51 leading to induction of apoptotic cell death in all triple negative breast cancer (TNBC) cell lines tested. We have confirmed the selectivity of our compound by kinase profiling and by comparing the gene expression profile by RNA-seq of cells treated with compound or infected with CRISPR sgRNA targeting Cdk12 and/or Cdk13. Importantly, our compound acts in synergy with the chemotherapeutic agents Cisplatin, Irinotecan and Olaparib. Finally, in preclinical efficacy studies, our lead compound blocked tumor progression in two different PDX models of TNBC and demonstrated tumor regression and enhanced efficacy over single treatment when dosed in combination with selected chemotherapeutic agents.
Small-molecule screening nominates diverse combination therapies that sensitize BRCA mutant and wild-type triple negative breast cancer to PARP inhibition

Sarah Sammons\textsuperscript{1}, Catherine Yip\textsuperscript{1}, Grace Anderson\textsuperscript{1}, Jeremy Force\textsuperscript{1}, Kelly Marcom\textsuperscript{1}, Kelly Westbrook\textsuperscript{1}, Carey K Anders\textsuperscript{2}, Kimberly Blackwell\textsuperscript{1} and Kris Wood\textsuperscript{1}. \textsuperscript{1}Duke University Hospital/ Duke Cancer Institute, Durham, NC and \textsuperscript{2}University of North Carolina, Chapel Hill, NC.

Background: Triple negative breast cancer (TNBC) remains a heterogeneous clinical phenotype with few, known therapeutic targets. PARP inhibitors (PARPi) are the first approved, targeted therapy in TNBC, limited to germline \textit{BRCA} mutant (\textit{BRCA}m) cancers that lack homologous recombination repair capacity. Even in this context, resistance quickly emerges via secondary mutations that restore DNA repair ability. While DNA damage repair is an intriguing target in \textit{BRCA} wild type (\textit{BRCA}wt) TNBC due to inherent, genomic instability, PARPi alone have been ineffective in unselected populations. Systematic approaches to define novel drugs that sensitize \textit{BRCA}wt and \textit{BRCA}m TNBC to PARPi would greatly improve therapeutic efficacy and durability.

Methods: \textit{BRCA}wt (HCC1806) and \textit{BRCA}m (SUM149PT) cell lines were screened in duplicate using a 2,100-compound small molecule library. Cell lines were plated in media containing DMSO or sub-lethal doses of the PARPi, olaparib, onto Selleck Bioactive drug plates. Cell viability was assessed after 72 hours, then normalized to vehicle control. Hit cut-offs were predefined as log\textsubscript{2} drug/DMSO of $\leq -0.7$ with a viability difference greater than 20\% - where stringent scoring thresholds were chosen to exceed the full range of scores observed in 816 empty control wells. Hits were sorted by target and pathway to provide mechanistic insight into the synergy of combinations. Drug combinations with the highest potential for near term translation were validated using GI\textsubscript{50} viability assays in 9 \textit{BRCA}wt and \textit{BRCA}m TNBC cell lines. The most promising combination was further validated via immunoblotting, colony formation, and apoptosis assays.

Results: Several drug classes affecting well-known oncogenic signaling pathways conferred sensitivity to PARPi, with more hits in the \textit{BRCA}m cell line. Relevant druggable targets sensitizing cells to olaparib in \textit{BRCA}m TNBC that met the predefined cut-point were inhibitors of PI3K (pan-PI3K, PI3K\textalpha and PI3K\textbeta specific), VEGFR, MEK, EGFR, NF-\textkappaB, aurora kinase and several DNA damaging agents. Aurora kinase, EGFR, and NF-kB inhibition sensitized cells to olaparib, yet upon further validation, synergy was mild. The screen identified ATM inhibitors, KU-55933 and KU-60019, as sensitizers of \textit{BRCA}m cells to olaparib. The potent ATM inhibitor, AZD0156, and olaparib were a highly synergistic combination validated in all 9 \textit{BRCA}m and \textit{BRCA}wt TNBC cell lines via cell viability, annexin V, and colony formation assays. Immunoblotting of relevant DNA damage repair proteins showed that olaparib caused upregulation of p-ATM in \textit{BRCA}m and \textit{BRCA}wt cells. p-ATM expression decreased in response to combination ATM and PARP inhibition. Attenuated levels of p-ATM resulted in increased levels of p- and T-\gamma H2AX, indicating an accumulation of double stranded DNA breaks.

Conclusion: \textit{In vitro}, inhibition of several relevant, oncogenic pathways yielded sensitivity to PARPi in TNBC. We identified the ATM inhibitor, AZD0156, and olaparib as a potent combination regardless of \textit{BRCA} status, a finding currently being evaluated in patient-derived \textit{in vivo} models. Combination ATM plus PARP inhibitor therapy is a promising and feasible approach for near term translation in metastatic TNBC.
Mre11 mediates a p53-independent quiescence program in response to mammary oncogene activation

Rashmi J Kumar¹, Hui Chao Xiao², Katerina Fagan-Solis¹, Jeremy Purvis² and Gaorav P Gupta¹. ¹University of North Carolina Lineberger Comprehensive Cancer Research Center, Chapel Hill, NC and ²UNC School of Medicine, Chapel Hill, NC.

Background: Oncogenic mutations drive uncontrolled proliferation, imposing significant replication stress and activating the DNA damage response (DDR) in early tumorigenesis. The accumulation of double strand breaks (DSBs) is recognized by the Mre11-Nbs-Rad50 (MRN) Complex, a critical sensor that mediates damage signaling and cell cycle checkpoint responses. The mechanism by which the DDR acts as an anti-tumor barrier is in part due to activation of p53 tumor suppressor. However, the role of the DDR in a p53 null or deficient setting has been poorly investigated. In basal-like breast cancer (BLBC) where p53 loss is ubiquitous, the functional consequence of the DDR is in need of further delineation. Previously, we have observed that Mre11 suppresses proliferation in hyperplastic mammary epithelium through a p53-independent mechanism. Here, we evaluate how Mre11 affects cell cycle regulation in p53 deficient primary mammary epithelium induced to overexpress the oncogene c-Myc, a known driver of BLBC.

Methods: We performed single-cell live imaging on primary murine mammary epithelial cells (mMECs) induced to overexpress c-Myc and be p53 deficient, with or without additional mutations in Mre11. Cells were further infected with a fluorescent cell cycle reporter: Proliferating Cell Nuclear Antigen (PCNA)-mCherry. By tracking PCNA foci changes via time-lapse imaging modalities, we were able to calculate distinct cell cycle phase lengths, identify disruption of cell cycle, visualize mitotic aberrancies, and characterize the cell cycle profile of p53 deficient, c-Myc activated primary mammary epithelial cells with or without intact DDR.

Results: Our results indicate that the presence of Mre11 mediates a quiescence phenotype even in the absence of p53 tumor suppressor with up to 75% of the cell fraction becoming quiescent. This fraction is significantly reduced (p<0.0001) when Mre11 is targeted using gene editing giving rise to highly aberrant multinucleated mMECs capable of unrestrained replication and entry into mitosis. Cells with intact Mre11 undergo cell cycle arrest post abnormal mitoses and are characterized by quiescent cells with classic micronuclei formation. In contrast, mMECs without Mre11 are likely to be multinucleated with reduced micronuclei formation and rarely undergo cell cycle arrest. The loss of Mre11 enables these cells to continue cell cycle progression despite tremendous mitotic aberrancies. Impact: Mre11 is an important mediator of a p53 independent quiescence program in c-Myc expressing cells. It regulates the proliferative activity of multinucleated daughter cells and their ability to become quiescent. Furthering our understanding of how Mre11 regulates this molecular quiescence program may provide new insights into drivers of genomic instability in BLBC and novel therapeutic targets.
Direct ex vivo observation of homologous recombination defect reversal after DNA damaging chemotherapy in metastatic breast cancer patients

Titia G Meijer¹, Nicole S Verkaik¹, Carolien HM Van Deurzen¹, Hendrikus J Dubbink¹, T Dorine Den Toom¹, Winand NM Dinjens¹, Roland Kanaar¹, Dik C Van Gent¹ and Agnes Jager¹. ¹Erasmus MC Cancer Institute, Rotterdam, Netherlands.

Introduction

Better predictive biomarkers for response to Poly ADP-Ribose inhibitors (PARPi) are required, since on the one hand evidence is emerging that PARPi are also effective beyond germline BRCA mutated (gBRCAm) cancers and on the other hand gBRCAm cancers can become resistant to PARPi. Therefore, we previously developed a functional homologous recombination (HR) assay exploiting the formation of RAD51 foci in proliferating cells after ex vivo irradiation of fresh primary breast cancer (BrC) tissue (n=148): the REpair CAPacity (RECAP) test. The aim of the current study is to molecularly characterize real-time HR deficient (HRD) tumors and explore the utility of RECAP as a predictive biomarker for PARPi treatment in metastatic BrCs.

Material and method

Patients with advanced or recurrent BrC with easily accessible metastases were eligible. Fresh tissue biopsies from metastatic BrC lesions were collected in customized medium, irradiated with 5 Gy and cultured for 2 hours. Molecular characterization of functional HRD biopsies as well as platinum/PARP resistant biopsies was performed by targeted sequencing (BRCA1/2, TP53, CHEK2, PALB2), BRCA1 promoter methylation analysis and multiplex ligation-dependent probe amplification (MLPA) analysis of BRCA1 and BRCA2 to identify large rearrangements.

Results

41 biopsies were derived from 38 patients with recurrent or metastatic BrC. The RECAP test had a high success rate (93%) when performed on core needle or punch biopsies, and test results were available within 1 week. HRD was detected in 13 out of 41 biopsies (32%), among which 5 were gBRCAm, indicating that the RECAP test identifies more patients who may benefit from PARPi treatment than gBRCA analysis only. Among the 8 non-gBRCAm HRD tumors was one tumor with a germline PALB2 mutation, one with BRCA1 promoter hypermethylation and two with somatic variants of unknown significance (VUSes) in BRCA2. In three gBRCAm patients BRCA reversion was detected, as the HRD tumors became HR proficient (HRP) after showing in vivo progressive disease (PD) on cisplatin/PARPi treatment. One of these patients obtained a secondary BRCA1 mutation that restored the open reading frame and led to production of full-length BRCA1 protein, while the causative molecular event in the other patients is still elusive.

Conclusion

The RECAP test is a robust and reproducible HRD test which identifies approximately 60% more potential candidates for PARPi treatment, as 40% of HRD tumors were caused by gBRCAm. Due to its functional character, the RECAP test reflects the real-time HR status regardless of BRCA mutational status and therefore detects HR reversal upon therapy resistance. Thus, RECAP shows great potential as a predictive biomarker for PARPi treatment of metastatic BrC.
Characterization of chromosomal instability in the TNT trial: A randomized phase III trial of carboplatin compared with docetaxel for patients with metastatic or recurrent locally advanced triple negative or BRCA1/2 breast cancer (CRUK/07/012)

Orsolya Sipos¹, Holly Tovey², Jelmar Quist³, Syed Haider¹, Salpie Nowinski⁴, Patrycja Gazinska¹, Sarah Kernaghan², Christy Toms², Kirsten M Timms⁵, Jerry S Lanchbury⁴, Sabine C Linn⁶, Sarah E Pinder⁷, Judith M Bliss², Andrew Tutt¹,³, Maggie CU Cheang⁶ and On behalf of the TNT Trial Management Group and Investigators².

¹The Institute of Cancer Research, The Breast Cancer Now Toby Robins Research Centre, London, United Kingdom; ²The Institute of Cancer Research, Clinical Trials & Statistics Unit (ICR-CTSU), London, United Kingdom; ³King’s College London, Faculty of Life Sciences and Medicine, School of Cancer & Pharmaceutical Sciences, Breast Cancer Now Research Unit, Cancer Bioinformatics, London, United Kingdom; ⁴King’s College London, Faculty of Life Sciences and Medicine, School of Cancer & Pharmaceutical Sciences, Amsterdam, Netherlands and ⁵King’s College London, King’s Health Partners Cancer Biobank, London, United Kingdom.

Background
A distinctive trait of triple negative breast cancer (TNBC) is the acquisition of genome wide highly aberrant copy number states, which is more evident in metastatic settings. The level of copy number alterations can be characterized by quantitative estimates of chromosomal instability, such as allelic imbalanced copy number aberrations, telomeric allelic imbalance (NtAI), homologous recombination deficiency (HRD) score, referred here as genomic scars. Several of these scars are reported as being indicative of BRCAAness and potential predictive and/or prognostic biomarkers of chemotherapy response, currently mostly demonstrated in neoadjuvant settings in TNBC.

Aims
Using several genomic scar measures, we aim to capture chromosomal instability and test their predictive and prognostic value in metastatic or recurrent locally advanced triple negative or BRCA1/2 mutated breast cancer in the TNT trial.

Methods
Patients recruited to TNT (n=376) had ER-/PR-/Her2- breast cancer or were germline BRCA mutation carriers. Genome-wide copy numbers (CN) were derived from FFPE samples including primary tumours and positive lymph nodes (n=183, docetaxel=93, carboplatin=90; BRCA1 mut=25). Genomic scars were generated using ASCAT (Van loo et al., PNAS 2010) CN profiles. HRD scores were established by Myriad Genetics, Inc. assay (n=272). BRCA1-like classifier was applied as described in Schouten et al., Mol Onc 2015. Shannon diversity index was calculated using ASCAT raw CN profiles. Association of genomic scars with PAM50 subtypes and BRCA1 deficiency status were evaluated using Kruskal-Wallis test; p-values were adjusted for multiple comparisons (Dunn’s test). Statistical significance was defined as p<0.05. Association of genomic scars with objective tumour response rate (ORR) and Progression Free Survival (PFS) was assessed using logistic regression and restricted mean survival analysis, respectively.

Results
HRD and NtAI scores were higher in basal like samples compared to non-basal like (median diff. HRD=11.5, p=0.005; NtAI=3, p=0.04). HRD (p=2e-14) and NtAI (p=0.003) scores were also higher in BRCA1 deficient (BRCA1 germline/somatic mutant or BRCA1 methylated) samples compared to non-deficient. Using the BRCA1-like classifier, 42 out of 50 BRCA1 deficient samples and 93 out of 133 BRCA1 non-deficient/undetermined samples were identified as BRCA1-like. The Shannon diversity index, measuring CN heterogeneity, clustered samples into 3 groups. Analysis of ORR showed non-significant trends to preferential response rates with docetaxel in cluster 1 and 3. Membership of cluster 2 predicted higher ORR to carboplatin over docetaxel (interaction p=0.017). PFS indicated a treatment effect in cluster 2, but not in cluster 1 or 3; there was no evidence of interaction between subgroups and treatment (p=0.15).

Conclusions
Our results suggest that the overall heterogeneity of the copy number landscape is a promising area for seeking predictive/prognostic biomarkers in metastatic TNBC, and combined with other modalities of high-dimensional omics data could provide essential treatment response information.
A p53-independent DNA damage response that regulates breast cancer phenotypes

Katerina D Fagan-Solis¹, Dennis A Simpson¹, Maryna Kapustina¹, Luciano Martelotto², Jorge S Reis-Filho², John HJ Petrini² and Gaorav P Gupta¹. ¹University of North Carolina Chapel Hill, Chapel Hill, NC and ²Memorial Sloan-Kettering Cancer Center, New York, NY.

Defects in the DNA damage repair system result in increased genomic instability and have recently been implicated as being drivers of tumorigenesis in both familial and sporadic breast cancers. To maintain genomic integrity, cells have a DNA damage response (DDR) mechanism that functions to repair damaged DNA efficiently and commits cells to death if damage is irreparable. Failure of this mechanism results in genomic instability and cancer predisposition. Widespread chromosomal instability is a characteristic feature of Triple-Negative Breast Cancer (TNBC), making it difficult to decipher between genes that drive cancer development from those that play a bystander role. Little is known about what gives rise to the extensive genomic instability of TNBC, and presents a major deficit in our scientific and clinical knowledge.

Oncogene induced hyper-proliferation results in replication-associated double strand breaks (DSBs) that engage an Mre11-Rad50-Nbs1 complex-dependent DDR. Classically, the oncogene induced DDR is believed to suppress tumorigenesis due to downstream activation of p53. Using genetically engineered primary mammary epithelial cell models, we demonstrate p53-independent effects of the Mre11-dependent DDR in suppressing proliferation and DNA damage induced by diverse oncogenic drivers. Single cell whole genome sequencing in Her2/Neu expressing primary mammary epithelial cells reveals a landscape of stochastic copy number aberrations induced by oncogenic stress that becomes enriched for a genomic scar pattern of larger-size deletions in cells with Mre11 hypomorphism. We identify Mre11 pathway hypomorphism in a subset of basal-like breast cancers (BLBC), which confers vulnerability to specific DNA damaging agents and DDR inhibitors in murine models of p53-deficient BLBC. Thus, assessing the functional status of the Mre11-dependent DDR pathway in p53-mutant breast cancers may provide an opportunity for therapeutic exploitation.
Combined tandem affinity purification mass-spectrometry technique with genome-editing CRISPR-Cas9 knockout screening to identify potential subunits in the BRCA1 complex

Haiyun Zhao¹, Hesheng Jiang¹, Weili Sun¹, Zhimin Shao¹ and Xin Hu¹. ¹Fudan University Shanghai Cancer Center, Shanghai, China and ²Shanghai Medical College, Fudan University, Shanghai, China.

Background: Genomic instability is one of tumor characteristics. Enhancing the DNA damage load or impairing the ability of DNA damage repair has been therapeutics of cancer. Breast cancer type 1 susceptibility gene (BRCA1) has been studied a lot about the DNA damage and repair in breast cancer and ovarian cancer. BRCA1 mutation increases the risk of developing breast cancer by an eighth to tenth. The C terminal domain of BRCA1 can associates with three proteins Abraxas, Bach1 and CtIP in a phosphorylation-dependent manner forming mutually exclusive complexes, namely BRCA1-A, B, and C complexes. The BRCA1-A complex is necessary in DNA damage repair, and study implicates the complex play roles in chemotherapy resistance.

Methods: We explored tandem affinity purification mass-spectrometry (TAP-MAS) technique to identify potential subunits associated with NBA1(one component of BRCA1-A complex). Then we made the genome-editing CRISPR-Cas9 sgRNA library into lentivirus to infect U2OS cells. And 5 Gy dose of Ionizing radiation (IR) was used to induce DNA damage on the cell. After 14 days cultivation, we extracted the DNA from the cells, performed polymerase chain reaction (PCR) and analyzed the correlation between potential genes and DNA damage-repair passage by bioinformatics methods. We generated 200 breast cancer patient tissue samples in our cancer center and performed immunostaining assay.

Results: By the TAP-MAS technique of NBA1 tagged with HA and Flag, we found 93 potential subunits except those known subunits in BRCA1-A complex. Combined with CRISPR-Cas9 sgRNA library screening, we scored the relativity of DNA damage and repair passageway of identified 93 potential subunits. We found that nucleoside-triphosphatase, cancer-related (NTPCR) as a new potential subunit of BRCA1-A complex (p value=0.0034) had the highest score. Endogenous and exogenous co-IP validated NTPCR physically associates with subunits within BRCA1-A complex. Besides, we found that NTPCR associated with the same domain of NBA1 as the other subunits in BRCA1-A complex. Immunohistochemistry of patient tissue samples indicated that high levels of NTPCR expression was correlated with poor prognosis in multivariate analysis (HR: 4.990; 95%CI: 1.433-17.378; p value: 0.012).

Conclusion: NTPCR is a new subunit in BRCA1-A complex. And high expression of NTPCR is a negative prognostic factor in breast cancer patients.
Microsatellite instability in triple negative breast cancers

Kanako Kurata¹, Makoto Kubo¹, Hitomi Mori¹, Hitomi Kawaji², Yurina Motoyama¹, Lumi Kuroki¹, Mai Yamada¹, Kazuhisa Kaneshiro¹, Masaya Kai¹ and Masafumi Nakamura¹. ¹Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.

Background: Microsatellite instability (MSI) is a phenotype resulting from defect in mismatch repair genes. The Food and Drug Administration approved anti-programmed death 1 (PD-1) immune checkpoint inhibitor for any solid tumor with MSI-high (MSI-H). Some tumors had good response to PD-1 blockade and it is a promising treatment for a part of refractory breast cancers. Our goal was to determine the frequency of MSI in triple negative breast cancer (TNBC), one of the most clinically aggressive subtypes.

Patients and Methods: This study included 228 patients with primary TNBC underwent resection without neoadjuvant chemotherapy between January 2004 and December 2014. Genomic DNA was extracted from formalin-fixed and paraffin-embedded tissue. Tumor and control DNA were amplified by polymerase chain reaction at the following 5 microsatellite markers: NR-21, BAT-26, BAT-25, NR-24, MONO-27. We classified the tumors as microsatellite stable (MSS), MSI-low or MSI-H.

Results: The mean age of patients was 59 years (range: 30-89) and all were women. T1 tumors were 57.9% and N0 were 67.5%. Meanwhile, the tumors with nuclear grade 3 were 66.2% and high Ki-67 (> 30%) were 66.7%. Among the 228 tumors, 222 tumors (97.4%) revealed MSS, of which 6 (2.6%) revealed MSI and 2 (0.9%) were MSI-H. Among the MSI tumors, T and N factor were showed as follows: T1: 2 tumors, T2: 3 tumors, T3: 1 tumor, N0: 5 tumors and N1: 1 tumor. Of two MSI-H tumors, one showed T1N0 and another showed T2N0. The both of them showed nuclear grade 3, high Ki-67 (> 30%) and had common following instable markers: NR-21, BAT-26 and BAT-25.

Conclusions: Our results demonstrated that the frequency of MSI-H was 0.9% (2/228). MSI might not be useful as a biomarker for immune check point inhibitors. MSI should be combined with another biomarker such as tumor mutational burden in TNBC.
Novel role of the tumor suppressor ductal epithelium associated ring chromosome 1 (DEAR1) in regulation of breast stem/progenitor cell properties

Uyen Le¹, Nanyue Chen¹, Seetharaman Balasenthil¹ and Ann M Killary¹. ¹The University of Texas M.D. Anderson Cancer Center, Houston, TX.

Introduction: Breast cancer is the most commonly diagnosed cancer and third-leading cause of cancer-related deaths in women in America. A quarter of lesions diagnosed annually are ductal carcinoma in situ (DCIS), one of the earliest pre-invasive forms of invasive ductal carcinoma (IDC). Without therapeutic intervention, 30-50% of DCIS cases can progress to IDC. Understanding the mechanisms regulating progression from DCIS to IDC would help identify biomarkers to stratify DCIS patients at higher risk of progression or recurrence. Cumulative literature suggests the earliest phase of dissemination from the primary tumor is driven by the epithelial-mesenchymal transition (EMT) program. DEAR1 is a tumor suppressor gene which is mutated, undergoes loss of heterozygosity in breast cancer, and is downregulated in DCIS lesions. DEAR1 regulates acinar morphogenesis and cell polarity, and is a negative regulator of TGF-beta-driven EMT by binding to and ubiquitinating SMAD3, thereby limiting the amount of SMAD3 available to activate an EMT signature. Overexpression of EMT master regulators, or exposure to TGF-beta in immortalized human mammary epithelial cells (HMECs), results in mammosphere formation and breast stem cell markers, thus linking the EMT process to acquisition of stem cell characteristics.

Methods: Stable lentiviral shRNA knockdown, in vitro mammosphere assay, cytospin, immunofluorescence, immunoprecipitation, western blot analysis, ubiquitination and real-time quantitative PCR were performed.

Results: DEAR1 knockdown in immortal HMECs resulted in a significant enhancement of primary mammosphere formation and growth compared to controls, suggesting that DEAR1 may regulate stem/progenitor cell properties; this effect was greater when cells were exposed to TGF-beta. To determine if DEAR1 regulates stem cell properties through regulation of SMAD3 levels, DEAR1-SMAD3 double knockdown clones were examined for mammosphere formation. Results indicated fewer mammospheres in double knockdown clones, but only in the presence of TGF-beta, suggesting that the mammosphere phenotype is partially dependent on the TGF-beta-SMAD3 pathway. The observation that loss of DEAR1 alone results in a stem/progenitor cell phenotype indicates that DEAR1 may regulate mammosphere formation independent of its role in regulating the TGF-beta pathway. HMEC mammospheres express higher levels of stem cell marker aldehyde dehydrogenase (ALDH1) and co-express luminal and basal cytokeratins, suggesting bipotential capacity. We also observed upregulation of SNAI2 and ZEB1, master EMT and stem cell regulators, in DEAR1 knockdown HMECs. DEAR1 interacted with SNAI2 by co-immunoprecipitation analysis and also promoted the polyubiquitination of SNAI2.

Conclusions: Loss of the tumor suppressor/polarity regulator DEAR1 promotes stem cell properties in part through the DEAR1-TGF-beta-SMAD3 axis. We demonstrate a DEAR1-SNAI2 axis that may partially regulate stem/progenitor cell properties in HMECs through the polyubiquitination of SNAI2, a master regulator of EMT and stemness. These mechanisms governing acquisition of the stem cell properties may contribute to understanding how DCIS progress to IDC.
BCL6: A novel target of triple negative breast cancer stem cells

Massimo Di Nicola¹, Tatiana Volpari¹, Giovanni Fucà¹, Sandra Romero Cordoba¹, Francesca De Santis¹, Ornella Rondinone¹, Simona Faraci¹, Francesco Ferris¹, Chiara Puricelli¹, Lorenzo Castagnoli¹, Rossella Marullo², Leandro Cerchietti² and Serenella Pupa¹. ¹Fondazione IRCCS Istituto Nazionale Tumori, Milan, Italy and ²Cornell University, New York.

Introduction: Despite improvements in breast cancer treatment in recent years, triple negative breast cancer (TNBC) is still characterized by a poor prognosis and a lack of specific actionable alterations. Thus, the identification of new molecular targets represents a clinical priority. BCL6 is a well-known transcriptional modulator that acts as a repressor of DNA-damage sensing and cell cycle progression pathways in the context of B-cell lymphomas, while its implication in controlling breast cancer cell growth, survival, and invasiveness has been recently described. This study investigated the role of BCL6 expression in TNBC initiation and stemness (TNBCSCs).

Methods: The correlation between BCL6 expression and the overall survival (OS) of TNBC patients, as well as the association with stemness-related pathways were assessed in silico using the METABRIC dataset. Following BCL6 silencing or pharmacological inhibition by the small molecule FX1, mammosphere-forming efficiency (MFE) and ALDH and CD44 CSC markers expression were evaluated in SUM149 and SUM159 TNBC cell lines.

Results: In silico analysis of the METABRIC dataset has showed that BCL6 overexpression is associated with poor overall survival and enrichment in stemness signatures in TNBC patients. In vitro, BCL6 silencing resulted in a significantly reduced number of mammospheres compared to internal control, as well as a simultaneous decreased percentage of ALDH⁺ and CD44⁺ cells in all the TNBC cell lines tested. Moreover, blocking the transcriptional repressor activity of BCL6, using its selective inhibitor FX1, confirmed the impairment of the MFE. Of note, following BCL6 silencing, we observed a global reduction in the repressive marker H3K27me3, suggesting a cooperation between BCL6 and the breast EMT- and stemness-related enzyme EZH2 in inducing specific gene transcription repression in TNBC.

Conclusion: Downregulation and pharmacological inhibition of BCL6 significantly impaired TNBC stem-like phenotype, suggesting a critical role of BCL6 in regulating TNBCSC self-renewal. This still unknown BCL6 biological feature could be mediated by BCL6-dependent epigenetic silencing of stemness-related genes, even though further ongoing studies will be necessary to precisely elucidate such mechanism. Overall, we identified BCL6 as a novel target to counteract TNBCSCs paving the way to a novel “tailored” cure for TNBC.
Associations of epidemiologic and clinical features with intensity of immune infiltrates in postmenopausal breast cancer cases from the cancer prevention study-II cohort

Mia M Gaudet¹, Maret M Mellow¹, Samantha Puvanesarajah¹, Susan M Gapstur¹, Mark E Sherman² and Ted Gansler¹. ¹American Cancer Society, Atlanta, GA and ²Mayo Clinic, Jacksonville, FL.

Stromal tumor-infiltrating lymphocytes (sTILs) are often prominent in HER2-enriched and triple negative breast cancers and predict a favorable prognosis for these subtypes. Clinical and epidemiological determinants of sTILs have not been defined in large cohorts. Accordingly, we analyzed these associations for 702 eligible, postmenopausal invasive breast cancer cases from the Cancer Prevention Study (CPS)-II Nutrition cohort. CPS-II included 97,786 women who completed baseline and follow-up surveys since 1992. Women with self-reported breast cancer diagnoses were consented for medical record and tumor tissue retrieval. We analyzed pre-diagnostic data from the survey prior to diagnosis on personal history of benign breast disease (BBD), menopausal hormone use, alcohol intake, cigarette smoking status, waist circumference, body mass index, adult weight gain, nonsteroidal anti-inflammatory drugs, and physical activity. One pathologist (TG) evaluated sTILs using whole slide images of H&E stained sections according to recommendations by the International TILs Working Group 2014. sTIL levels were dichotomized: none/minimal (0-10%) and moderate/high (>10%). We compared the sTIL levels by clinical and epidemiologic risk factors using chi-square statistics. Odds ratio (ORs) and 95% confidence intervals (CIs) for the associations of clinical and epidemiologic risk factors with sTILs were estimated with multivariable logistic regression.

Mean age at diagnosis was 71.9 years; 44% of cancers were moderate grade, 74% were localized staged and 88% were luminal-like. Cancers with high/moderate sTIL levels (n=614), compared to none/minimal (n=88), were more likely to be high grade (54% vs. 20%; p-value <0.001), node-positive (41% vs. 22%; p-value <0.001), and non-luminal (36% vs. 8%; p-value <0.001). In a model mutually-adjusted for age at diagnosis and clinical factors, all clinical factors were associated with moderate/high sTIL levels: node-positive (OR=2.15, 95% CI 1.28 – 3.58), high grade (OR=3.98, 95% CI 1.88 – 9.06), and non-luminal subtype (OR=3.65, 95% CI 2.00 – 6.59). Age at diagnosis was not associated with sTIL levels (per year: OR=1.01, 95% CI 0.97 – 1.05).

Women with BBD were less likely to have moderate/high sTIL levels than minimal/none sTIL levels (38% vs. 54%; age-adjusted OR=0.50, 95% CI 0.31 – 0.79). Ever smokers also were less likely to have moderate/high sTIL levels (38% vs. 49%) with an OR=0.61 (95% 0.38 – 0.97). Other risk factors were not significantly associated with sTIL levels.

In this large epidemiologic cohort, non-luminal cancers had more sTILs than luminal cancers. Women with a personal history of BBD and ever cigarette smokers had significant lower levels of sTILs. Our study is among the first to examine pre-diagnostic risk factors in relation to sTILs and provides the impetus for larger, population-based studies with phenotypic characterization of immune cells.
An early look at incidence and survival by HR and HER2 status among young US women with stage I-III breast cancer: SEER 2010-15

Alexandra Thomas¹, Anthony Rhoads², Elizabeth Pinkerton², Susan Melin¹, Jacob J Oleson², Lacey R McNally¹, W G Hundley¹, Kristin Conway², Charles F Lynch² and Paul A Romitti². ¹Wake Forest University Medical Center, Winston-Salem, NC and ²University of Iowa, Iowa City, IA.

Background: Population-based contemporary incidence and survival patterns for breast cancer by receptor status (hormone receptor [HR]; human epidermal growth factor receptor 2 [HER2]) among young US women have not been described.

Methods: We identified pre-, peri-, and early postmenopausal women ages 20-29 (n=1,617), 30-39 (n=12,910), 40-49 (n=47,313), and 50-59 (n=68,870) diagnosed with Stage I-III breast cancer from 2010-15 in the Surveillance, Epidemiology and End Results (SEER) database using SEER*Stat version 8.3.5. Of these, respective totals for women with reported HR and non-borderline HER2 status were 1533 (94.8%), 12,225 (94.6%), 44,684 (94.4%), and 64,844 (94.2%). Using this analytic sample, we estimated annual percentage change (APC) in incidence. Restricting the sample to women diagnosed from 2010-14, we estimated four-year survival (maximum available follow-up). Analyses were stratified by age group and receptor status.

Results: The proportion of HER2+/HR+ cancer was highest among women 20-29, decreasing with increasing age; that for HER2+/HR- cancer was lower, differing less across age groups (Table 1). For HER2- cancer, the proportion of HER2+/HR+ cancer was lowest for women 20-29 and increased with age; the opposite pattern was observed for HER2-/HR- cancer. Overall, stage I-III breast cancer increased in incidence from 2010-15 for all age groups, with the APC greatest in women 20-29 [2.20](30-39 [1.98], 40-49 [1.91], 50-59 [1.62]). The patterns for the APCs by age and receptor status tended to reflect those for the observed proportions, except those for women with HER2+/HR- cancer, which tended to increase with increasing age (Table 1). Four-year survival estimates for women 20-29, although imprecise, differed by HER2 status, being higher for those with HER2+ than HER2- cancer, and this difference persisted for HR+ and HR- cancers among these women (Table 2). In the other age groups, survival differed by HR status, being higher for women with HR+ than HR- cancer.

Conclusions: Using SEER data representative of over one-quarter of the US population, Stage I-III breast cancer has increased among young women in recent years. In particular, HER2+/HR+ and HER2-/HR- cancers were over-represented and estimated to have the highest APCs among women 20-39 compared to those 40-59. Receptor status was observed to influence survival differently across age groups. The differences in four-year survival observed among women 20-29 with HR+ cancers may have implications as we consider anti-estrogen therapy options for these youngest premenopausal women.

Type 2 diabetes and survival outcomes among a multi-ethnic cohort of breast cancer patients

Anu R Neerukonda¹, Olufunmilayo I Olopade¹, Elbert Huang¹ and Dezheng Huo¹. ¹University of Chicago, Chicago, IL.

BACKGROUND: With increasing prevalence of type 2 diabetes, it has become one of the common comorbidities among breast cancer patients. Few contemporary studies have examined the effect of preexisting diabetes on survival outcomes in breast cancer patients. Furthermore, both breast cancer mortality and diabetes prevalence are higher in African American women compared to Caucasian women, yet data on whether diabetes can explain racial disparity in breast cancer mortality is scarce.

OBJECTIVE: To compare clinopathological characteristics and survival outcomes between breast cancer patients with and without co-existing diabetes, and to explore the contribution of diabetes to breast cancer survival differences between African Americans and Caucasians.

METHODS: We analyzed data from the Chicago Multiethnic Epidemiologic Breast Cancer Cohort (ChiMEC) comprising of 3170 histologically confirmed breast cancer patients diagnosed between 2004 and 2017. The cohort consists of 55% Caucasians, 38% African Americans, and 7% other ethnicities. Cox models were used to analyze data on several clinical outcomes [Table 1].

RESULTS: 245 patients (8%) in the cohort had co-existing diabetes at time of breast cancer diagnosis, with African Americans having highest prevalence (14%). Patients with diabetes were older (mean 66 vs. 56 years old) and had higher proportion of obesity (67% vs. 34%) and Charlson comorbidity index >2 (27% vs. 10%) than those without diabetes. The two groups were similar in terms of surgery, radiation, and hormonal therapy received, while patients with diabetes had slightly more advanced stage (15% vs. 10%). After adjusting for multiple prognostic factors, patients with diabetes had a 97% higher risk of dying from breast cancer and a 62% fold higher risk dying from other causes than patients without diabetes (Table). The two groups had no significant difference in risk of recurrence. In addition, the hazard ratio (HR) comparing African Americans with Caucasians was 2.35 (95% confidence interval [CI] 1.90-2.91), and it changed to 2.19 (95% CI 1.76-2.33) after the adjustment for diabetes.

CONCLUSIONS: Pre-existing diabetes among breast cancer patients was associated with higher risk of breast cancer specific and all-cause mortality. About 11% of racial disparities in breast cancer mortality could be attributed to higher difference in diabetes prevalence in African American patients. Further research investigating how pre-existing diabetes may influence breast cancer treatment and survival are warranted.

Changes in breast cancer diagnosis and treatment after Medicaid expansion in Pennsylvania

Neal Spada\textsuperscript{1}, Emily Geramita\textsuperscript{1}, GJ van Londen\textsuperscript{1} and Lindsay Sabik\textsuperscript{1}. \textsuperscript{1}University of Pittsburgh, Pittsburgh, PA.

\textbf{Background:} In January 2015, Pennsylvania expanded Medicaid eligibility to all legally present adults in the Commonwealth of Pennsylvania with household incomes up to 138 percent of the federal poverty level under the Affordable Care Act. Pennsylvania is the most populous state to expand Medicaid that did not previously have a large expansion of the program to adults, making it an ideal setting to study the impacts of the program. By March 2017, an estimated 716,000 people had enrolled in Pennsylvania’s expanded Medicaid program. We aim to determine how Pennsylvania’s Medicaid expansion has impacted breast cancer diagnosis and treatment in the state.

\textbf{Methods:} The Pennsylvania Cancer Registry was queried for all women aged 18 to 64 years newly diagnosed with breast cancer between 2007 and 2015. Demographic, tumor, and treatment characteristics were evaluated for each year during this time span. In order to assess the impact that Medicaid expansion had on these variables, they were compared for the years 2007 to 2014 (before Medicaid expansion) and the year 2015 (after).

\textbf{Results:} Between 2007 and 2015, 49,606 cases of invasive breast cancer were diagnosed among women aged 18-64 and residing in the state of Pennsylvania, 43,920 of which were diagnosed and treated between 2007 and 2014, and 5,686 of which were diagnosed and treated in 2015. Initial analysis indicates that more women were diagnosed with localized breast cancer (SEER summary stage 1) following Medicaid expansion in 2015 compared to the period of 2007 to 2014 (63.07% v. 60.62%, \(p = 0.0004\)). Meanwhile, the proportion of women diagnosed with metastatic breast cancer did not change before and after Medicaid expansion (6.52% v. 6.86%, \(p = 0.3298\)). Subsequent analysis will assess changes in treatment outcomes including time to treatment and receipt of guideline-concordant care.

\textbf{Conclusion:} The expansion of Medicaid in Pennsylvania in 2015 under the Affordable Care Act resulted in an increase in the proportion of localized (SEER summary stage 1) breast cancer diagnoses, though there was no change in the proportion of metastatic cases in the first year following expansion. The results suggest a possible increase in earlier stage diagnosis associated with increased access to health insurance. Additional analysis will examine the impact on treatment-related outcomes.
Risk factors for high-grade and low-grade DCIS in the cancer prevention study-II nutrition cohort

Samantha Puvanesarajah, Susan M Gapstur, Ted Gansler, Alpa V Patel and Mia M Gaudet. *Behavioral and Epidemiology Research Group, American Cancer Society, Atlanta, GA.

Background: Nuclear grade, believed to be established early in carcinogenesis, is an indicator of ductal carcinoma in situ (DCIS) prognosis. Women with high-grade DCIS have a higher risk of local recurrence compared to women with low-grade DCIS. Risk factors for DCIS overall are well-characterized but risk factors by grade are not. Given the prognostic capabilities of grade for DCIS, it is of interest to identify whether risk factors by DCIS grade differ.

Methods: Among 75,630 women enrolled in the Cancer Prevention Study-II Nutrition Cohort in 1992-1993, we identified 422 who were diagnosed with low-moderate grade DCIS (i.e. grades 1 or 2) and 355 who were diagnosed with high-grade DCIS (i.e. grade 3) during follow-up through 2013. Beginning in 1997, biennial questionnaires were administered to update exposure status, including screening mammography in the previous two years. For this analysis, these questionnaires were used to partition follow-up time into approximately two-year intervals. Because screening is strongly linked to diagnosis of DCIS, contribution of person-time within a specific interval was conditional on reporting a screening mammogram in the interval prior. Multivariate joint Cox proportional hazards regression models were used to estimate adjusted hazard ratios (HR) and 95% confidence intervals (CI) for the associations of known breast cancer risk factors with DCIS overall, and with high-grade and low-grade DCIS individually.

Results: Parity (HR=0.70; 95% CI: 0.63-0.78, parous vs. nulliparous), smoking status (HR=0.69; 95% CI: 0.58-0.82, current vs. never smoking) and menopausal status (HR=0.79; 95% CI: 0.73-0.87, natural menopause <50 years vs. natural menopause ≥ 50 years) were inversely associated with risk of DCIS overall. Whereas, positive family history of breast cancer (HR=1.46; 95% CI: 1.36-1.57), personal history of benign breast disease (BBD) (HR=1.73; 95% CI: 1.62-1.85), and current use of combination estrogen and progestin hormone replacement therapy (HR=1.15; 95% CI: 1.04-1.28) were associated with higher risk of DCIS. In analyses stratified on DCIS grade, history of BBD was more strongly associated with higher risk of low-grade (HR=2.21; 95% CI: 1.81-2.70) than with high-grade DCIS (HR=1.29; 95% CI: 1.04-1.60) (p for heterogeneity=0.001). Current combination estrogen and progestin hormone replacement therapy use was associated with a higher risk of high-grade DCIS (HR=1.40; 95% CI: 1.03-1.90) but not low-grade DCIS (HR=1.02; 95% CI: 0.75-1.40), but the difference by grade was not statistically significant (p=0.5).

Conclusions: In this study, which is the first to comprehensively assess risk factors by DCIS grade, the association between personal history of BBD and risk of DCIS appeared to differ by grade. Due to limited power for some risk factor analyses, future studies using larger prospective cohorts or pooled data should be conducted to better identify these associations.
High risk of recurrence up to 30 years after diagnosis among breast cancer patients aged <45 years

Elisabetta Rapiti¹, Robin Schaffar¹, Christine Bouchardy¹, Isabelle Neyroud-Caspar¹ and Simone Benhamou¹,². ¹Geneva Cancer Registry, University of Geneva, Geneva, Switzerland and ²INSERM, UMR 946, Genetic Variation and Human Diseases Unit, Paris, France.

Introduction
In the recent years, the incidence of breast cancer (BC) among young women increased in several Western countries. Furthermore, compared to older women with BC, young women present in general more aggressive biological characteristics: higher stage at diagnosis and lower survival rates. Except for cancer arising in high genetic risk individuals, BC occurring at young age represents a poorly comprehensible epidemiological situation.

We had constituted a population-based cohort of BC patients aged less than 45 years derived from the Geneva cancer registry with the aim of investigating patient's, tumour's, treatment's characteristics and long-term health outcomes of these young patients.

Patients and methods
Between 1970 and 2012, 1'586 women were identified as resident in the canton of Geneva, Switzerland and diagnosed with a primary invasive non-metastatic BC at the age of 45 years or less. From the pathological and medical files, we collected numerous variables including social environment, family history, fertility and pregnancy. Women were followed up for local and distant recurrences, second cancer occurrence or death up to 31/12/2015. Cumulative incidence was estimated for local and distant recurrences in the competing risks framework considering deaths (from BC or other causes) as competing events. Analyses were stratified according to age groups and stage of the disease.

Results
BC was diagnosed before the age of 35 years for 225 women (14.2%), between 35 and 39 years for 368 women (23.2%) and between 40 and 45 years for 993 women (62.6%). Most of the patients were diagnosed with luminal A or luminal B molecular subtypes (respectively 32.8 and 37.5%), stages I or II tumours (75.2%), positive estrogen (74.8%) and progesterone (67.5%) receptors. Regarding treatment, almost all women underwent surgery (breast-conserving surgery for 62% and mastectomy for 36% of the patients). Radiotherapy, chemotherapy and hormonotherapy were administered respectively to 70%, 55% and 36% of the patients. At a median follow-up of 10.2 years, 16.7% of the women (N=265) developed local recurrences and 25.4% (N=403) developed distant metastases, while 66.3% (N=1051) did not present any recurrences. Regarding mortality, 474 (29.9%) women deceased during the study period, 347 of whom (73.2%) from BC. Competing risks analyses shows that women remained at risk of developing both types of recurrences up to 30 years after diagnosis. The probability of presenting distant metastases was higher for all ages and all stages except for patients with stage I who were more likely to have local recurrences.

Discussion
This study presents the very long term outcomes of young women diagnosed with BC. While the vast majority of the patients did not develop any recurrences, some of them were still at risk even after 30 years of follow-up. The main hazard was of distant rather than local recurrence. Further analyses on this cohort will allow to assess the determinants of these risks.
Breast cancer-related deaths according to grade in ductal carcinoma in situ: A Dutch population-based study on patients diagnosed between 1999 and 2012

Marissa C van Maaren\textsuperscript{1,2}, Mirelle Lagendijk\textsuperscript{3}, Madeleine MA Tilanus-Linthorst\textsuperscript{3}, Linda de Munck\textsuperscript{1,4}, Ruud M Pijnappel\textsuperscript{5}, Marjanka K Schmidt\textsuperscript{6}, Jelle Wesseling\textsuperscript{6}, Linetta B Koppert\textsuperscript{3} and Sabine Siesling\textsuperscript{1,2}. \textsuperscript{1}Netherlands Comprehensive Cancer Organisation (IKNL), Utrecht, Netherlands; \textsuperscript{2}University of Twente, Enschede, Netherlands; \textsuperscript{3}Erasmus MC Cancer Institute, Rotterdam, Netherlands; \textsuperscript{4}University Medical Center Groningen, Groningen, Netherlands; \textsuperscript{5}University Medical Centre Utrecht, Utrecht, Netherlands and \textsuperscript{6}Netherlands Cancer Institute-Antoni van Leeuwenhoek, Amsterdam, Netherlands.

Background
The incidence of ductal carcinoma in situ (DCIS) has drastically increased over the past decades. Since DCIS is resected after diagnosis similarly to invasive breast cancer, the natural cause and behaviour of DCIS is not well known. We aimed to determine breast cancer-specific (BCSS) and overall survival (OS) according to grade in DCIS patients after surgical treatment in the Netherlands.

Patients and methods
All DCIS patients diagnosed between 1999-2012 were selected from the Netherlands Cancer Registry. Cause of death was obtained from 'Statistics Netherlands'. BCSS and OS were estimated using multivariable Cox regression in the entire cohort and stratified for grade.

Results
In total, 12,256 patients were included, of whom 1,509 (12.3%) presented with grade I, 3,675 (30.0%) with grade II, 6,064 (49.5%) with grade III and 1,008 (8.2%) with an unknown grade. During a median follow-up of 7.8 years, 1,138 (9.3%) deaths were observed, and 179 (1.5%) were breast cancer-related. Of these, 10 patients had grade I, 46 grade II, 95 grade III and 28 an unknown grade. After adjustment for confounding, grade II and III were related to worse BCSS compared to grade I with HRs of 1.92 (95% CI:0.97-3.81) and 2.14 (95% CI:1.11-4.12), respectively. No association between grade and OS was observed.

Conclusion
BCSS and OS rates in DCIS patients are excellent. Since superior rates were observed for low-grade DCIS, and earlier studies have shown that low-grade DCIS have a very low chance on recurrence or upstage to invasive cancer, it seems justified to investigate whether active surveillance may be a balanced alternative for conventional surgical treatment.
Insulin resistance and breast cancer incidence and mortality in postmenopausal women

Rowan T Chlebowski¹, Kathy Pan², Joanne Mortimer¹, Elizabeth M Cespedes Feliciano³, Marc J Gunter⁴, Arti Hurria¹, Thomas Rohan⁵, Mara Z Vitolins⁶, Lucile Adams-Campbell⁷, Gloria Ho⁸, Ting-Yuan David Cheng⁹ and Rebecca Nelson¹. ¹City of Hope National Medical Center, Duarte, CA; ²Los Angeles BioMedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA; ³Kaiser Permanente Northern California, Oakland, CA; ⁴The International Agency for Research on Cancer, Lyon, France; ⁵Albert Einstein College of Medicine, Bronx, NY; ⁶Wake Forest School of Medicine, Winston-Salem, NC; ⁷Georgetown University, Washington DC; ⁸Northwell Health, Great Neck, NY and ⁹University of Florida, Gainesville, FL.

Background: Obese postmenopausal women are at higher breast cancer risk potentially driven by hyperinsulinemia. However, reports of insulin level associations with breast cancer incidence and survival are inconsistent. Therefore, we examined associations among insulin resistance by homeostasis model assessment-insulin resistance (HOMA-IR) index and incident breast cancer, deaths from breast cancer, and deaths after breast cancer in postmenopausal women participating in the Women's Health Initiative (WHI).

Patients and Methods: From the 161,808 postmenopausal women, aged 50-79 years, enrolled at 40 US clinical centers from 1993 through 1998 in WHI clinical trials or the observational study, 22,837 with available fasting serum insulin and glucose by the same methodology and no prior breast cancer represent the current study population. The exposure was insulin resistance (HOMA-IR index) as [fasting insulin (µIU/ml) times fasting glucose (mg/dL) / 22.5. Survival by cause was determined by central medical record or death certificate review, enhanced by National Death Index queries. Breast cancers, initially ascertained by serial survey, were confirmed by medical record review. Associations between HOMA-IR quartiles and breast cancer outcomes were examined using Cox multivariate proportional hazards models with results reported as hazard ratios (HR) and 95% confidence intervals.

Results: At entry, women in the highest HOMA-IR quartile were more likely to be Black, have lower education level, have higher body mass index (BMI), higher waist circumference ≥ 88 cm and lower physical activity levels, but have lower calculated five-year breast cancer risk. After 18.1 years median follow-up from randomization with 1,148 incident breast cancers, breast cancer incidence was higher in women in the highest, compared to the lowest, HOMA-IR index quartile (HR 1.39 95% CI 1.14 -1.69, P = 0.0012). Of the women with incident breast cancer, 353 (31%) have died, with cause of death available on 334 (95% of cases) where breast cancer was the most common cause of death (33%); followed by cardiovascular disease (24%); and other cancers (13%). With median post-breast cancer diagnosis follow-up of 10.5 years, breast cancer mortality was examined from breast cancer diagnosis. No association was found between death from breast cancer and HOMA-IR. However, women with breast cancer in the highest HOMA-IR quartile, compared to women in the lowest, were significantly more likely to experience death after breast cancer from any cause (HR 1.45 95% CI 1.00 - 2.09, P = 0.0488) and were at somewhat higher risk of death from cardiovascular disease (HR 1.51 95% CI 0.67 - 3.41) and other causes (HR 1.93 95% CI 0.87-4.27).

Conclusion: In postmenopausal women, higher insulin resistance is associated with higher breast cancer incidence and more deaths after breast cancer, likely due to insulin influence on several causes of death. However, deaths from breast cancer, even in this older postmenopausal population, remains a major factor limiting survival which needs to be addressed. The findings suggest insulin resistance represented a potential intervention target for postmenopausal women with early stage...
breast cancer.
The impact of existing comorbidities on survival disparities among women diagnosed with invasive breast cancer

Avonne E Connor¹, Betty May¹, Chester L Schmaltz², Jeannette Jackson-Thompson³ and Kala Visvanathan¹. ¹Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; ²Missouri Cancer Registry and Research Center, University of Missouri-Columbia, Columbia, MO and ³Missouri Cancer Registry & Research Center; U. of Missouri (MU) School of Medicine and MU Informatics Institute, Columbia, MO.

Missouri is one of many states in the US burdened by high rates of mortality from female breast cancer (BC) as well as comorbidities such as Type-2 diabetes, cardiovascular disease (CVD), and hypertension. These comorbidity rates are higher among vulnerable populations including individuals in poverty and/or living in rural areas, African Americans, and the elderly. There is evidence that women with comorbidities at the time of BC diagnosis have a worse prognosis. We hypothesize that the co-existence of comorbidities is likely to impact survival and may contribute to survival disparities observed among women diagnosed with BC from these vulnerable populations.

Objective: To examine whether the number and/or type of comorbidity at BC diagnosis is associated with higher BC and all-cause mortality among women diagnosed with invasive BC in Missouri between 2004 and 2012.

Methods: Women age 18+ diagnosed with BC in Missouri during 2004–2012 were identified from the Missouri Cancer Registry. These data were then merged with hospital discharge data from the Missouri Patient Abstract System. Associations were evaluated in all women and by race, neighborhood poverty level, rural/urban residence, and age at diagnosis. A comorbidity score was constructed to account for the number of comorbidities (Type-2 diabetes, hypertension, and CVD) identified for each individual. Hazard ratios (HR) and 95% confidence intervals (CI) were calculated using Cox proportional hazards regression models, adjusting for age at diagnosis, race, tumor hormone receptor status, stage, BC treatment, and rural/urban residence. Models were further stratified by race, poverty level, rural/urban residence, and age group.

Results: A total of 31,133 women with incident invasive BC and with comorbidity data at the time of BC diagnosis were included in the analysis. After a median follow-up time of 79 months, 9,912 deaths occurred, of which 4,900 deaths were due to BC. Increasing number of comorbidities was significantly associated with BC mortality ($p_{\text{trend}} < 0.001$). BC mortality (HR, 1.33; 95% CI 1.19-1.49) and all-cause mortality (HR, 1.51; 90% CI 1.32-1.61) were significantly higher in women with ≥2 comorbidities. CVD accounted for the largest increase in BC mortality (HR, 1.36; 95% CI 1.19-1.55). In stratified analyses, we did not observe significant differences in associations by race, poverty, rural/urban residence, or age; however, there was a statistically significant interaction with age when modeled as a continuous measure, comorbidity score, and risk of mortality outcomes ($p< 0.001$). White women with all 3 comorbidities had the highest risk of death (BC-specific: HR, 1.95; all-cause: HR, 2.28). Women in rural areas with ≥2 comorbidities were 1.78 times more likely to die of BC while women living in the metro with all 3 comorbidities were almost 2 times more likely to die of any cause.

Conclusion: Our results demonstrate the negative impact that comorbidities such as diabetes, CVD, and hypertension can have on BC and overall mortality in a diverse group of BC patients diagnosed and treated in Missouri. The data produced from this study can be utilized to identify and implement targeted preventive strategies to improve the quality of life and survival of BC patients.
Trends in incidence of bilateral breast cancer: A Population-based comparative study of the United States and Japan

Takehiko Sakai¹, Enver Ozkurt¹, Stephen Desantis¹, Stephanie Wong², Laurel Rosenbaum¹, Hui Zheng³, Shinji Ohno⁴ and Mehra Golshan¹. ¹Brigham and Women’s Hospital/Dana-Farber Cancer Institute, Boston, MA; ²McGill University Health Centre, Montreal, QC, Canada; ³Biostatistics Center, Massachusetts General Hospital, Boston, MA and ⁴Breast Oncology Center, Cancer Institute Hospital of the Japanese Foundation for Cancer Research, Tokyo, Japan.

**Background:** Previous studies demonstrated that the incidence rate of invasive contralateral breast cancer (CBC) was 5% within the first 10 years after the primary breast cancer (BC). However improving long-term breast cancer survivorship and advancements in diagnostic imaging have resulted in an increased detection of bilateral breast cancer (BBC), and trends of bilateral invasive and in situ breast cancer are not well established. The aim of this study was to assess national trends of BBC incidence of the United States (US) and Japan.

**Methods:** The Surveillance, Epidemiology, and End Results (SEER) database (1973-2014) and the clinical database of Breast Oncology Center of Cancer Institute Hospital in Tokyo, Japan (Ganken) database (1946-2015) were used to identify $n_{\text{SEER}}=11,771$ and $n_{\text{Ganken}}=1,499$ women diagnosed with BBC, respectively. BBC was defined as invasive BC and/or ductal or lobular carcinoma in situ diagnosed in both breasts simultaneously or after primary breast cancer diagnosis. BBC was grouped into synchronous or metachronous BBC by the interval between first BC and contralateral BC; synchronous cases were defined as CBC diagnosed at the same time or within an interval of 1 year from primary BC diagnosis whereas metachronous cases were defined as a diagnosis occurring 1 year following the primary BC. We assessed trends of BBC incidence and characteristics of BBC cases between the two countries. To determine temporal trends in the incidence of BBC and proportion of the characteristics, we compared them using the Cochrane-Armitage test for trend.

**Results:** The rates of BBC have significantly increased in both countries (Table 1, 2) [1975: 2.6%; 2014: 7.5% in SEER (p<0.001), 1946-1980: 3.3%; 2011-2015: 10.7% in Ganken (p<0.001)]

</tbody>
</table>

The increase was identified in both synchronous and metachronous BBC. In SEER, 40% of synchronous BBC were found as in situ BC and about 15% of BBC presented as invasive lobular carcinoma. More recently, CBC was more likely to be diagnosed at
early stages (in situ and local disease) than in previous years [1975: 65%; 2014: 85% in SEER (p<0.001)]. The interval between first BC and contralateral BC have shortened, and CBC were more likely to be operated simultaneously in both countries [1985: 40%; 2014: 51% in SEER, 1946-1980: 24%; 2011-2015: 74% in Ganken].

**Conclusion:** In the modern era, the number of BBC cases have increased and are more likely to be found at an early stage. Further studies are needed to demonstrate the usefulness of early detection of CBC and to define the best means to tailor therapy for patients with bilateral disease.
A prospective evaluation of HLA expression in breast implant associated anaplastic large cell lymphoma to identify disease susceptibility

Sarah E Tevis¹, Kelly K Hunt², Roberto N Miranda², Charles E Butler² and Mark W Clemens². ¹University of Colorado, Denver, CO and ²MD Anderson Cancer Center, Houston, TX.

Background: Breast implant-associated anaplastic large cell lymphoma (BIA-ALCL) is a rare T-cell lymphoma found to occur in association with breast implants. Proposed pathogenic factors for BIA-ALCL include immunologic reaction to textured implants, bacteria and biofilm, chronic inflammation, autoimmune disease, or genetic predisposition. While HLA alleles have been found to be associated with other forms of lymphoma, the frequency of HLA allele polymorphisms have not been described for BIA-ALCL. The aim of this study is to evaluate the frequency of HLA alleles in patients with BIA-ALCL.

Methods: We prospectively evaluated HLA alleles in 13 patients with BIA-ALCL seen at a single institution from 2017 to 2018. HLA testing was carried out using probe based sequence specific testing and sequence based typing. The frequency of HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1 were evaluated in the study population. Allele frequencies in the Caucasian European general population were obtained from the National Marrow Donor Program for normative controls. We estimated the relative risk of BIA-ALCL with 95% confidence intervals for each HLA allele using a t test. All statistics were performed using SPSS.

Results: Thirteen patients with BIA-ALCL and HLA testing were identified with ages ranging from 37 – 76 years. We identified 10, 11, and 9 HLA A, B, and C alleles respectively. There were 8 DRB1 alleles and 5 DQB1 alleles in the BIA-ALCL patients. The following alleles occurred more than two times more frequently in patients with BIA-ALCL as compared with the general population: A*31, A*32, A*68, B*27, B*39, B*49, B*51, and C*15. Conversely, the A*01, A*24, and B*35 alleles occurred less frequently in patients with BIA-ALCL. The A*26 allele was found to occur significantly less often in BIA-ALCL patients (0.2992 vs. 0.07692, p<0.001) versus normative controls.

Conclusions: Our results identify differences in the frequency of specific HLA alleles in patients who develop BIA-ALCL compared with the general population. These alleles may signify genetic susceptibility factors for germline genetic variation in HLA in Caucasian patients with BIA-ALCL. Further work is needed to elucidate if these alleles confer susceptibility or resistance and are predictive for the disease in women with textured surface breast implants.
Trend of utilization of Oncotype DX testing among female hormone receptor positive breast cancer patients in 17 SEER registries, 2004-2015

Lu Zhang¹, Mei-Chin Hsieh¹, Valentina I Petkov², Qingzhao Yu¹ and Xiao-Cheng Wu¹. ¹Louisiana State University Health Sciences Center, New Orleans, LA and ²National Cancer Institute, Rockville, MD.

Background: Oncotype DX, a 21-gene Recurrence Score (RS) assay, has been validated as assay that effectively predicts recurrence and chemotherapy (chemo) benefits for hormone receptor positive (HR+) human epidermal growth factor receptor 2 negative (HER2-) breast cancer (BC). Although guidelines recommend the test to lymph node (LN) negative (PN0) BC patients, it has also been used in patients with 1-3 positive LN (PN1) in clinical practice. The study aimed to 1) examine the trend of utilization of Oncotype DX testing for HR+ and PN0 or PN1 BC patients from 2004 to 2015, as well as the trend in patients with different clinical risk; 2) investigate the trend of having reported chemo in patients with low, intermediate, and high RS; and 3) compare cause-specific survival (CSS) and overall survival (OS) between patients who had test and those who did not.

Methods: Data from Genomic Health Inc., the sole Oncotype DX testing provider in the U.S., was linked with routinely collected data from 17 SEER registries. Women who received surgery for stage I-III, HR+ and PN0 or PN1 BC diagnosed in 2004-2015 were included. The Cochrane-Armitage trend test was conducted for trend analysis. Using the overall sample as standard population (frequency of each age-racial group in overall sample as weight), age-race standardized percentage of test use was calculated. Since HER2 data was available only after 2010, survival analysis was restricted to HR+/HER2- patients diagnosed in 2010-2014 whose BC was the only primary tumor. Patients who used and those who did not use the test were matched on propensity score, which was calculated based on age, race, marital status, insurance, grade, tumor size, surgery type, radiation, and chemo within each diagnosis year. Stratified Cox proportional hazards model was used to compare survival between two matched groups. Proportional hazard assumption was met for each model.

Results: Out of 346,380 PN0 and 103,317 PN1 patients, the percentage of using Oncotype DX test increased from 2.0% to 38.2%, and from 0.5% to 28.0% from 2004 to 2015, respectively (P-for-trend < 0.0001 for each). Age-race standardized percentage of test use was the highest and increased most rapidly for tumors with intermediate clinical risk (moderately differentiated or tumor size 2.1-5.0cm) among PN0 patients, but for tumors with low clinical risk (well differentiated or tumor size ≤2.0cm) among PN1 patients. From 2004 to 2015, the percentage of having reported chemo decreased in patients with low (PN0: 14.7% to 1.8%; PN1: 27.3% to 16.2%) and intermediate RS (PN0: 36.1% to 28.6%; PN1: 60.0% to 44.7%), but increased among patients with high RS (PN0: 59.0% to 75.4%; PN1: 66.7% to 74.2%). Test use was associated with better CSS (PN0: hazard ratio [HR] 2.15, 95% CI 1.73-2.67; PN1: HR 2.83, 95% CI 2.02-3.95) and OS (PN0: HR 2.05, 95% CI 1.81-2.33; PN1: HR 2.65, 95% CI 2.10-3.35).

Conclusions: The use of Oncotype DX test has increased steadily among female HR+ BC patients since 2004. It reduced unnecessary chemo among patients with low or intermediates RS, and increased chemo use in patients with high RS. Among HR+/HER2- patients, those who used test had better CSS and OS than those who did not.
Characteristics of long-term survivors with metastatic breast cancer

Mark E Burkard\(^1\), Kayla Lemmon\(^1\), Aidan D Gilbert\(^2\), Xiao Zhang\(^3\), Amy Trentham-Dietz\(^3\), Eileen Dahl\(^4\) and Gabrielle Rocque\(^2\).
\(^1\)UW Carbone Cancer Center and University of Wisconsin--Madison, Madison, WI; \(^2\)University of Alabama, Birmingham, Birmingham, AL; \(^3\)University of Wisconsin--Madison, Madison, WI and \(^4\)Advocate, Toronto, ON, Canada.

**Background:** Survival with metastatic breast cancer (MBC) is highly variable and only ~16% survive 10 years from the primary cancer diagnosis. In addition to treatments, proposed contributors to increased survival include cancer subtype, distribution of metastases, diet, exercise, and use of complementary and alternative medicine (CAM). We aimed to characterize long-term survivors with MBC through a self-administered survey.

**Methods:** Patient advocates and researchers collaborated on developing and administering an ongoing web-based questionnaire (outliers.cancer.wisc.edu). Participants were recruited to this IRB-approved project through fliers, social media, MBC conferences, and Susan Love's Army of Women, with a recruiting focus on long-term survivors. Women and men are eligible if they are age ≥18 years old and have MBC by self-report. Eligible participants were invited to complete a detailed 28-part survey in English. Preliminary analysis was conducted by descriptive comparison of survivors ≥10 years from primary diagnosis versus those < 10 years.

**Results:** Between March 6 and June 17, 2018, a total of 475 women and 1 man self-reported as living with MBC consented and completed the survey. Participants represented 48 U.S. states (n=414), and other countries on 4 continents (n=54). Two thirds of respondents (315) reported using medical records in preparing responses. Age of respondents ranged from 32-83 years (median 55), and participants survived from 4 months to 50 years (median 8.7), from primary breast cancer diagnosis. A total of 206 had lived ≥10 y from primary diagnosis and 270 <10 y (Table).

*Number/site of tumors at time of metastatic presentation

As expected, longer-term survivors were older and were less likely to have been diagnosed at stage 4. Surprisingly, there were no major differences in prevalence of breast cancer subtypes, though triple-negative breast cancer was rare in both groups. Long-term survivors reported modestly more alcohol intake and lower BMI. The two groups were well matched for oligometastatic and bone-only disease, which have been previously associated with longer survival. Additionally, there were similar rates of prior smoking, CAM use, and sedentary behavior.

**Conclusion:** Interim analysis of this ongoing survey of MBC survivors finds that many disease and behavioral characteristics are similar between long-term versus short term survivors. Additional factors such as treatments, diet, and supplements will be reported. Other possible factors, including tumor genetics, treatments and immunologic factors will be evaluated separately.
The influence of patient fitness on the likelihood of receiving primary surgery in older women with breast cancer: A population based cohort study

Yasmin Jauhari1, Melissa Gannon1,2, Jibby Medina1, Kieran Horgan1,3, David Dodwell1,3 and David Cromwell1,2. 1Clinical Effectiveness Unit, Royal College of Surgeon, London, United Kingdom; 2London School of Hygiene & Tropical Medicine, London, United Kingdom and 3Leeds Teaching Hospital NHS Trust, Leeds, United Kingdom.

Introduction: There is evidence of variation in the patterns of treatment of older women with breast cancer (BC). As women age, there are less similarities in terms of their functional ability, physiology and social wellbeing. This multifaceted relationship between disease and ageing makes the interpretation of age-related differences in BC management and outcomes at a population level complex. Measuring frailty is as an emerging concept and offers a way to standardise how characteristics of ageing are used in BC.

Objective: We compared the primary treatment patterns of women aged ≥70yrs compared to those aged 50–69yrs, with early invasive BC (EIBC; stage 1-3A); using a novel measure of frailty in addition to commonly used patient fitness measures.

Methods: Women aged ≥50yrs, diagnosed with unilateral EIBC in England and Wales between 01/01/2014 and 31/12/2016; were identified by linkage of several national datasets. Patient fitness was measured by the reported WHO performance status (WHO PS), a calculated Charlson comorbidity score (CCS) and a developed frailty measure based on the electronic Frailty Index (eFI). Multilevel logistic regression was used to account for clustering in the data.

Results: Among 126,111 women aged ≥50yrs with BC, 88,028 had EIBC: 88% in women aged 50-69yrs and 75% in women aged ≥70yrs. Table 1 describes the proportion of women who received surgery by age and measures of fitness. Overall, older women were less likely to undergo primary surgery, regardless of fitness. For each measure of fitness, fewer women in both age groups underwent surgery as their levels of fitness decreased; the magnitude of this change was greater for women aged ≥70yrs. Older women were also less likely to receive BCS for tumours <5cm, compared to women aged 50-69yrs.

Receipt of surgery in women aged ≥50years with EIBC according to CCS, eFI and WHO PS status, by age at diagnosis

The association between independent factors of ageing and fitness, and 'no surgery' remained after accounting for case-mix differences and clustering within geographical region. Compared to women aged 50–69yrs, there was strong regional variation in the adjusted rate of surgical treatment for EIBC in women aged ≥70yrs.

**Discussion:** Older women are less likely to undergo surgery for EIBC. Even a minor decrease in fitness levels significantly impacts the likelihood of receiving surgery in women ≥70yrs; such a pattern is not observed in women aged 50–69yrs. Long-term follow up of these women will enable further understanding of the implications of this variability in practice on outcomes. We also acknowledge poor data completion for the WHO PS, and propose that eFI is suitable replacement measure of fitness in older patients with BC.
Pharmacy refill synchronization and oral endocrine therapy adherence

Joan M Neuner, Nicole Fergestrom, Ann B Nattinger, Purushottam W Laud and Liliana Pezzin. 'Medical College of Wisconsin, Milwaukee, WI.

**Background:** One-third to one-half of patients prescribed adjuvant endocrine therapy with tamoxifen or an aromatase inhibitor either discontinue early or skip a substantial number of pills. Research to improve this has been disappointing. We investigated whether poor pharmacy synchronization of medications is an unrecognized barrier to adherence. **Methods:** A cohort of women aged 66-90 years old with Stage 0-3 hormone receptor-positive breast cancer were identified from the Surveillance, Epidemiology and End Result (SEER)-Medicare claims-linked cancer registry. Women with Medicare pharmacy claims documenting at least one endocrine therapy prescription fill and at least one other medication fill were identified, and the 3-month synchronization of their medication fills was calculated as the quotient of the number of pharmacy visits and the number of filled medications subtracted from one. Logistic regression was used to assess the association between synchronization stratified by the number of medications and adherence to endocrine therapy (defined as medication possession ratio >80%) over the subsequent year. **Results:** The study cohort included 3,112 women treated with endocrine therapy for breast cancer (Table 1). Over 31% were age 70 or younger, and 38.0% had stage 2 or 3 disease. During the three months after the first endocrine therapy prescription, the mean number of unique medications was 8.0 (S.D. 6.0) and the mean number of pharmacy visits was 8.6 S.D. 4.7) for a mean synchronization of 0.3 (S.D. 0.2). In adjusted model, compared with the highest synchronization, those in the lowest synchronization quantile were less likely to be adherent (MPR >=80%) (Odds Ratio 0.71 (95% CI 0.57, 0.88)) as were those in the second-lowest (0.81 (0.65, 0.99). Neither age nor race/ethnicity were associated with adherence, and results were unchanged with inclusion of information about duration of fills (30 vs 90 days). **Conclusions:** Prescription fill synchronization is strongly associated with adherence to endocrine therapy. Research into interventions to improve adherence should include prescription synchronization and other health systems barriers.
Initiating adjuvant endocrine therapy: Choice of drugs and changes in the patent status of aromatase inhibitors

Xuanzi Qin\textsuperscript{1}, Peter Huckfeldt\textsuperscript{1} and Beth A Virnig\textsuperscript{1}. \textsuperscript{1}University of Minnesota Twin Cities, Minneapolis.

**Background:** Aromatase inhibitors (AIs) and tamoxifen are guideline recommended adjuvant endocrine therapies for postmenopausal women diagnosed with hormone-receptor positive (HR+) breast cancer. Before 2010, all AIs were brand-name, while tamoxifen was generic. In June 2010, anastrozole became the first AI with generic versions available. Generic exemestane became available in April 2011, and generic letrozole in June 2011. We study the associations between the generic drug availability, choice of drug initiated and changes in out-of-pocket (OOP) costs for elderly women in the Medicare program newly diagnosed with HR+ breast cancer.

**Methods:** From the SEER-Medicare linked database, we selected women whose first HR+ breast cancer was diagnosed at age 65 or older between 2007 and 2013, and who had Medicare Part D (pharmacy) coverage in the 12 months following the diagnosis (or until death).

**Results:** Prior to the availability of all generic AIs, the average monthly OOP costs of AIs were as high as $150 with a yearly repeating pattern of highs and lows. Consistent with Part D benefit design, the average monthly OOP costs for patients were the lowest around February and the highest around October. The percent of patients who initiated endocrine therapy was stable (60%). After all AIs had generic versions available, the OOP costs decreased, and fluctuations of the average monthly OOP costs disappeared. The OOP costs for the two AIs with the highest market shares stabilized to around $10. The average monthly OOP costs of tamoxifen were constantly around $10. Compared to the dramatic changes in the OOP costs of AIs, the changes in utilization were modest. The percent of patients who initiated any drug increased to 70% in 2012-14. The percent of patients choosing anastrozole, exemestane and tamoxifen increased by 3-5%, while letrozole decreased by 10%, compared to that in 2007-2009. Increases in anastrozole were only substantial before generic letrozole was available (June 2010-May 2011).

**Conclusions:** With generic entry, dramatic decreases in the prices and increases in initiations would be expected. We saw dramatic decreases in average monthly OOP costs. Changes in choice of AI were modest, especially considering tamoxifen initiation also increased after all generic AIs were available.
10-year conditional recurrence risks, overall and relative survival for breast cancer patients in the Netherlands: Taking account of event-free years

Marissa C van Maaren¹,², Luc JA Strobbe³, Marjolein L Smidt⁴, Martine Moossdorff⁵, Philip MP Poortmans⁶ and Sabine Siesling¹,².
¹Netherlands Comprehensive Cancer Organisation (IKNL), Utrecht, Netherlands; ²University of Twente, Enschede, Netherlands; ³Canisius Wilhelmina Hospital, Nijmegen, Netherlands; ⁴Maastricht University Medical Centre, Maastricht, Netherlands; ⁵Zuyderland Medical Centre, Sittard-Geleen, Netherlands and ⁶Institut Curie, Paris, France.

Background
Survival estimates valid at the time of diagnosis are of limited value for (ex-)breast cancer patients who survived several years, as it includes information on already deceased patients. This study analyzed the 10-year conditional risk of recurrent breast cancer in specific prognostic subgroups according to T and N stage and breast cancer subtypes. Secondly, we investigated 10-year conditional overall (OS) and relative survival (RS), adjusted for confounding.

Patients and methods
We selected all women diagnosed in 2005 with operated T1-2N0-1 breast cancer from the Netherlands Cancer Registry. Patients were classified into T1N0, T1N1, T2N0 and T2N1 stage. Ten-year conditional recurrence rates were calculated for every year from diagnosis for patients without an event (local (LR), regional recurrence (RR), distant metastasis (DM) or death). Ten-year conditional OS was calculated using multivariable Cox regression. RS was estimated by dividing patient survival rates by those of the general Dutch population.

Results
We included 7,969 patients: 52.3% had T1N0, 15.3% T1N1, 19.9% T2N0 and 12.5% T2N1 stage. For T1N0, 10-year LR rates changed from 4.6% at diagnosis to 0.5% in year 10. RR rates decreased from 2.3% to 0.2% and DM rates decreased from 7.8% to 0.6%. For T2N1 stage, the LR, RR and DM rates decreased from 6.2% to 0.8%, 5.2% to 0.4% and 19.6% to 1.5%, respectively. Of all patients, 1,702 patients (21.4%) had an unknown breast cancer subtype and were consequently excluded from the analyses according to subtype. Of the remaining 6,267 patients, 3,774 (60.2%) had luminal A, 1,465 (23.4%) had luminal B, 314 (5.0%) had HER2 positive and 714 (11.4%) had triple negative disease. For the luminal A subtype, LR, RR and DM rates ranged from 3.9% to 0.4%, 1.7% to 0.5% and 7.3% to 1.1%, while for triple negative these rates ranged between 5.6% to 0.7%, 4.9% to 0.2% and 16.7% to 0%, respectively. Differences between subgroups attenuated over time and all recurrence rates became ≤1.5% in year 10. Ten-year OS and RS, adjusted for confounding, showed diminishing risk differences between subgroups over time.

Conclusion
Differences in recurrence rates, OS and RS between prognostic subgroups decreased as years passed by. These results highlight the importance of taking into account disease-free years to more accurately predict (ex-)breast cancer patients' prognosis over time.
Healthcare use in the last six months of life in advanced breast cancer: An analysis from the Southeast Netherlands Advanced Breast Cancer (SONABRE) registry

Maaike de Boer¹, Renée SJM Schmitz¹, Khava IE Ibragimova¹, Marianne van Kleef¹, Sandra ME Geurts¹ and Vivianne CG Tjan-Heijnen¹. ¹Maastricht University Medical Center, Maastricht, Netherlands.

In advanced breast cancer (ABC), a growing number of treatment options have become available the past 10 years, increasing overall survival. Healthcare use near the end of life has increased, although specific data for ABC are limited. This study describes healthcare use during the last 6 months of life in patients diagnosed with ABC in Maastricht University Medical Center (MUMC+).

Methods: From our Southeast Netherlands Advanced Breast Cancer (SONABRE) Registry, we selected all patients from MUMC+ who were diagnosed with ABC and who also had passed away between January 1st, 2007 and October 1st, 2017. Patient, disease and treatment characteristics and data regarding health care use in the last period of life defined as ongoing chemotherapy ≤14 days before death, start of a new line of chemotherapy ≤30 days before death, and radiotherapy, hospital admission, surgery, intensive care unit (ICU) admission, mechanical ventilation, cardiopulmonary resuscitation (CPR) ≤6 months before death, and cause and place of death were collected by trained registration clerks. Healthcare use was described and univariate analyses were carried out for ongoing chemotherapy ≤14 days or start chemotherapy line ≤30 days before death, admission and death in the hospital using chi square and Fisher's exact test. The SONABRE Registry was approved by the Medical Research Ethics Committee of Maastricht University Medical Center.

Results: Of 203 included patients, chemotherapy was continued ≤14 days before death in 21%, and a new line of chemotherapy ≤30 days before death was started in 9% of patients. In the last 6 months of life, radiotherapy was applied in 21% of patients. Hospital admission occurred in 76% of patients, because of tumor-related symptoms in 60%, and because of toxicity in 12% of these. Surgery (4%), ICU admission (6%), mechanical ventilation (5%), and CPR (2%) occurred infrequently. Of all patients, 25% died in the hospital; 74% due to progressive disease, 12% due to complications of therapy for ABC and 14% non-breast cancer related. Ongoing chemotherapy ≤14 days before death was associated with age<65 years (p<0.001) and negative hormone receptor (HR) status (p=0.04); start of a new line of chemotherapy ≤30 days before death was associated with age<65 years (p<0.001). Hospital admission was associated with age<65 years (p=0.008), de novo ABC (p=0.01), negative HR status (p=0.04) and chemotherapy as last line of therapy (p=0.001). Death in the hospital was associated with ongoing chemotherapy ≤14 days (p<0.001) and start of a new line of chemotherapy ≤30 days before death (p<0.001).

Conclusion: During the last 6 months of life, admission due to tumor-related symptoms occurred frequently, whereas ICU admission, mechanical ventilation and CPR occurred rarely. Death in the hospital occurred in a quarter of patients, and more frequently in those receiving chemotherapy shortly before death, which in turn was associated with younger age. Insight in real-life healthcare use may improve shared decision making and advanced care planning for patients with ABC.
Association of depression and anxiety disorder with the risk of mortality in breast cancer: A national health insurance service study in South Korea

Yoo Seok Kim¹, Eun-Jung Shim², Jong Won Lee³, Jihyoung Cho⁴, Hong Kyu Jung⁵, Nam Hyoung Kim⁶, Jung Eun Lee⁷, Junwon Min⁸, Woo Chul Noh⁹ and Sung-Hwan Park¹⁰. ¹Chosun University College of Medicine, Gwangju, Republic of Korea; ²Pusan National University, Busan, Republic of Korea; ³University of Ulsan College of Medicine, Asan Medical Center, Seoul, Republic of Korea; ⁴Keimyung University School of Medicine, Daegu, Republic of Korea; ⁵Seran General Hospital, Seoul, Republic of Korea; ⁶Kaywon University of Art and Design, Uiwang-si, Republic of Korea; ⁷Seoul National University, Seoul, Republic of Korea; ⁸Dankook University College of Medicine, Cheonan, Republic of Korea; ⁹Korea Institute of Radiology and Medical Science, Korea Cancer Center Hospital, Seoul, Republic of Korea and ¹⁰Daegu Catholic University Medical Center, Daegu, Republic of Korea.

PURPOSE: To examine whether depression, anxiety disorder and their co-occurrence would increase the risk of mortality in patients with breast cancer, and whether antidepressant treatment would reduce the same.

PATIENTS AND METHODS: Data were retrieved from the database of the Korean National Health Insurance Service. Of 145,251 patients diagnosed with breast cancer between 2007 and 2014, 20,870 patients diagnosed with depression or anxiety disorder one year before breast cancer diagnosis were excluded. Thus, data of 124,381 patients were included in this study.

RESULTS: Anxiety disorder was more prevalent than depression in patients with breast cancer, and similar factors were associated with both depression and anxiety disorder. Overall, female sex, older age, residence in metropolitan areas, lower income, higher comorbidity, carcinoma in situ, and the receipt of any type of cancer therapies were associated with an increased risk of depression or anxiety disorder. Depression and anxiety disorder were associated with an increased risk of mortality (Hazard Ratio (HR) = 1.26, 95% CI=1.18–1.36; HR=1.14, 95% CI=1.08–1.22, respectively) and their co-occurrence further increased the risk (HR=1.38, 95% CI=1.24–1.54). Antidepressant treatment was related to a reduced risk of mortality. Compared to patients with no depression, among those with depression, the risk of mortality was 2.18 times higher (95% CI =1.69–2.81) in patients who did not receive antidepressant treatment and 1.25 times higher (95% CI =1.17–1.32) in those who received antidepressant treatment.

CONCLUSION: The current findings suggest that psychiatric comorbidities are markers of increased mortality risk in patients with breast cancer. This underscores the need for screening and treating depression and anxiety disorders to improve survival in breast cancer.
Adenosquamous carcinoma of the breast, an uncommon diagnosis with poor prognosis – Lessons learned from analysis of the National Cancer Data Base 2004-2015

Katherine Cochrane1, Robert E Heidel1, John L Bell1 and Amila Orucevic1. *University of Tennessee Medical Center, Graduate School of Medicine, Knoxville, TN.

Background
Adenosquamous carcinomas (ASQ) of the breast is rare, with a reported incidence of <1%. This tumor is considered to belong to the metaplastic breast carcinoma category and is commonly low grade. It has a distinct adenocarcinomatous component comprised of infiltrating small glands with varying degrees of squamous differentiation. The significance of ASQ differentiation and its impact on diagnosis, treatment and prognosis is based primarily on results from small retrospective case series reports. The objective of our study is to define prevalence, clinicopathologic characteristics, treatment patterns and prognosis of ASQ and compare these to the most frequent invasive breast carcinoma (BC), ductal (IDC), through analysis of the National Cancer Data Base (NCDB).

Methods
A retrospective observational study of NCDB patients (pts) compared all ASQ pts to the same number of randomly selected IDC pts (ICD-O-3 diagnosis codes 8560 and 8500, respectively) using SPSS software. Patients’ clinicopathologic characteristics, treatment, and overall survival (OS) were analyzed using frequency statistics, t-tests, Mann-Whitney U tests, chi-square, Kaplan-Meier and logistic regression.

Results
From 1,932,688 female pts with invasive BC, 1,421,250 had IDC (73.5%); 453 had ASQ (0.0002%). ASQ pts were significantly (p<0.05) more likely to be: older, have grade 1 tumors, negative lymph nodes, ER, PR, and HER2-negative tumors when compared to IDC. No significant difference was found in tumor size, TNM stage, or treatment. ASQ pts had significantly worse 5-year OS than IDC pts (p<0.025; 73% vs 82% at 60 months, respectively).

Conclusion
Our study is the largest study to date on ASQ revealing that this unique disease is an aggressive carcinoma and carries a significantly worse prognosis than IDC. Since prospective randomized clinical trial(s) are unlikely, further studies on the genomic make-up of ASQ are needed in order to understand biology and personalize treatment of pts with this uncommon BC.

*Significant (p<.05)
Hormone receptor status may impact the survival benefit between atypical medullary carcinoma of the breast and medullary breast carcinoma: A population-based study

Yuan-Sheng Zang¹, Feng Qi¹ and Wen-Xing Qin¹. "Changzheng Hospital, Shanghai, China.

**Purpose:** Atypical Medullary Carcinoma of the Breast (AMCB) is a subtype of breast cancer with a more adverse prognosis, compared with Medullary Carcinoma of the Breast (MBC). Our study was designed to identify the prognostic factors of AMCB, MBC and invasive ductal carcinoma (IDC).

**Methods:** Using the Surveillance, Epidemiology and End Results (SEER) database from 2004 to 2013, 147 eligible AMCB patients were compared for tumor characteristics and overall survival with 1863 MBC and 446708 IDC patients.

**Results:** Kaplan-Meier analysis and multivariate Cox analysis showed that patients with AMCB (5-year OS = 86.4%) had significantly worse overall survival (OS) compared to MBC (5-year OS = 93.8%, p = 0.013) (HR = 0.525, 95% CI 0.305-0.905) but similar to IDC (5-year OS = 90.4%, p = 0.477) (HR = 1.097, 95% CI 0.612-1.684). In addition, it was found that age (HR = 1.259, 95% CI 1.228-1.291), high grade (HR = 2.510, 95% CI 2.371-2.657), large tumor size (HR = 2.504, 95% CI 1.851-3.386) and hormone receptor status (HR = 1.439, 95% CI 1.392-1.486) were significantly associated with poor prognosis. In the hormone receptor (HR)-positive population, the AMCB group and MBC group had a similar survival (p = 0.656). In the HR-negative population, the MBC group gained an additional survival benefit compared with the AMCB group (p = 0.006).

**Conclusions:** Patients with AMCB showed worse overall survival than the MBC group. In HR+ patients, there did not appear to be a difference between AMCB and MBC given the similarities in prognosis; however, in the HR- population, AMCB did not gain a survival benefit.
Conditional survival of breast cancer patients: Korean nationwide registry

So-Youn Jung¹, Kyu-Won Jung¹, Young-Joo Won¹, Youngmee Kwon¹, Johyun Ha¹, Young Ae Kim¹, Sun-Young Kong¹ and Eun Sook Lee¹. ¹National Cancer Center, Goyang, Republic of Korea.

Purpose: Conditional relative survival (CRS) could provide more relevant information on the current prognosis of cancer survivors than standard 5-year relative survival (RS). This study aimed to estimate the 5-year CRS of Korean breast cancer patients.

Patients and Methods: We identified 145,083 breast cancer cases with diagnosis between 2002 and 2013 in the Korea Central Cancer Registry. The CRS was estimated for every year after diagnosis, according to sex, age, histologic types, stage, and year of diagnosis.

Results: The 5-year RS at diagnosis was 90.8% and 10-year RS was 85.7%. Five-year CRS was 91.0% and 94.3% at 1-year and 5-year after diagnosis. Women had better 5-year CRS than men after 5 years of survival (94.3% vs. 79.5%), and very young and very old patients had worse 5-year CRS after 5 years of survival than other age groups (92.2% in <40yr, 92.6% in ≥70yr vs. 95.4% in 40-49, 94.3% in 50-59, and 93.7% in 60-69, relatively). In histologic types, CRS of metaplastic carcinoma has improved from 82.0% to 95.2%, compared to CRS of lobular carcinoma (from 93.1% to 92.5%). Hardly any excess mortality (5-year CRS ≥ 95%) was seen since 7 years after diagnosis. There was hardly any excess mortality at 5 years of survival, for the patients with 40-49 years (95.4%), with localized disease (97.8%), and with metaplastic carcinoma (95.2%).

Conclusion: This study showed that CRS of breast cancer survivors in Korea has been improved, which varied by sex, age, stage, and histologic types. These CRS analysis could provide a more detailed information for survival to breast cancer survivors and clinicians.
Factors associated with survival in a 20-year historical cohort in Brazil

Maira Caleffi¹, Rodrigo A Ribeiro¹ and Daniela D Rosa¹. ¹Hospital Moinhos de Vento, Porto Alegre, Brazil.

In Brazil (population over 200 million), breast cancer is the leading cause of death from cancer among women. Nevertheless, little information is available regarding the characteristics of patients. Given this scenario, a private non-profit hospital located in Porto Alegre – the Brazilian city with the highest incidence of breast cancer (crude rate estimated at 114.25/100,000 for 2018) (1) – established a comprehensive breast cancer center (Núcleo Mama Moinhos, NMM). We investigated variables associated with mortality in 896 women diagnosed and treated at NMM over 20 years. The study was approved by the research ethics committee. Only women with centrally reviewed histological confirmation of breast cancer were included. The primary outcome was survival following diagnosis. The correlation between survival and the following variables was tested: age at diagnosis, disease stage at diagnosis, schooling, smoking, body mass index (BMI), menopausal status, hormone replacement therapy (HRT), family history of breast cancer, pathological grading, hormone receptor status, HER2 status, molecular subtype, and biomarker KI67. The impact of variables as predictors of mortality was analyzed using Cox and Kaplan-Meyer models. Mean age at diagnosis was 53.7 years (SD 13.087). Clinical staging at diagnosis was: 107 patients with stage 0 (12.3%), 440 stage I (50.7%), 244 stage II (28.1%), 67 stage III (7.7%), 10 stage IV (1.2%), and 28 with missing data. At 5 years, 96.4% of the patients were alive, and at 10 years 86.6% were alive. At the end of the observation (20 years), 67% were alive. Obesity (BMI>30) was detected in 136 (15%) women; 574 (64.0%) were menopausal, and 244 (27.2%) received hormone therapy. HER2 status was available for 782 cases of invasive breast cancer (87.3%), and 131 (16.8%) were HER2-positive. Triple negative cases were 14.3%. According to multivariate analysis (table 1), increasing stage and age at diagnosis, KI67, and distant recurrence were significantly associated with survival. None of the other variables, including smoking status, years in school, BMI, and HER2 status, was associated with mortality.

Missing information: 26 patients for staging; 138 patients for KI67. Age: hazard ratio for each additional year.

To the best of our knowledge, this is the largest breast cancer cohort with the longest follow-up time in Brazil. These results suggest that Brazilian patients who receive early treatment at a comprehensive cancer center will achieve outcomes that are similar to those of developed countries. The high breast cancer mortality in Brazil seems dependent on the health care that is...
available to women (2).

Advanced stage at diagnosis and worse clinicopathologic features in young woman with breast cancer. A sub-analysis of Brazilian population through the AMAZONA III study (GBECAM 0115)

BACKGROUND: Breast cancer (BC) in young women is uncommon and often more aggressive. There are disparities in terms of screening coverage, diagnostic features and access to optimal treatment among young BC patients worldwide. To better understand this scenario through real world data we performed a sub-analysis of AMAZONA III study. METHODS: The AMAZONA III study (GBECAM 0115) is a prospective registry that included 2950 women newly diagnosed with invasive BC in Brazil during the period of January 2016 to March 2018 within 22 sites. Of them, 2888 patients had valid data regarding age at diagnosis and complete baseline information. For the purpose of comparisons of epidemiologic and clinicopathologic features at the time of diagnosis of BC, patients were divided in two groups: women aged ≤40 years (Group 1) and >40 years (Group 2). Quantitative variables were expressed with mean, while categorical variables were described as their count and percentage and compared using the chi-square test. RESULTS: Of 2888 women, 486 (17%) were ≤40 years of age. No differences were found between ethnicity, performance status, body mass index, personal income, health insurance and family history of cancer between the two groups. Young women had higher educational level (p<0.001), were more involved into a labor activity (p<0.001) and were more frequently married (p<0.001). There were also significant differences regarding nulliparity (p<0.001) and previous use of oral contraceptives (p<0.001). Mode of detection of BC was symptomatic in 73.4% of young group versus 64.5% in older group and screen-detected was only 26.6% vs. 35.5% respectively (p<0.001). Table 1 describes clinicopathological characteristics of the two groups. Young women presented more frequently with stage III, T3/T4, Grade 3 tumors and HER-2 positive, Luminal B and triple negative subtypes. Women older than 40 years had more stage I, Luminal A and Grade 1/2 tumors. CONCLUSION: Brazilian women under the age of 40 have unfavorable clinicopathological features of BC at diagnosis with more aggressive subtypes and advanced stage compared with older women. No differences in socioeconomic and ethnicnal aspects were found but a higher percentage of young women had symptomatic detection of BC which could explain the later stage of disease at diagnosis. Young women were economically active and the majority married which highlights the socioeconomic impact of this disease in Brazil.

Impact of surgery and time to surgery on breast cancer survival in the United States, 2004–2014 (N=2,211,245)

Maharaj Singh¹, Santhi D Konduri¹, George C Bobustuc², Richard A Rovin³ and Amin B Kassam³. ¹Aurora Research Institute, Aurora Health Care, Milwaukee, WI; ²Aurora Health Care, Milwaukee, WI and ³Aurora Neuroscience Innovation Institute, Aurora Health Care, Milwaukee, WI.

Background: Surgery is very common for patients diagnosed with breast cancer. Its impact on survival depends on diagnostic, patient, tumor-related, and other-treatment factors. Moreover, time to surgery from the date of diagnosis is also a critical factor affecting outcome.

Objective: In this study we investigated the impact of surgery on survival in breast cancer patients using two methods: (1) multivariate regression; and (2) propensity score matching. For the patients undergoing surgical intervention, we aimed to identify the optimum time from diagnosis to surgery.

Methods: The study population was taken from the National Cancer Database over the years 2004 through 2014. Of 2,211,245 patients, 99.1% were female, 0.9% male, 85% non-Hispanic white, 10.5% black, 0.7% Hispanic, and 14.5% other races. Mean age of the patient population was 60.0 ± 13.4 years (range: 18–90). The majority of the patients (92.9%) underwent a surgical procedure.

Results: Overall, the patients who did not undergo surgery were 6.7 times more likely to die within the study time period (95% confidence interval [CI]: 6.7–6.8, p<0.001) than those who did. However, after adjusting for patients' demographics, tumor-related factors, cancer stages, and combination of other treatments, the risk for dying of patients without surgery was 2.3 times higher (hazard ratio [HR]: 2.3, 95% CI: 2.3–2.4, p<0.001). In the propensity-matched cohort of 51,630 patients that was divided equally into two groups — those who underwent surgery and those who did not — the risk of mortality remained 2.4 times higher for patients without surgery (HR: 2.4, 95% CI: 2.3–2.4, p<0.001). Regarding time to surgery from the date of diagnosis, patient survival was best for the patients whose time to surgery ranged from 31 to 60 days. The next best timeframe was 61 to 90 days, followed by 30 days or fewer, then 91 to 120 days, and finally 120 and more days (p<0.001).

Conclusion: Using two different statistical methods, surgery is clearly an independent predictor of survival for patients with breast cancer. After matching for other factors, patients not having surgery were more than twice as likely to die as their surgical counterparts. Time to surgery from the date of diagnosis confirmed earlier findings that surgery is most beneficial within 2–3 months from the date of diagnosis. These findings can provide clinical guidance to clinicians and patients for planning treatment.
Current status of clinical and pathological characteristics of breast cancer patients in Brazil: Results of the AMAZONA III study (GBECAM 0115)

BACKGROUND
Breast cancer (BC) is the most common tumor in women in Brazil with about 60 thousand new cases estimated per year. In low and middle-income countries, patients with BC are diagnosed with more advanced stages as compared with high-income countries. In Brazil, disparities in access to new therapies are recognized; previous data suggests worse survival of BC patients treated in the public system. The aim of AMAZONA III study (GBECAM 0115) is to describe the current status of BC care in Brazil. Here we report patients data at baseline.

METHODS
The AMAZONA III is a prospective BC registry that included women 18 years or older with newly diagnosed stage I to IV BC from 22 sites in Brazil in the period of January 2016 to March 2018. All patients provided written informed consent; data was collected from interview and medical charts, comprising clinical-demographic variables, initial treatment and a planned follow-up for 5 years. BC subtypes were defined by hormone receptor (HR) expression, HER2 status and grade according to von Minckwitz G. et al 2012. Here we present a descriptive analysis of the patients’ baseline characteristics. Continuous variables are shown as mean (standard-deviation) and categorical variables by its absolute and relative frequencies. The study is registered in clinicaltrials.gov NCT02663973.

RESULTS
A total of 2950 patients were included in the study. Median age at diagnosis was 53 years old (8.4% <= 35 years, 34.8% 36-50 years, 58.6% > 50 years), 58.6% were white, 34.4% had brown skin-color, 83% had children before BC diagnosis (median of 1 child/patient) and 63.1% had public health insurance. In terms of method of detection 34% were screen-detected whereas 66% were symptomatic, the last was even higher (70%) in patients in younger than 50 years. The distribution of BC stage at diagnosis was I (26.4%), II (41.6%), III (27%) and IV (5%). The most common histologies were ductal (80.9%) and lobular carcinoma (6.9%). The pathological characteristics were HR positive in 78.0%, HER-2 positive in 23.4% and grade 2 in 51%. BC subtypes were as follows: Luminal A 48%, Luminal B 12%, Luminal HER2 positive 17%, Non-luminal HER2 positive 7.3% and Triple negative 15.5%.

DISCUSSION
Breast cancer is diagnosed at an earlier age among Brazilian patients. The majority of patients were detected through symptomatic BC and therefore a significant proportion is still diagnosed in stages III and IV. Among other factors, these findings could have a significant impact in treatment outcomes. Further analysis of this large cohort of patients will help to identify other important elements and direct future strategies for breast cancer control.

Triple negative breast cancer: Does ethnicity impact survival?

Moira Rushton-Marovac¹, Tinghua Zhang² and Xinni Song¹. ¹The Ottawa Hospital Cancer Centre, Ottawa, ON, Canada and ²The Ottawa Health Research Institute, Ottawa, ON, Canada.

Background:
Triple negative breast cancer (TNBC) is a heterogeneous disease with poor outcomes relative to hormone positive breast cancer. Observations in the clinical setting lead to the hypothesis that there may be phenotypic differences among ethnic groups. Previous studies have conflicting results; some suggesting no differences, others showing inferior outcomes for black patients (pts). The purpose of this study was to use a population-based approach to examine survival amongst different ethnicities in triple negative breast cancer (TNBC).

Methods
Retrospective population-based study using data from the surveillance epidemiology and end results (SEER) database to identify TNBC cases diagnosed 2010 - 2014. We divided pts into 6 ethnic groups: White, Black, American Indian/Alaskan Native (AIAN), Pacific Islander (PI), Asian and Asian Indian (AI). Primary outcome: overall survival (OS); secondary outcome: breast-cancer specific survival (BCSS). Survival analysis was performed using Cox proportional hazards and Kaplan-Meier models.

Results
31482 pts were included; 22752 (72.3%) were white, 6319 (20.4%) black, 1720 (5.5%) Asian, 262 (0.8%) AI, 179 (0.6%) AIAN, and 150 (0.5%) PI. Asian pts had the best OS (HR 0.82, 95% CI 0.72-0.94), while Black pts had the worst (HR 1.21 95% CI 1.13-1.29) when compared with White pts. Differences between other ethnicities were not statistically significant for OS. Black pts had significantly worse BCSS (HR 1.20, 95% CI 1.12 -1.29); no other ethnicity had statistically significant differences compared to Whites. Comparing Asian with Black pts in multivariate analysis the HR was 0.68 (95% CI 0.59 – 0.79) for OS and 0.71 (95% 0.61 – 0.84) for BCSS. Older age, advanced stage, male sex, and lack of chemotherapy, radiation or surgery were also found to be statistically significant variables in multivariate analysis.

Conclusions
In this large population study, we found Asian pts had significantly better OS and Black pts had significantly worse OS and BCSS. These findings confirm the clinical observation and warrant closer molecular analysis of TNBC phenotypes based on patient's ethnicity. Findings may offer insight into the biology of TNBC and lead to development of innovative treatment options.
Comparing estimates of survival for breast cancer patients

Hava Izci¹, Harlinde De Schutter¹, Hans Wildiers¹ and Patrick Neven¹. ¹KU Leuven - University of Leuven, Leuven, Belgium and ²Belgian Cancer Registry, Brussels, Belgium.

Introduction
Net survival can be considered as the most accurate evaluation of survival from cancer, as it encompasses the survival that would occur if the only possible underlying cause of death was the cancer under study. Both relative survival (RS) and cause-specific survival (CSS) have been developed as approaches to estimate net survival at the population level. Given the debated accuracy of death certificates in identifying the underlying cause of death, RS measures are most commonly used by cancer registries. However, RS calculations can also be biased as it is sometimes unavoidable to match a group of cancer patients with a non-comparable disease-free population group.

In this study, we aim to compare RS and CSS using causes of death obtained from death certificates in a cohort of Belgian breast cancer patients by evaluating them to CSS using causes of death obtained from medical files.

Methods
A total of 3,205 breast cancer patients diagnosed and treated in University Hospitals Leuven between 2009-2014 were included in this study. RS was calculated with the Ederer II method, dividing the observed survival by the expected survival for females of the same age and region. CSS was calculated using cause of death information either gathered from death certificates or collected from medical files. The estimates for RS and CSS as obtained from death certificates were compared to CSS obtained from medical files. Follow-up was guaranteed until 31th of December 2014.

Results
From the included cohort of breast cancer patients, 255 were deceased. Cause of death was available for 254 patients from death certificates and for 191 patients from medical files. By considering the available cause of death information, 3,141 patients were included to calculate the survival estimates. The 1-year relative survival estimate was 99.3% (95%CI, [98.7, 99.8]), while 1-year cause-specific survival based on death certificates was 99.0% [98.5, 99.3]. The 1-year survival estimate according to CSS based on medical files was 98.1% [97.5, 98.5]. The 5-year survival estimates were 95.8% [94.0, 97.4] for RS, 93.3% [91.8, 94.4] for CSS based on death certificates and 89.7% [88.0, 91.2] for CSS based on medical files.

Conclusion
This study used causes of death information as derived directly from medical files to calculate CSS in order to compare it with RS and CSS derived from death certificates. This allowed an evaluation of the RS and CSS estimates commonly used at the population level against the presumably more reliable CSS as obtained from medical files. Both RS and CSS from death certificates were divergent from CSS from medical files, but the CSS from death certificates appeared to be a closer estimate to CSS from medical files. After longer follow-up, both survival estimates seemed to deviate more from the CSS from medical files.
Treatment delivery waiting times for stage I-III breast cancer patients in Switzerland: A pooled analysis of 7 cancer registries over the 2003-2008 period

Daniel R Zwahlen¹, Christian Herrmann², Mohsen Mousavi³, Andrea Bordoni³, Christine Bouchardy⁴, Isabelle Konzelmann⁵, Katharina Staehlin⁶, Sabine Rohrmann⁷, Christoph Oehler¹ and Michel Zimmermann¹. ¹Kantonsspital Graubunden, Chur, Switzerland; ²Kantonsspital Sankt Gallen, Sankt Gallen, Switzerland; ³Registro Tumori del Ticino, Locarno, Switzerland; ⁴Registre Genevois des Tumeurs, Geneva, Switzerland; ⁵Registre Valaisan des Tumeurs, Sion, Switzerland; ⁶Krebsregister beider Basel, Basel, Switzerland and ⁷Krebsregister der Kantone Zurich und Zug, Zurich, Switzerland.

Background: To examine time intervals between needle/core biopsy, breast cancer diagnosis, surgery and radiotherapy (RT) as quality metrics in the management of stage I-III breast cancer in a representative Swiss population sample.

Methods: Based on seven regional cancer registries covering 45% of the Swiss population, we identified 2628 women which underwent surgery for stage I-III breast cancer without receiving (neo)-adjuvant chemotherapy between January 1, 2003 and December 31, 2005.

Four different time intervals were defined: a) time between needle/core biopsy and diagnosis of breast cancer, b) time between diagnosis of breast cancer and surgery, c) time between needle/core biopsy and surgery, d) time between surgery and adjuvant RT.

These four time intervals were analyzed according to age, nationality, health insurance status, public vs. private hospitals and geography. We also investigated whether case discussion at tumor board delayed patient management.

A one-way analysis of variance (ANOVA) and multiple comparison tests were used to assess differences between groups. All tests were performed using STATA v.15.

Results: 2628 women were identified, median age was 67 years (IQR: 58-77). Breast-conserving surgery was performed in 1899 cases (72.3%), mastectomy in 539 cases (20.5%), unspecified surgery /missing data in 190 cases (7.2%). Adjuvant RT was delivered in 1546/2628 patients (58.8 %).

Time interval between biopsy and surgery was age-dependent, ranging from 22 days (95% CI: 19.6 - 25.2) for women < 60 years to 39 days (95% CI: 27.0-50.3) for women 80+ years old (p<0.001). After biopsy, women waited on average 19 days until surgery in private clinics (95% CI: 16.4-21.6) and 30 days in public hospitals (95% CI: 26.6-33.3) (p<0.001). Women with private insurance were operated 24 days after biopsy (95% CI: 17.0-31.1), compared with 30 days (95% CI: 27.1-33.2) (p<0.01) for women with basic state insurance. After biopsy, time interval for foreign nationals was significantly longer than for Swiss citizen (30 vs 24 days, p<0.01). Tumor board presentation postponed surgery by 10 days (31 vs 22 days, p<0.01).

Time between surgery and RT did not correlate with age (p=0.83); the interval was 33% longer in tertiary teaching hospitals than in private clinics (61 vs. 46 days, p<0.001), and 8 days longer for patients with private insurance than for those without (61 vs 53 days, p<0.01). There was a trend for foreign nationals to receive adjuvant RT later than Swiss citizen (58 vs 55 days, p=0.09). RT started later in larger metropolitan areas compared to more rural regions (59 vs 53 days, p<0.01). Presenting patients at a tumor board after surgery had no impact on RT start (p=0.12).

Conclusions: Major differences in treatment waiting times were observed between patients with stage I-III breast cancer. Elderly and foreign patients were at risk for delayed surgery after biopsy. Data from patients with longer timelines need to be analyzed to identify further reasons for delays.
Molecular breast cancer subtypes in a Guatemalan population. Classification according to immunohistochemical markers: Clinicopathologic feature and survival analysis

Hugo Castro¹, Luis Garcia¹, Francisco Jimenez¹, Pier Ramos¹ and Noe Castro¹. ¹Instituto Guatemalteco de Seguridad Social -IGSS, Guatemala City, Guatemala.

Introduction: Breast cancer is a heterogeneous malignancy and it's possible to identify by simple techniques, such as immunohistochemistry, four subtypes with different clinical and biological behavior. Our aim was to evaluate the influence of these subtypes on the local and distant recurrences rates.

Method: data of 954 unilateral breast cancer patients primarily treated with radical or conservative surgery from 2008 to 2014 were obtained from medical records. Breast cancer subtypes were categorized in Luminal A (RE+ and/or RP+, HER2-), Luminal B (RE+ and/or RP+, HER2+ o Ki-67> 14%); HER2 (RE-, RP-, HER2+) and triple negative tumors (TNT) (RE-, RP-, HER2-).

Patterns of recurrence for each subtype and clinicopathological variables and the influence of each variable on the overall survival (OS) by the Kaplan-Meier method. In all cases, we determined histological type, grade nuclear (low, intermediate vrs high), tumor size, lymph node involvement

Results: Median age at diagnosis was 52 years (range, 23-95). Of these patients 55% were premenopausal. We found that 522 (56%) of the cases were luminal A breast cancer, 190 (20%) of the cases were triple negative tumors (TNT), luminal B were 73 (8%) and it was HER2-positive in 152 (20%) of cases. Nine patients (3%) had other breast cancer contralateral. In 70% of all the cases were found in locally advanced stages (IIB – IIIC). In 438 (70%) of all the cases were found in locally advanced stages (IIB – IIIC), 773 (81%) patients underwent radical mastectomy and 181 (19%) undergoing conservative surgery. We performed univariate analysis to evaluate recurrence-related factors. Variables included in the analysis clinical stage (I – IIa vs IIb – IIIC; 88% vs 70%; p = 0.001), nuclear grade (grade 1, 2 vs 3; 83% vs 62%; p = 0.01) and pathologic response (total vs parcial, stable disease; 76% vs 54%; p = 0.01), and status Her-2 subtype so borderline (positive vs negative; p= 0.079). A univariate survival analysis stratification according to clinicopathologic characteristics. Clinical stage, histologic grade, response to neoadjuvant and tumor size were identified as significant factors of prognosis for the OS. (p=0.5) and histological subtypes Luminal A (94%), Luminal B (75%), HER2 (79%) and TNT (68%), p= 0.001.

Conclusion: this study demonstrates that treatment efficacy is similar to that reported in the literature and emphasizes the need for establishing the molecular breast cancer subtypes and efforts should be made to reduce the high frequency of advanced-stage diagnoses.
Treatment across the four molecular types of breast cancer: Insight from the national cancer database, 2010–2014 (N=827,888)

Santhi D Konduri¹, Maharaj Singh¹, George C Bobustuc², Richard A Rovin² and Amin B Kassam². ¹Aurora Research Institute, Aurora Health Care, Milwaukee, WI and ²Aurora Neuroscience Innovation Institute, Aurora Health Care, Milwaukee, WI.

Background: For patients diagnosed with breast cancer treatment plans are usually determined by biomarkers such as ER, PR and HER2, the absence or presence of which determines molecular subtype of the tumor (luminal A, luminal B, triple-negative, and HER2-enriched). However, it is unclear to what extent each treatment plan contributes to overall survival across these four molecular types of breast cancer (as determined by the presence or combination of biomarkers).

Objective: Assuming inherent heterogeneity among breast cancer patients, we sought to determine the benefit of any one or combination of treatment methods among surgery, chemotherapy, radiation, immunotherapy, and hormonal therapy and whether differences exist among various subgroups for predicting mortality risk.

Methods: A total of 827,888 patients diagnosed with breast cancer from the National Cancer Database were analyzed. The patient population was 99.1% female, 0.9% male, 75.5% white, 11.2% black, 0.8% Hispanic, and 12.5% other races. Most of the patients (97.1%) were diagnosed with invasive breast cancer; the remaining 2.9% were diagnosed with in situ and/or carcinoma in situ. For molecular subtypes, the distribution of patients was 72.7% with luminal A, 10.4% luminal B, 4.7% HER2-enriched and 12.2% triple-negative.

Results: Overall, patients who did not receive treatment were 6.9 times more likely to die (95% confidence interval [CI]: 6.7–7.0) than those who did. Within molecular subtypes, hazards ratios [HR] were for dying without treatment were7.0 (95% CI: 6.8–7.1) for luminal A, 7.8 (95% CI: 7.3–8.3) for luminal B, 6.9 (95% CI: 6.6–7.2) for triple-negative, and 8.9 (95% CI: 8.2–9.7) for HER2-enriched tumor. Overall survival was best for luminal A, followed by luminal B, HER2-enriched and triple-negative (p<0.001). Multivariate Cox regression showed that the five most significant factors predicting mortality for luminal A were surgical treatment (HR: 0.4, p<0.001), patient age (HR: 1.1 one year increment , p<0.001), cancer stage (HR: 1.2, 2.1, 4.1, and 7.4 for stage I, II, III, and IV [all vs stage 0], respectively, p<0.001), Charlson/Deyo score (HR: 1.4, 2.1, and 2.9 for score 1, 2, and ≥3 [all vs score 0], respectively, p<0.001), and tumor grade (HR:0.8, 0.5, and 0.4 for poorly, moderately, and well-differentiated tumors [all vs undifferentiated], respectively). For luminal B, HER2-enriched molecular types, and for triple negative chemotherapy (HR: 0.5, 0.6, 0.5, respectively) replaced grade differentiation as one of the top five predictors.

Conclusion: Despite recent suggestions of over diagnoses and unnecessary treatment for certain types of tumor, this retrospective study suggested that treatment remains highly beneficial for breast cancer patients. Among treatments, surgery remains a strong predictor of survival across the board; however, for luminal B, HER2-enriched, and for triple negative subtype chemotherapy along with surgery provides additional survival benefit. Overall survival was better for luminal A, followed by luminal B, HER2 and triple negative breast cancer. These results can provide guidance for clinicians as well as for patients.
CD8+ T-cell gene expression and signatures in breast cancer and adjacent normal breast tissue: Association with body mass index, alcohol intake, and age at diagnosis

Adrienne Damicis¹, Yujing J Heng², Kevin Kensler³, Sarah Asad¹, Elizabeth Adams¹, Jasneet Singh¹, Yiqing Zhang¹, William Nock¹, Robert Wesolowski¹, Nicole Williams¹, Raquel Reinbolt¹, Sagar Sardesai¹, Jeffrey VanDeusen¹, Anne Noonan¹, Maryam B Lustberg¹, Bhuvaneswari Ramaswamy¹, A Heather Eliassen³, Susan E Hankinson⁴, Rulla Tamimi³ and Daniel G Stover¹. ¹Ohio State University Stefanie Spielman Comprehensive Breast Center, Columbus, OH; ²Beth Israel Deaconess Medical Center, Boston, MA; ³Harvard T.H. Chan School of Public Health, Boston, MA and ⁴University of Massachusetts Amherst, Amherst, MA.

**Background:** Our understanding of mediators of immune infiltration in breast cancer and normal breast tissue remains limited. We hypothesize that patient factors known to be associated with inflammation and immune subsets, including body mass index, alcohol intake, and age and diagnosis, may play an important role in the tumor-immune microenvironment. Analyses of immune gene expression and signatures facilitate interrogation of the immune microenvironment in large patient cohorts.

**Methods:** Participants from the Nurses’ Health Study cohorts I and II diagnosed with invasive breast cancer were included. Total RNA extracted and microarray performed for 882 tumor and 695 tumor-adjacent samples, of which 623 tumors have matched tumor-adjacent data. CD8+ T-cell expression metrics were assessed: CD8A single gene expression (CD8Agene), a CD8 T-cell signature (CD8sig), and a tumor infiltrating lymphocyte signature derived from the GeparSixto clinical trial (GSAct). Standard clinicopathologic features were evaluated, as well as body mass index (BMI) one year prior to diagnosis, cumulative average alcohol intake, and age at diagnosis.

**Results:** Overall, tumor and adjacent normal tissue demonstrated positive correlation of CD8Agene, CD8sig, and GSAct (n=623 pairs, Pearson's r = 0.46, 0.36, 0.31, respectively; all p<0.001). Similar correlations were present in TCGA breast cancer, an independent cohort (n=112 pairs, Pearson's r = 0.34, 0.17, 0.45, respectively; all p<0.001). We evaluated paired tumor and adjacent normal samples within individual immunohistochemical (IHC) subtype or PAM50 subtype by Wilcoxon signed-rank test. There was not a consistent trend for CD8Agene, CD8sig, nor GSAct to be greater in tumor or normal within subtypes. We then evaluated patient features/exposures and tumor immune expression metrics. For tumor-adjacent normal, there was no significant association of alcohol intake, BMI, or age at diagnosis with CD8 gene/expression metrics. For tumor tissue, a multivariate model demonstrated that BMI one year before diagnosis was significantly associated with CD8Agene expression. There was no significant association of alcohol intake or age at diagnosis with CD8 gene/expression metrics. We are currently evaluating the association of these CD8 T-cell gene expression signatures with CD8 T-cell immunohistochemistry in a subset of patients, which will be reported at the time of abstract presentation.

**Conclusion:** In this cohort of over 600 tumor:normal pairs and a separate validation cohort, multiple distinct CD8+ T-cell expression metrics are correlated between breast cancer and tumor-adjacent normal breast tissue. This suggests that the adjacent normal breast may reflect an altered immune microenvironment in the context of breast cancer. While age at diagnosis and alcohol intake are not significantly associated with tumor CD8 expression metrics, BMI was significantly associated with tumor CD8Agene expression in a multivariate model.
Prevalence of genetic mutations in patients with second primary breast cancers

Katharine Yao¹, Jacob Clifford², Shuwei Li², Holly LaDuca², Peter J Hulick¹, Jianfeng Xu¹, Stephanie Gutierrez² and Mary Helen Black². ¹NorthShore University HealthSystem, Evanston, IL and ²Ambry Genetics, Aliso Viejo, CA.

Background: Women newly diagnosed with primary breast cancer (PBC) often undergo multi-gene panel testing to determine their contralateral breast cancer (BC) risk and whether a contralateral prophylactic mastectomy is warranted. However, with the exception of BRCA1/2, gene-specific associations with contralateral or second PBC (SPBC) have not been established.

Methods: The study sample was comprised of 83,278 women with BC referred to a single diagnostic laboratory for multi-gene panel testing. The frequency of pathogenic/likely pathogenic variants in clinically-actionable genes (CAG), including highly penetrant genes (HPG: BRCA1, BRCA2, TP53, PTEN) and moderately penetrant genes (MPG: ATM, CHEK2, PALB2, CDH1, NBN, NF1) was compared between women with a PBC and SPBC. Women with a SPBC <1 year from their first diagnosis were excluded. Logistic regression burden tests were used to test for associations between mutated genes and SPBC adjusting for age at diagnosis of first BC, histology, presence of first- or second-degree relative with BC, and race/ethnicity.

Results: The study included 75,550 women with PBC and 7,728 with SPBC. The median (IQR) time between primaries for the SPBC group was 11 (6,17) years. Women with SPBC were slightly more likely to be Caucasian (67.8% vs. 63.4%; p<0.001), older when referred for genetic testing (mean difference 9.7 years, p<0.001), slightly younger at first BC diagnosis (mean difference 2.1 years, p<0.001) and slightly more likely to have >1 first or second degree relative with BC (62.2% vs. 60.8%; p=0.004) than PBC. Among women tested for all CAGs, 4,883 (8.1%) were carriers of pathogenic/likely pathogenic variants (11.1% SPBC vs. 7.8% PBC). CHEK2 was the most frequently mutated gene (3.4% SPBC vs. 2.3% PBC), followed by BRCA1 (2.7% SPBC vs.1.6% PBC), BRCA2 (2.2% SPBC vs. 1.8% PBC), and PALB2 (1.4% SPBC vs. 0.9% PBC). In fully adjusted models, women with SPBC were 1.38 times as likely (p<0.0001) as women with PBC to test positive for a CAG (OR=1.35 for HPG and 1.34 for MPG). BRCA1 (OR=1.49; p<0.0001), followed by CHEK2 (OR=1.36; p<0.0001) and PALB2 (OR=1.53; p<0.001) were most significantly associated with SPBC. TP53, BARD1, ATM and BRCA2 were marginally associated with SPBC (p=0.01 to 0.06). When results were stratified by race/ethnicity, ORs among Caucasians were similar to those observed overall. Among African Americans, women with SPBC were 1.76 times as likely to carry a CAG (p<0.0001) than their PBC counterparts. PALB2 (OR=2.69; p=0.002), BRCA2 (OR=1.85; p=.004), and TP53 (OR=3.88; p=.009) were most significantly associated with SPBC followed by BRCA1 (OR=1.63; p=.002). Analysis of gene associations for other racial/ethnic groups was limited by small sample size.

Conclusions: There is a significantly higher prevalence of CAG mutations among women with SPBC, even after adjusting for age at diagnosis and family history. These findings support SPBC as a standalone indication for multigene panel testing. Additional studies aimed to assess cumulative risk of SPBC for CAG beyond BRCA1/2 are needed to help guide clinical management decisions for mutation carriers.
Association between a breast cancer polygenic risk score and contralateral breast cancer risk

Iris Kramer¹, Maartje J Hooning², Breast Cancer Association Consortium (BCAC)³, Nasim Mavaddat³, Sander Canisius¹, Renske Keeman¹, Alexandra J van den Broek¹, Ewout Steyerberg², Michael Hauptmann¹, Paul DP Pharoah³, Douglas F Easton³, Per Hall⁶ and Marjanka K Schmidt¹. ¹Netherlands Cancer Institute, Amsterdam, Netherlands; ²Erasmus Medical Centre, Rotterdam, Netherlands; ³University of Cambridge, Cambridge, United Kingdom; ⁴Leiden University Medical Centre, Leiden, Netherlands; ⁵Karolinska Institutet, Stockholm, Sweden and ⁶South General Hospital, Stockholm, Sweden.

Background
Breast cancer patients are at significant risk of a second contralateral, breast cancer (CBC). Identification of women at high or low CBC risk could improve patient management decisions. Previous research has shown that breast cancer-associated single nucleotide polymorphisms (SNPs) summarized in a polygenic risk score (PRS) predict the risk of a first breast cancer with an odds ratio (OR) per 1 SD of 1.55 (95% confidence interval (95%CI)=1.52-1.58) (77-SNP PRS). The aim of this study was to evaluate the association between a recently developed PRS and CBC risk.

Methods
We identified 19 studies from the Breast Cancer Association Consortium (BCAC) with follow-up information on participating patients and at least 10 patients diagnosed with CBC. This included 38,228 females of European ancestry diagnosed with first invasive breast cancer since 1990. Genotyping was done using the iCOGS array or OncoArray, with genotypes for SNPs not on the arrays estimated by imputation. We used a 313-SNP PRS, optimized for prediction of overall (first) breast cancer in the BCAC dataset. Metachronous CBC risk by PRS was quantified using univariable and multivariable Cox regression analyses stratified by country and adjusted for multiple patient, tumor, and treatment characteristics. We assessed PRS interaction with age, family history, adjuvant systemic therapy, and ER-status.

Results
Median time to develop a CBC (N=1,046) after a first breast cancer was 5.8 years (range 0.3-21.9). Higher PRS was associated with increased CBC risk: hazard ratio (HR) per 1 SD=1.31 (95%CI=1.23-1.39). Patients in the highest and lowest 5% of the PRS had 1.95 fold and 0.67 fold risks of CBC, respectively, compared with patients in the middle quintile. Adjustments for age, year of diagnosis, family history, tumor size, nodal status, ER-status, or treatment (chemotherapy, endocrine therapy, radiotherapy) did not substantially alter these results. We found an interaction with age at first breast cancer diagnosis (P_interaction=.002); the PRS was associated with an increased CBC risk for patients aged ≥40 years (HR=1.37, 95%CI=1.28-1.47), but not for patients <40 years (HR=1.06, 95%CI=0.93-1.21).

Conclusion
The PRS is predictive for the development of CBC in patients ≥40 years at first breast cancer diagnosis. For this group, the PRS could be incorporated in CBC risk prediction models to help define high and low risk patients, and hence optimize screening and treatment strategies.
Clinical and genomic characteristics of borderline ER-positive breast cancers

Halei C Benefield\textsuperscript{1}, Emma H Allott\textsuperscript{1}, Xuezheng Sun\textsuperscript{1}, Katherine E Reeder-Hayes\textsuperscript{1} and Melissa A Troester\textsuperscript{1}. \textsuperscript{1}University of North Carolina - Chapel Hill, Chapel Hill, NC.

**Background:** Though current guidelines classify breast tumors with \( \geq 1\% \) estrogen receptor (ER) positivity by immunohistochemistry as ER positive, “borderline” tumors expressing \( \geq 1 – <10\% \) positivity have biological similarities to ER negative tumors in prior studies. We sought to describe molecular features of ER-borderline breast cancer in a diverse cohort of incident cases and identify characteristics associated with high-risk borderline tumors.

**Methods:** We used the Carolina Breast Cancer Study, a large population-based study that oversampled young and black women in 44 counties of North Carolina, to study characteristics of ER-borderline cases compared to other ER-positive and ER-negative tumors. Gene expression of \textit{ESR1}, PAM50 subtype, and risk of recurrence score (ROR-PT, calculated from subtype, proliferation level, and tumor size; categorized as low, medium, high) were quantified using RNA counting methods, with finite mixture modeling to establish a cutoff for \textit{ESR1}-high vs. -low tumors. The relative frequency differences of clinical and genomic features of borderline vs. positive/negative tumors were estimated using linear regression, adjusted for age and race. Recurrence risk was evaluated by ER status, with and without receipt of endocrine therapy using Kaplan-Meier curves and Cox proportional hazards models.

**Results:** Of 2,859 eligible patients, 8\% (n=217) were ER borderline, 26\% (n=757) were ER negative and 66\% were ER positive. Compared to other ER positive tumors (which were 5\% basal-like, 89\% luminal, 8\% high ROR-PT, 16\% \textit{ESR1}-low), borderlines (40\% basal-like, 42\% luminal, 26\% high ROR-PT, 71\% \textit{ESR1}-low) had a higher relative frequency of basal-like subtype (+37.7\%, 95\% CI 27.1, 48.4), high ROR-PT (+52.4\%, 95\% CI 36.8, 68.0), and \textit{ESR1}-low status (+26.3\%, 95\% CI 20.2, 32.5). In log-rank analysis, recurrence risk in borderlines was not significantly different from ER negatives. However, after adjusting for patient and tumor factors, recurrence risk in borderlines treated without endocrine therapy was the highest of all subtypes (HR 2.9, 95\% CI 1.6, 5.0) and persisted after further adjusting for ROR-PT. Results are summarized in Table 1. Frequency of high ROR-PT was 22\% among white women with borderline tumors but was significantly more common among black women with borderline tumors (+26.0\%, 95\% CI 7.1, 45.0). Among borderlines, high grade was associated with basal-like subtype (+43.4\%, 95\% CI 18.7, 68.0; reference = non-basal subtype, 52\% high grade).

<td>1.5 (0.9, 2.4)</td>
</tr>
</tbody>
</table>

Adjusted for (1) age, race, stage, grade, year of diagnosis, (2) variables in (1) and ROR-PT

**Conclusion:** Consistent with prior studies, borderline tumors demonstrated characteristics that were intermediate between other ER positive and negative tumors, with heterogeneity of genomic features. Given the higher recurrence risk among borderlines, identifying aggressive borderline tumors is important. Black women and those with high tumor grade may benefit from further genomic assessment to guide treatment decisions.
Gene-set enrichment analysis (GSEA) of breast tissue from healthy women with less than six months history of breastfeeding shows enrichment in Hedgehog signaling, notch signaling and luminal progenitor gene signatures

Mustafa M Basree¹, Neelam Shinde², Marilly Palettas³, Daniel Weng⁴, Daniel G Stover², Gina M Sizemore⁴, Peter Shields⁴, Sarmila Majumder² and Bhuvaneswari Ramaswamy². ¹University of Pikeville - Kentucky College of Osteopathic Medicine, Pikeville, KY; ²The Ohio State University Wexner Medical Center, Columbus, OH; ³The Ohio State University Center of Biostatistics, Columbus, OH and ⁴The Ohio State University Comprehensive Cancer Center, Columbus, OH.

Introduction: Multiple epidemiological studies have shown that prolonged breastfeeding is associated with a reduced risk of developing triple negative/basal-like breast cancer (TN/BLBC). We have modeled abrupt involution (AI) due to lack of breastfeeding and gradual involution (GI) of the mammary gland that occurs over time upon prolonged breastfeeding in wild-type FVB/N mice and discovered prominent histological and molecular changes in the AI glands over time. Our studies revealed for the first time a clear and persistent expansion of mammary luminal progenitor (LP) epithelial cells in AI glands (AACR abstract#2242, 2018). Here, we corroborate animal studies using normal human breast tissue obtained from a reduction mammoplasty tissue collection study (OSU-2011C0094).

Methods: Breast tissue obtained from parous premenopausal women with no history of breast cancer who breastfed for ≥6 months (GI, n=16) versus those who breastfed for <6 months (AI, n=16) (OSU-2011C0094) was used for gene expression analysis. RNA isolated from these normal mammary tissues was analyzed using Affymatrix Gene ChIP Human Transcriptome array 2.0; Gene Set Enrichment Analysis (GSEA) was used to analyze the microarray data. Molecular Signatures Database was used in GSEA querying C2 curated gene sets, Hallmark gene sets, and Lim-Mammary-Luminal-Progenitor gene sets. H&E sections of the breast tissue were used to assess lobular type by counting number of ductules per terminal ductal lobular unit (TDLU). False discovery rate (FDR) q-values and p-values were used for multiple comparison adjustment.

Results: GSEA revealed that breast tissue obtained from women in the AI cohort exhibited strong positive enrichment for Notch and Hedgehog Signaling (Hhg) pathways (FDR q-value= 0.20 and 0.12, respectively). In GI women, GSEA showed an overall trend towards enrichment in metabolic pathways and immune system functions. Moreover, there was non-significant trend towards positive enrichment of mouse LP gene signature in AI women only (FDR q-value= 0.30). Age and BMI were not statistically different between AI and GI cohorts. Analysis of TDLU, the primary anatomical source of most breast cancers, revealed that breast tissue from AI women had proportionally higher lobular type 1 only epithelium than GI women who exhibited more differentiated lobular epithelium (p-value= 0.049).

Conclusion: We report here for the first time that mammary glands from women who breastfed <6 months were enriched for stem-cell signaling pathways and LP gene signature. This reflects some similarity to BRCA1 mutation carriers, who demonstrate expanded luminal progenitor population. In addition, higher Type 1 TDLU’s are seen in breast tissue from parous women who breastfed <6 months. Together, these data demonstrate features for TN/BLBC precursors enriched in patients who breastfed for <6 months. Understanding this mechanistic link will help in developing prevention strategies, particularly for African-American women who have lower prevalence of breastfeeding and higher incidence of TN/BLBC.
Breast cancer characteristics and outcomes in patients with TP53 germline mutation

Melanie Tran¹, Delphine Loirat¹, Chrystelle Colas¹, Laurence Bozec¹, Valerie Laurence¹, Florence Lerebours¹, Luc Cabel¹, François-Clement Bidard¹, Dominique Stoppa-Lyonnet¹, Anne Vincent-Salomon¹, Marion Gauthier-Villars¹, Marion Lavigne¹ and Antoine De Pauw¹. ¹Institut Curie, Paris, France.

Introduction
Li-Fraumeni syndrome (LFS) resulting from monoallelic germline TP53 gene mutation is a rare hereditary cancer predisposition. Breast cancer (BC) is the most common cancer among women with TP53 germline mutation with a risk ranging from 49% to 85% by the age of 60 years old. Most of these cancers are early onset. Few patients’ cases have been reported so far in the literature. Our aim was to describe the medical history of a cohort of LFS women diagnosed with BC recruited from a single institution. The characteristics combined were genetic alteration diagnosis, tumor characteristics, treatment, outcome, and LFS associated cancers.

Methods
We retrospectively identified breast cancer patients with TP53 germline mutation from the Institut Curie (Paris, France) database and described their cancer characteristics and medical history.

Results
From 1989 to 2015, 25 patients affected with BC (31 tumors) and TP53 germline mutation carrier were identified, with a median follow up of 6.5 years. Median age at BC diagnosis was 30.5 years. All patients were women. 33% had a previously identified TP53 mutation in their family. 70% of them had BC as their first cancer event. 60% of the patients presented with another LFS associated cancer or non-related cancers: osteosarcoma (22%), glioblastoma (18%), pulmonary carcinoma (13%), gastric linitis plastica (9%), malignant hemopathy (9%), soft tissue sarcoma (9%), adrenocortical carcinoma (4%), ovarian cystadenocarcinoma (4%), renal tumor (4%), choroid plexus carcinoma (4%).
92% of the breast tumors were ductal carcinoma (28% DCIS and 64% IDC), 7% were sarcoma (1 phyllodesarcoma, 1 pleiomorphic liposarcoma); there were no lobular carcinoma. Among the IDC, 50% were HER2 positive, 72% were hormone-receptor positive.
Most patients had a mastectomy (64%), and most of them received radiation (55%). However, when TP53 mutation had been identified prior to the treatment, none of the patients received radiotherapy (5 patients). Most patients received chemotherapy (70%) (37% in neoadjuvant setting, 33% in adjuvant setting, 25% for metastatic setting). 40% of the patients received hormone therapy (37% as adjuvant treatment, 7% for metastatic disease).
Most of the patients did not relapse from BC (75%). Overall, only 17% of the patients had metastatic BC. To date, 12 patients of our series have died (48%), 6 patients (24%) from other LFS-associated cancers and 4 patients from BC (16%).

Conclusion
To the best of our knowledge, this descriptive series is the largest study of tumor characteristics and medical history of LFS-women with BC, the most frequent cancer among women with TP53 germline mutation. It confirms the higher HER2 overexpression rate observed in LFS-patients BC, as suggested in the literature and showed a high rate of DCIS at initial presentation. Most of the patients developed other LFS-associated cancers. In depth molecular analysis of these BC will be performed in order to gain insight into their biological specificities and to adapt the therapeutic management of this poor prognosis syndrome.
Hormonal factors associated with elevation of DNA methylation age in breast tissue of healthy women

Mary E Sehl\textsuperscript{1}, Jill E Henry\textsuperscript{2}, Anna Maria Storniolo\textsuperscript{2}, Steve Horvath\textsuperscript{1} and Patricia A Ganz\textsuperscript{1}. \textsuperscript{1}University of California, Los Angeles, Los Angeles, CA and \textsuperscript{2}Susan G. Komen Tissue Bank at the Indiana University Simon Cancer Center, Indianapolis, IN.

Background: Healthy breast tissue appears older than matched peripheral blood, when using a biologic aging measurement based on DNA methylation markers. The underlying cause of this acceleration is not known. We hypothesize that cumulative estrogen exposure is associated with accelerated breast epigenetic aging. In this study, we examined factors associated with breast epigenetic age in a healthy population of women.

Methods: We used breast tissue samples from 232 healthy women donors (119 pre-menopausal, 113 post-menopausal) to the Komen Tissue Bank, with data available on variables related to cumulative estrogen exposure, including age at menarche, gravidity, parity, and menopausal status. DNA methylation experiments were performed using the Illumina EPIC 850K array platform. DNA methylation age (DNAm age) was calculated using the epigenetic clock methods developed by Horvath (2013). Total years of estrogen exposure was calculated as the difference between age at menopause (or current age) - number of live births x 9 months – number of miscarriages x 3 months. Nonparametric group testing was used to compare mean levels of the difference between DNAm age and chronologic age for pre- and post-menopausal groups. We examined the outcome “age acceleration”, calculated using the residuals of the regression of DNAm age versus chronologic age, because it is age-adjusted and independent of cell distribution. Multivariate linear regression models were used to examine for associations between age acceleration and each of our covariates.

Results: Our sample included women aged 19-90 years (mean age 50.7, SD 11.8), with 114 nulliparous women. We confirmed that DNAm age in breast tissue is strongly correlated with chronologic age (\(\rho=0.89, p<0.0001\)). The difference between DNAm age and chronologic age is greater at earlier ages, and is significantly greater in premenopausal women (mean 8.9 years, SE 0.04), compared with postmenopausal women (mean 2.7 years, SE 0.05) (\(p<0.0001\)). Age acceleration was significantly associated with earlier age at menarche (\(\beta=-0.395\) for each year, \(p=0.036\)). For women with limited total years of exposure to estrogen (<19 years), there was a significant association between age acceleration and total estrogen exposure and \(\beta=0.673\) for each year, \(p=0.028\).

Conclusion: Acceleration of epigenetic age in breast tissues occurs in healthy women and is most pronounced in the pre-menopausal period. Earlier age at menarche and total years of estrogen exposure are associated with higher degree of acceleration, suggesting that cumulative estrogen exposure drives this process.
Octogenerian breast cancer was associated with higher infiltration of M2 macrophages and tregs and worse disease free survival

Maiko Okano1, Ahmed Elkhanany1, Qianya Qi1, Li Yan1 and Kazuaki Takabe1. 1Roswell Park Comprehensive Cancer Center, Buffalo, NY.

**Backgrounds:** It is known that elderly patients have worse prognosis of breast cancer and commonly the blame is on their medical comorbidities and access to care. We question this dogma and hypothesized that extreme elderly (octogenerians over 80 years old) have biologically worse cancer that can be defined by mutation load, tumor heterogeneity, and its tumor immune microenvironment.

**Patients and Methods:** Two groups; Control (patients aged 40-65), and octogenerians (age over 80) at the time of breast cancer diagnosis were compared in The Cancer Genomic Atlas (TCGA; n=1093) and the Molecular Taxonomy of Breast Cancer International Consortium (METABRIC; n=2506) cohorts. Cytolytic activity score (CYT), CIBERSORT analysis, tumor mutation load, as well as mutant-allele tumor heterogeneity (MATH) score were conducted as previously published.

**Results:** The total number of patients in the control group and octogenarians were 675 and 54 in TCGA, and 1001 and 121 in METABRIC, respectively. Octogenerians had significantly worse disease free survival in addition to overall survival in both cohorts (p<0.01 in both), which suggested that they had worse cancer biology. In terms of subtypes, octogenerians had significantly higher rate of ER positive cancers than control group in both cohorts (75.3% vs 87.0%, p<0.01 in TCGA, 72.9% vs 90.0%, p<0.01 in METABRIC), but there was no significant deference in PgR or Her2 positivity. With regard of PAM50 classification, luminal-A and B subtypes were significantly higher in octogenerians (44.6% vs 34.7%, 31.4% vs 20.5%, respectively, p<0.01), whereas basal (7.4% vs 11.2%) and claudin-low (2.5% vs 11.8%) subtypes were significantly lower (p<0.05) in octogenarians in METBRC cohort. Given that octogenerians had subtype with favorable prognosis, we examined whether they had higher mutation load or heterogeneity of the tumor. There were no significant difference in tumor mutation load and MATH score that reflect tumor heterogeneity in both cohorts. On the other hand, breast tumors of octogenerians were significantly associated with immune-suppressive cells, such as M2 type macrophages and regulatory T cells in both cohorts (p<0.05), whereas they were negatively associated with immune- eliminating cells, such as activated memory CD4 T-cells and M1 type of macrophages in METABRIC cohort (p<0.05). There was no significant difference in CYT in TCGA cohort.

**Conclusion:** Our result demonstrated that octogenerians breast tumors were infiltrated with more immune-suppressive cells that may contribute to their biologically worse behavior.
Molecular and genetic characterisation of contralateral breast cancers in Northern Ireland: Opportunities for personalised surgery

Colin G McIlmunn\(^1\), Finian J Bannon\(^2\), Deirdre Fitzpatrick\(^3\), Aaron Ervine\(^4\), Clinton Boyd\(^6\), Iain Cameron\(^6\), Tejas Harita\(^1\), Jacqueline James\(^1\), David Gonzalez de Castro\(^1\), Kieran I Savage\(^1\) and Stuart A McIntosh\(^1,7\).

1Centre for Cancer Research and Cell Biology, Queen's University, Belfast, United Kingdom; 2Centre for Public Health, Belfast, United Kingdom; 3Northern Ireland Cancer Registry, Belfast, United Kingdom; 4Craigavon Area Hospital, Southern Health and Social Care Trust, Craigavon, United Kingdom; 5Antrim Area Hospital, Northern Health and Social Care Trust, Antrim, United Kingdom; 6Altnagelvin Area Hospital, Western Health and Social Care Trust, Derry, United Kingdom and 7Belfast City Hospital, Belfast Health and Social Care Trust, Belfast, United Kingdom.

Contralateral breast cancer (CBC) incidence is reported as 0.4-0.7% per year, equating to an approximate 10-15% 20 year risk after primary cancer diagnosis. Young age at primary diagnosis and a strong family history are consistently cited as significant risk factors for CBC development. Requests for contralateral prophylactic mastectomy (CPM) are rising, despite a lack of evidence that CPM significantly improves breast cancer specific survival. Therefore, a method to stratify CBC prognosis and risk at an individual level is required to allow us to personalise surgical decision-making for individual patients.

This study aims to:
1. Explore prognostic factors following CBC diagnosis;
2. Investigate metastatic CBC prevalence by determining clonal relationships between primary and CBC tumours;
3. Assess the rate of germline predisposition gene mutations in a large cohort of Northern Irish CBC cases.

A cohort of 403 CBC patients and 1:1 matched unilateral breast cancer controls (matched for age, year of diagnosis, nodal positivity and tumour morphology) were identified from the Northern Ireland Cancer Registry. Archival primary, CBC and normal lymph node tissue from these CBC patients were obtained for somatic and germline sequencing of a custom 94-gene panel, comprising genes most commonly mutated in breast cancer and all known predisposition genes.

CBC patients had a significantly increased risk of breast cancer specific mortality when compared with 1:1 matched unilateral breast cancer controls (HR 6.45, CI 4.27-9.77). Within the CBC cohort, a shorter time interval between primary and CBC diagnosis is associated with increased breast cancer mortality, whereby women with <5 years between diagnoses have the poorest survival (p=0.001). In terms of receptor status, the PR status of ER positive primary and CBC tumours differed significantly (p<0.001). 89.1% of ER positive primary tumours were PR positive, whilst PR positivity was only 54.4% in ER positive CBCs. Indeed, 36.6% of patients with an ER+/PR+ primary BC developed an ER+/PR- CBC, after exposure to anti-oestrogen therapy.

Targeted next generation sequencing of 42 cases to date has provided evidence of shared somatic mutations suggestive of metastatic clonality between primary and CBC in four cases (9.5%). Germline pathogenic predisposition gene mutations were identified in five (11.9%) patients and a further ten (23.8%) patients were noted to have germline predisposition variants of unknown significance.

Breast cancer specific mortality risk was significantly higher in CBC patients compared with matched unilateral cancer controls, in excess of what would be expected from two primary cancer events. This finding suggests that there are as yet unquantified factors contributing to this excess hazard. Poorer outcome with shorter inter-tumour diagnostic intervals, in addition to evidence of primary-CBC clonality in some cases, suggests that metastatic CBC may play a role in excess risk. Additionally, the significant reduction in PR positivity of ER positive CBC tumours after ER+/PR+ primary tumours, could suggest that acquired hormonal resistance following primary anti-oestrogen therapy exposure may contribute to this additional mortality hazard.
Prognostication of genetic alterations of ESR1 in estrogen receptor positive metastatic breast cancers using targeted ultra-deep sequencing data analysis

Ji-Yeon Kim1, Kyung Hee Park2, Woong-Yang Park2, Seok Jin Nam1, Seok Won Kim1, Jeong Eon Lee1, Se Kyung Lee1, Jong Han Yu1, Jin Seok Ahn1, Young-Hyuck Im1 and Yeon Hee Park1. 1Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea and 2Samsung Genome Institute, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea.

Introduction: Genetic alteration of Estrogen Receptor 1 (ESR1) gene have been associated with acquired endocrine resistance and occurred in about 20% of endocrine resistant estrogen receptor (ER)-positive metastatic breast cancer (MBC). Mutations in ligand binding domain of ESR1 lead to constitutive activity of the ER without ligand estrogen and stimulated downstream cell growth signal. Therefore, ESR1 ligand binding domain alteration is known resistant mechanism of aromatase inhibitor. Among these ESR1 mutations, Y537S, one of the ligand binding domain mutations, caused ER antagonist, fulvestrant resistance. Therefore, assessment of ESR1 mutation in ER-positive MBC had significant benefit to further precision medicine for MBCs. In this study, we explored to identify the frequency and type of ESR1 genetic alterations of ER-positive MBC.

Methods: We performed targeted ultra-deep sequencing (CancerSCAN™) using BC tissue specimens. This sequencing was covered entire coding area of ESR1 gene and also detected copy number alteration and translocation of ESR1.

Results: Targeted ultra-deep sequencing of ESR1 was performed using 990 BC tissues. Of 990 tissue samples, 341 (34.5%) were MBCs. Of MBCs, 112 (11.3%) were ER-positive and human epidermal growth factor receptor 2 (HER2)-negative BCs. In ER-positive HER2-negative MBCs (N=112), 21 ESR1 genetic alterations were identified in 19 BCs (17.0%). Nineteen were single nucleotide variants (SNVs) and three were copy number (CN) amplification. Most commonly detected single nucleotide variant (SNV) was D538G (6 of 19, 31.6%) followed by Y537N, Y537S, V382I (4, 2 and 2 cases, respectively). Three mutations occurred in non-ligand binding domain (G415V, V392I and P79A). Two BC samples harbored two ESR1 mutations, respectively (Y537S and D538G, L536P and Y537N). In terms of treatment, 11 of 12 patients with ER-positive MBC harboring ESR1 mutation received palliative endocrine therapies. Eight patients received aromatase inhibitor and two patients received tamoxifen. One patient received letrozole plus palbociclib. In 2 MBCs with Y537S mutation, progression free survival (PFS) of endocrine therapy was 1.4 and 5.3 months. MBCs with D538G had 12.3 months of PFS (range, 5.3-23.7 months) and BCs harboring another ligand binding domain mutations (Y537N, L536H and L536P) had 15.7 months of PFS of endocrine therapy (range, 8.4-17.3 months). BC with mutation observed in non-ligand binding domain had short PFS (1.8 (V392I) and 2.7 (P79A) months, respectively). In terms of ESR1 CN amplification, patients could not receive endocrine therapy because their BCs rapidly progressed and extensive distant metastases were occurred within 3 months after curative surgery.

Conclusion: In this exploratory study, ESR1 genetic alterations were detected in about 20% of ER-positive MBC. The type of genetic alterations varied including SNVs, CNAs. Each locus of ESR1 mutation predicted endocrine resistance. In addition, we might suggest that ESR1 CN amplification is prognostic marker of ER-positive BCs.
TP53 expression in relation to clinical and etiologic factors in breast cancer subtypes

Xiaohong R Yang¹, Mustapha Abubakar¹, Changyuan Guo², Hela Koka¹, Hyuna Sung¹³, Jennifer Guida¹⁴, Joseph Deng¹, Bin Zhou², Nan Hu¹ and Ning Lu². ¹National Cancer Institute, NIH/DHHS, Bethesda, MD; ²Cancer Hospital, Chinese Academy of Medical Sciences, Beijing, China and ³American Cancer Society, Atlanta.

TP53 is a well-known tumor suppressor gene and mutations in TP53 are the most frequent genomic event in most cancers including breast cancer. Recent studies have shown that the frequency, spectrum, timing, and clinical implications of TP53 mutations varied in different molecular subtypes of breast cancer. For example, the frequency of TP53 mutations is the highest in basal-like subtype and lowest in luminal A tumors. However, the evaluation of TP53 protein expression, as a surrogate for TP53 mutations, in large studies in the context of tumor subtypes is limited. In addition, the etiologic relevance of TP53 expression is yet to be investigated. The goal of this study is to evaluate the association of clinical and breast cancer risk factors with TP53 expression, measured using immunohistochemistry (IHC), in breast cancer molecular subtypes. The analysis included 7,226 women with invasive breast cancer who were diagnosed and treated in a tertiary hospital in Beijing, China. Subtypes were defined as Luminal A: ER+ and PR+, HER2−, and low grade (grades 1 or 2); luminal B/HER2−: ER+ and/or PR+, HER2−, and high grade (grade 3); luminal B/HER2+: ER+ and/or PR+, HER2+ (regardless of grade); HER2-enriched: ER−, PR−, and HER2+; Triple-negative (TN): ER−, PR−, and HER2−. As expected, positive TP53 staining showed the lowest frequency in the luminal A (46%) and highest in the TN (61%) and HER2-enriched (63%) subtypes (P-value <0.001). Overall and particularly in luminal A patients, positive TP53 staining was associated with higher frequencies of aggressive tumor features such as higher grade, larger tumor size, higher proliferative index, and EGFR expression. Compared with TP53− patients, TP53+ patients were more likely to have younger ages at onset and increased parity, but these associations were largely driven by the luminal A subtype [OR (95% CI) vs nulliparity = 2.67 (1.59, 4.51); 2.63 (1.52, 4.55); 3.68 (2.01, 6.72) for 1, 2, and ≥3 children, respectively (P-trend = 0.006)]. Luminal A/TP53+ patients were also more likely to have breastfed [OR (95% CI) ever vs never = 1.38 (1.03, 1.85)] than luminal A/TP53− patients. These findings suggest that TP53 IHC staining might be used to further refine the classification of luminal A breast cancer into subgroups with distinct clinical and etiologic relevance.

A real world evidence study of BRCA mutations and survival in HER2-negative breast cancer

Tapashi Dalvi¹, Kimmie McLaurin¹, Josefa Briceno¹, Beth Nordstrom², James Bennett¹, Robert Hettle¹, Brian Murphy², Jenna Collins² and Susan McCutcheon¹. ¹AstraZeneca, Gaithersburg, MD and ²Real-World Evidence, Evidera, Waltham, MA.

Background: Limited data exist on the natural history (treated with standard of care) of metastatic breast cancer (mBC) characterized by germline breast cancer susceptibility gene mutations (gBRCAm). Real-world data examining survival for patients with gBRCAm mBC, overall and separated into gBRCA1m and gBRCA2m, compared to gBRCA wild type (wt) mBC, can help to clarify the prognostic outlook associated with the gBRCA mutation.

Methods: Adults with human epidermal growth factor receptor 2 negative (HER2-) mBC diagnosed from January 2013 – August 2017 were retrospectively selected from the Flatiron Health Oncology electronic medical record database. Patients were classified as having gBRCA1m, gBRCA2m, or gBRCAwt disease. Those who did not receive the genetic testing or who had equivocal results were classified as gBRCA unknown. Overall survival (OS) was calculated from first diagnosis of mBC, as well as from the start of first- and second-line therapy for metastatic disease. Lines of therapy included both hormonal and systemic therapies. Kaplan-Meier analyses provided median OS with 95% confidence interval (CI). Unadjusted log-rank tests compared OS between gBRCA1m and gBRCA2m, and between overall gBRCAm and gBRCAwt.

Results: Of 8,080 patients selected, mean age at first mBC diagnosis was 64 years, 98.7% were female, and 82.0% had evidence of hormone receptor positive disease. gBRCA status was known for 1,852 (22.9%) of patients, of whom 89 (4.8%) had gBRCA1m, 152 (8.2%) had gBRCA2m, and 8 (0.4%) had both gBRCA mutations. Patients with known gBRCA status were younger, with mean ages of 52 years for gBRCAm, 55 years for gBRCAwt, and 67 years for gBRCA unknown. Hormone receptor positive disease was less common among those with known gBRCA status (71.9%, 77.2%, and 83.6% for gBRCAm, gBRCAwt, and gBRCA unknown, respectively). Median (95% CI) OS from mBC diagnosis was 22 (14 - 26) months for gBRCA1m and 30 (27 - 37) months for gBRCA2m (p = 0.01), though numbers were quite small by the median timepoint. Overall gBRCAm disease was associated with median survival of 28 (25 - 32) months, compared to 32 (30 - 35) months for gBRCAwt (p = 0.07); survival was similar between groups for the first 24 months but declined thereafter in the gBRCAm group. Similar patterns were observed for OS after the start of first- and second-line therapy, although no comparisons were significant. Further analyses will present adjusted results and comparisons with outcomes for the patients with gBRCA unknown.

Conclusions: This real-world study of patients receiving care in largely community oncology clinics suggests that survival after diagnosis of mBC is reduced in patients with gBRCA1m compared to gBRCA2m disease and may be reduced in gBRCAm mBC overall. Effective treatments targeted for the gBRCAm subtypes of mBC appear to be needed.
Demographic, clinical/disease characteristics, and treatment of patients with germline mutated metastatic breast cancer: A CancerLinQ study

Tapashi Dalvi¹, Iksha Herr¹, Sharon Maclachlan¹, Josefa Briceno¹, James Bennett¹, Kimmie McLaurin¹, Robert Hettle¹ and Susan McCutcheon¹. ¹AstraZeneca, Gaithersburg, MD.

Objective: To describe the demographics, clinical/disease characteristics and treatment patterns of patients with germline BRCA mutated (gBRCAm) metastatic breast cancer (mBC) as compared to those with gBRCA wild type (wt) and those who are untested for gBRCA mutations.

Methods: The CancerLinQ Discovery Database (CLQ), launched by the American Society of Clinical Oncology (ASCO) in 2016, consists of longitudinal, demographic and geographic diverse data aggregated from oncology practice electronic health record (EHR) databases. Natural language processing and technology-enabled curation are utilized to identify records of most interest, followed by manual curation to abstract information from unstructured EHR fields. This cohort consists of 7,889 patients diagnosed with mBC between 1982 and 2018, and is enriched for patients with gBRCA testing through the curation process.

Results: Overall most patients were female (99.0%), white (55.3%), and the median age at mBC diagnosis was 63 years (yrs). The majority were not tested for gBRCA mutation (88.4%); 2.0% were gBRCAm, 9.2% were gBRCAwt, 0.4% had an undetermined test result, and 0.1% had a variant of unknown significance. Among those tested for estrogen-receptor (ER) (n=6,700) and progesterone-receptor (PR) (n=6,737) status, 76.6% were ER positive (+) and 62.2% were PR+. Among those tested for human epidermal growth factor receptor 2 (HER2) (n=6,696), 21.7% were HER2+. Among those with known results for ER, PR, and HER2 (n=6,063), 10.1% were hormone receptor (HR)+/HER2+, 10.6% were HR negative (-)/HER2+, 65.0% were HR+/HER2-, and 14.3% were HR-/HER2-. The median age at mBC diagnosis was 50 yrs for gBRCAm, 51 yrs for gBRCAwt and 64 yrs among the gBRCA untested group. A similar proportion of patients were diagnosed with metastatic disease among the gBRCAm and gBRCAwt groups (25.3% and 20.3%, respectively), while the proportion was higher among the gBRCA untested group (38.0 %). The most common site of metastasis for all groups was bone (35.1% for gBRCAm, 41.7% for gBRCAwt, and 36.5 % for gBRCA untested), followed by liver (16.2% for gBRCAm, 13.3% for gBRCAwt, and 8.5% for gBRCA untested). The most common first-line therapies for gBRCAm patients were tamoxifen (7.7%), letrozole (7.0%), cyclophosphamide+doxorubicin (6.3%), and paclitaxel (6.3%); for gBRCAwt patients they were cyclophosphamide+doxorubicin (6.6%), paclitaxel (6.4%), and tamoxifen (6.4%); and for gBRCA untested patients they were letrozole (11.1%), fulvestrant (9.3%), and tamoxifen (4.6%). The mean number of lines of therapy (including lines of chemotherapy and hormone therapy) were 3.5, 3.8, and 3.4 for the gBRCAm, gBRCAwt, and gBRCA untested groups, respectively.

Conclusions: Patients with gBRCAm were younger than the gBRCA untested group, and more patients had metastatic disease at diagnosis in the gBRCA untested group. Further analyses accounting for HR and HER2 status will be conducted and presented. This is the first example of research using curated breast cancer data from ASCO’s CLQ.
DNA methylation markers influenced by BMI are associated with breast cancer

Chunyan He¹, Nan Lin¹, James Castle¹, Jingpeng Liu¹, Yunlong Liu² and Chi Wang¹. ¹University of Kentucky, Lexington, KY and ²Indiana University, Indianapolis, IN.

Body mass index (BMI) is a well-established risk factor for breast cancer. However, the underlying molecular mechanism through which BMI acts on breast cancer remain largely unknown. DNA methylation plays a critical role in regulating gene expression. Aberrant DNA methylation has been implicated in breast cancer development. We hypothesize that BMI influences DNA methylation that in turn leads to breast cancer. We therefore conducted a molecular epidemiological study to identify DNA methylation markers that are associated with BMI in healthy women and further determine the association of these DNA methylation changes with breast cancer development and occurrence. We analyzed 270 normal breast tissue from healthy women and 109 tumor tissue from breast cancer patients for genome-wide DNA methylation profiling using the Illumina Truseq® Methyl Capture EPIC sequencing technology. After data quality control, approximately 3 million CpG sites (sequencing depth ≥10) were retained and included in further statistical analysis. Linear regression was performed to examine the association between BMI and each of CpG sites, adjusting for age and race. Bonferroni correction was used for control for multiple comparisons. We further investigated whether these BMI-associated DNA methylation markers were differentially methylated in normal and breast tissue. We found that 30 CpG sites were significantly associated with BMI (P< 1.5x 10^{-8}) in normal breast tissue. Many of these GpG sites were also differentially methylated in tumor and normal breast tissue. Top CpG hits are near novel and putative cancer genes mainly involved in lipid metabolism and related reproductive phenotypes that increase breast cancer risk, including KIAA0232, SHZ2, LACTB, PAPPA, and DLGAP2. The most significant CpG site associated with BMI is on chr. 4 in KIAA0232 gene. Little is known about the function of this gene, but genetic variant near the gene are associated with platelet count and volume in GWAS. The second most significant hit is on chr.20 in gene TSHZ2. This gene is found downregulated in breast and prostate cancer. LACTB gene is a tumor suppressor that modulates lipid metabolism and cell state. Its mechanism of action involves alteration of mitochondrial lipid metabolism and differentiation of breast cancer cells. PAPPA gene plays a role in inflammation and promote invasion of cancer cells. DLGAP2 is an imprinted gene, and SNPs near DLGAP2 are associated with age at menarche in AA women. Our results suggest DNA methylation may intermediate the observed association between BMI and breast cancer. Further research is warranted to validate these findings in larger studies as well as to understand the regulatory network by linking data with gene expression.
Defining the spectrum of germline variants among African American patients with triple negative breast cancer

Holly J Pederson¹, Brandie Heald¹, G T Budd¹, Ryan Bernhisel², Shelly Cummings², Jennifer R Saam², Johnathan M Lancaster², Stephen R Grobmyer¹ and Charis Eng¹. ¹Cleveland Clinic, Cleveland, OH and ²Myriad Genetic Laboratories, Inc., Salt Lake City, UT.

Background: African American (AA) women are more likely to have breast cancer at a younger age and be diagnosed with triple negative breast cancer (TNBC), which is as yet unexplained. We examined results of multi-gene panel testing in AA women with TNBC tested at a large commercial laboratory to assess the utility of gene panels and findings in this group.

Methods: We assessed individuals who had clinical hereditary cancer testing with a multi-gene panel between September 2013 and May 2018. Women were included for analysis if they had a personal history of TNBC and self-identified as having any AA ancestry (n=3,268) or only Caucasian (CA) ancestry (n=8,953). Clinical data was collected from provider-completed test request forms. Comparisons were performed using descriptive statistics, t-tests (continuous variables), and chi-square tests (categorical variables) adjusting for multiple testing when necessary.

Results: In this cohort, AA women were significantly more likely than CA women to meet NCCN guidelines (97.5% vs. 96.6%, p=0.010) and significantly less likely to have an additional personal (16.2% vs. 21.8%, p<0.001) or family (79.3% vs. 86.3%, p<0.001) history of cancer. Overall, 11.5% of AA women were found to carry a pathogenic variant (PV) compared to 13.4% of CA women (p=0.004; Table 1). Compared to CA women, AA women with a PV were significantly younger at diagnosis (46.7 vs. 49.5 years of age; p<0.001). The prevalence of PVs in BRCA1, CHEK2 and the Lynch syndrome genes was higher in CA women, whereas the prevalence of BRCA2 PVs was higher in AA women. While the prevalence of PVs in individual genes was not significantly different according to ancestry after adjusting for multiple comparisons, AA women were significantly less likely to have a PV in any breast cancer-related gene compared to CA women (p=0.048). AA women were significantly more likely to have a Variant of Uncertain Significance (VUS; 35.6% vs. 20.9%; p<0.001) and to have >1 VUS (8.6% vs. 2.6%, p<0.001). Regardless of ancestry, patients diagnosed before age 40 were more likely to carry a PV (19.7% AA, 22.2% CA). However, the prevalence of PVs among patients diagnosed after age 60 was still striking (8.9% AA, 10.9% CA) and was similar to the PV prevalence among patients diagnosed between 40-60 (10.1% AA, 12.3% CA).

Conclusions: In the era of multi-gene panel testing, this large cohort of patients with TNBC supports the use of panel testing in AA women with TNBC regardless of age or additional personal/family history of cancer. While additional research to the rate and pathogenicity of VUS in AA women is needed, genetic counseling is necessary to explain the possibility and meaning of a VUS in this group.

Table 1. Distribution of PVs in BC-related genes according to ancestry
Type II diabetes and subtype-specific breast cancer risk in medically underserved black and white women

Amy L Gross¹, William J Blot¹ and Kala Visvanathan². ¹Vanderbilt University Medical Center, Nashville, TN and ²Johns Hopkins Bloomberg School of Public Health, Baltimore, MD.

Background: Type II diabetes (T2D) has been found to modestly (10-20%) increase risk for breast cancer (BC) in mostly white populations. Some studies indicate that this association varies by BC receptor subtype, suggesting that T2D increases risk specifically for the more aggressive estrogen-receptor (ER)-negative and triple negative subtypes. While black women are more likely than white women to develop both T2D and ER-negative BC, no studies to date have explicitly focused on subtype-specific risk by race. Further, no studies have examined this association in women from medically underserved areas, where the prevalence and severity of T2D is greater than in areas with adequate resources.

Methods: Participants were women from the Southern Community Cohort Study (2002-2009), which prospectively recruited individuals age 40-79 years, primarily from community health centers in medically underserved areas across the Southeastern US. We identified 39,687 women who were cancer-free at baseline and self-reported black or white race. Baseline T2D status was defined as a self-reported diagnosis of medication-treated T2D at age > 30 years. BC incidence and receptor status were ascertained by state cancer registry linkages and pathology reports. Cox proportional hazards regression was used to estimate the hazard ratio (HR) and 95% confidence interval (CI) for BC (overall and by subtype) associated with T2D. Models were first adjusted for, and then stratified by race. Exploratory analyses modeled self-reported diabetes medication adherence (taking as directed all the time or most of the time vs. sometimes, rarely or never) as an exposure.

Results: Among 39,687 women (29.9% white and 70.1% black), 7501 (18.9%) reported having T2D. Over a median of 10.3 years of follow-up, 929 incident cases of invasive BC occurred; 224 (24.1%) were ER-negative, and among those with complete receptor data (n=808), 138 (17.1%) were triple-negative. Women with T2D were significantly more likely to develop BC (HR: 1.19, 95% CI: 1.02-1.40) compared to non-diabetics in models adjusted for age, race, BMI, mammography screening, menopausal status, alcohol use, and family history of BC. In subtype-specific analyses, the risk associated with T2D was greatest for the ER-negative (HR: 1.45, 95% CI: 1.01-2.08) and triple-negative (HR: 1.53, 95% CI: 1.01-2.31) subtypes. Race-stratified models showed similar elevations in risk among black (HR: 1.16, 95% CI: 0.97-1.39) and white women (HR: 1.13, 95% CI: 0.83-1.53) for BC overall, and for triple-negative BC, with a HR of 1.61 (1.02-2.53) in blacks and 1.94 (0.74-5.07) in whites. Across both races and by subtype, women reporting lack of adherence to diabetes medications had far greater risk for BC compared to non-diabetics, with an overall HR of 2.15 (1.27-3.66).

Conclusion: In this study, T2D was associated with a 19% increased risk of BC and 53% increased risk for the triple-negative subtype, with similar results for black and white women. The risk was notably greater in women who reported lack of T2D treatment adherence. Given these findings and the prevalence of T2D in medically underserved areas, interventions aimed at T2D prevention and adherence to medications in all races could help reduce the BC burden in this population.
Real-world effectiveness outcomes by race in patients with metastatic triple negative breast cancer

Karen E Skinner¹, Robert Dufour¹, Amin Haiderali², Min Huang² and Lee S Schwartzberg³. ¹Vector Oncology, Memphis, TN; ²Merck, North Wales, PA and ³West Cancer Center, Germantown, TN.

Background: Age, race, and tumor environment are major contributors in the variance of treatment outcomes in patients (pts) with breast cancer. Few studies have evaluated outcomes in real-world pts to identify high-risk populations. We aimed to compare differences in effectiveness outcomes by race among pts with metastatic triple negative breast cancer (mTNBC).

Methods: This retrospective observational study evaluated effectiveness outcomes of progression-free survival (PFS) and overall survival (OS). Eligible pts were female, age ≥18 years, and diagnosed with mTNBC between 1/1/2010 and 1/31/2016 from 9 US community oncology practices. The sample was stratified by race (White, African-American [AA], Other). Kaplan-Meier methods were used to describe time-to-event outcomes. Cox regression models were used to examine the effect of race-based groups on PFS and OS.

Results: The study included 608 pts (60.2% White, 33.9% AA, 5.9% Other; mean [standard deviation] age 57.5 [13.5] years). Pt characteristics largely did not differ across groups, except AA pts appeared younger (AA: 55.3 years vs. White: 58.6 vs. Other: 58.6, p=0.015) and less likely to have brain metastasis (AA: 8.3% vs. White: 15.0% vs. Other: 19.4% p=0.034). 505 pts (83.1%) received anti-cancer treatment (treated) following mTNBC diagnosis, while 103 pts (16.9%) did not receive anti-cancer treatment (untreated). The prognosis for untreated pts who did not receive anti-cancer therapy was poor, with a median OS of 4.8 months from mTNBC diagnosis compared to 12.8 months for treated pts (p=0.030). The proportion of treated pts did not differ by race (AA: 85.0% vs. White 82.5% vs. Other: 77.8%, p=0.518). Treatment class also did not differ by race (p=0.861), with Taxane therapy being the most common treatment. Among treated pts, median PFS and median OS from the start of first line treatment were 4.2 months and 12.0 months, respectively (Table 1). AA pts had a poorer prognosis than White pts as they were more likely to have a PFS event and also more likely to have an OS event compared to White pts (Hazard Ratio [HR]: 1.24, p=0.042; HR: 1.35, p=0.006; respectively).

Conclusions: This evaluation of effectiveness outcomes indicates high unmet need as 1 in 6 mTNBC pts did not receive anti-cancer treatment. Furthermore, AA race was associated with poor outcomes. AA pts had shorter PFS and OS than other pts, and were more likely to experience progression or death than White pts.; despite being younger and less likely to have brain metastasis, which are typically associated with better outcomes. Future studies should be conducted to address unmet need and health outcome disparities in high-risk populations.

Racial and ethnic differences in weight gain during and after chemotherapy among women with early-stage breast cancer

Ruby Wu¹ and Katherine D Crew¹. ¹Columbia University Medical Center, NY, NY.

**Objective**
Clinically significant weight gain of ≥5% from baseline has been commonly reported during chemotherapy treatment for early stage breast cancer and persisting after completion. Based on the known poorer outcomes associated with weight gain after a breast cancer diagnosis, we evaluated differential weight gain by race/ethnicity as a potential explanation for disparities in breast cancer clinical outcomes among racial/ethnic minorities compared to non-Hispanic white women.

**Methods**
We conducted a retrospective cohort study among women diagnosed with stage I-III breast cancer between 2007 and 2016, who received chemotherapy at Columbia University Medical Center (CUMC) in New York, NY. We extracted data on demographics, clinical characteristics, chemotherapy regimens, and height/weight from the electronic health records. Our main exposure variable of interest was race/ethnicity. The outcome variable was dichotomized as ≥5% weight gain or stable weight (defined as <5% weight gain or loss/≥5% weight loss) from baseline at 3, 6, 12, and 18 months after initiating chemotherapy. We used multinomial logistic regression analyses to determine the association between race/ethnicity and weight gain before and after adjusting for confounders.

**Results**
Among 789 evaluable women, median age was 55 years (range, 19-92) and the study cohort was racially/ethnically diverse: 39.8% non-Hispanic white, 30.4% Hispanic, 18.0% non-Hispanic black, 10.4% Asian, and 1.4% other. Mean baseline body mass index (BMI) was highest among black women (30.7 kg/m² ± 7.0), followed by Hispanic (29.4 kg/m² ± 5.2), non-Hispanic white (27.9 kg/m² ± 6.9), and Asian (25.5 kg/m² ± 5.4) women. The proportion of women with ≥5% weight gain increased over time with 13.6% at 3 months, 15.2% at 6 months, 19.0% at 12 months, and 23.6% at 18 months. Compared to non-Hispanic whites, Asian women had a 63% lower odds of ≥5% weight gain (95% Confidence Interval [CI]: 0.15-0.92) at 3 months after initiating chemotherapy. No statistically significant associations were found between other racial/ethnic groups and ≥5% weight gain. Factors associated with weight gain after chemotherapy included younger age at diagnosis, lower baseline BMI, longer duration of chemotherapy, and having Medicaid insurance coverage.

**Conclusions**
Race/ethnicity was not significantly associated with weight gain after chemotherapy among women with early stage breast cancer. Socioeconomic status (SES) rather than race/ethnicity may be a contributing factor in disparities in weight gain and breast cancer clinical outcomes. Future weight loss programs should target younger, pre-menopausal women and those with lower SES.
Analysis of genetic mutation in ethnically diverse population with Breast and ovarian cancer: Single institution experience

Sangeeta Aggarwal, Charles Chu and Michael Ngumi. 1Santa Clara Valley Medical Center, San Jose, CA.

Only 5-10% of all breast and ovarian cancers have been attributed to inherited mutation. In unselected breast cancer patients, prevalence of germline BRCA 1 & 2 is about 2%. In Ashkenazi Jewish population the prevalence is estimated to be 11.7%. The rate of mutations in other populations has not been well characterized. The purpose of this study is to identify and characterize the risk of genetic mutations in an ethnically diverse population referred for genetic testing according to NCCN guidelines.

Method:
In this single institution retrospective study, we analyzed 782 patients referred for genetic testing between 2009-2018. Information regarding reason for referral, ethnicity, cancer history and results of genetic mutation using multigene panels were collected.

Results:
Reasons for referral were:
· Family History of cancer (142; 18.6%),
· Breast cancer diagnosed at early age (207; 26.4%),
· Triple negative breast cancer (12; 53%)
· Ovarian cancer (61; 7.8%)
· Multiple cancer (32; 4.09%)
· Known BRCA 1 or 2 mutation (51; 6.5%)
· Known other mutation (9; 1.15%)
· Family h/o cancer but not diagnosed with cancer (268)

Ethnic distribution:
· 328 Hispanic (41.94%)
· 177 Caucasian (22.6%),
· 27 Chinese, (3.4%)
· 52 Vietnamese (6.6%)
· 86 other- Asian (11%)
· 32 Middle eastern (4.1%),
· 14 South Asian (1.8%)
· 35 African American (4.5%)
· 8 Ashkenazi Jewish (1%)
· 19 Mixed Hispanic (2.1%)

Genetic testing was done in 545 /782 patients.

Deleterious Mutation detected: 88 patients (16.5% of tested)
· BRCA 1: 32 (5.8%)
· BRCA 2:28 (5.14%)
· MSH2:5 (0.9%)
· p53:39 (0.5%)
· PLB2:3 (0.38%)
· MUTYH:3 (0.38%)
· CDH1:2 (0.26%)
· PMS2: 2 (0.26%)
· ATM: 1 (0.13%)
· CCKn2A: 1 (0.13%)
· CHEK 2: 1 (0.13%)
· MET: 1 (0.13%)
· MSH6:1 (0.13%)
· RAD50:1 (0.13%)
BRCA1/BRCA2 mutation: 60

**Mutation in BRCA 1/2 distribution by ethnicity:**
- Hispanic (28; 8.54%)
- Chinese (4; 14.8%)
- Vietnamese (4; 7.7%)
- other Asian (12; 13.9%)
- African American (3; 8.5%)
- South Asian (0%)
- Caucasian (8; 4.5%)
- All Asian (20/165; 12.1%)

**Mutation in other gene by Ethnicity:** total 26
  Hispanic (16, 4.5%), Caucasian: (3, 1.7%) Asian other than Chinese and Vietnamese (4, 4.65%)

**Mutation in Breast cancer:** 333 Breast cancer patients tested, 39 patients (11.17%) were found to have mutations.
  10/32 triple negative (31%) 4/49 her2neu positive patients (8.1%) and 15/252 (5.9%) ER+ patients found to have mutations.
  17/39 breast cancer patients with mutation had prophylactic BSO.

**Mutation in BRCA 1 & 2 by reason for referral:**
- Known family h/o of BRCA1 or 2 mutations (18; 39.5%)
- Early age of cancer (10, 7.4%)
- Cancer with positive family history (17, 8.2%)
- Triple negative (2, 16%).

**Variant of Unknown significance (VUS):** 140 patients (25%)
  VUS in BRCA 2 were most common. VUS were found in 17% of Hispanic and African American patients.
  No significant difference in PFS and OS was found in patient with mutation and without mutation

**Conclusion:**
We found much higher rates (16.5%) than previously reported mutation detection in this very highly diverse patient population.
Rate of BRCA 1&2 mutation was 8.55% in Hispanic and 12.1% in Asian patients compared with 4.5% in Caucasian patient when selected for high risk factors.
We Also noted very high rate of VUS especially in Hispanic and African American patients.
High participation of African-American women veterans in high risk breast cancer screening pilot program

Yeun-Hee A Park, Alison T Keller, Balmatee Bidassie, Vickie L Venne, Bernadette B Heron, Lori Hoffman-Högglund, Douglas K Hawley, Ta-Chueh M Hsu, Sarah V Colonna and Anita Aggarwal. 1 James J. Peters Veterans Affairs Medical Center, Bronx, NY; 2 Veterans Health Administration, Indianapolis, IN; 3 George E. Whalen Veterans Affairs Medical Center, Salt Lake City, UT; 4 Veterans Health Administration, Pharmacy Benefits Management Services, Hines, IL; 5 Veterans Health Administration National Center for Health Promotion and Disease Prevention, Durham, NC; 6 Veterans Health Administration Office of Nursing Services, Washington, DC; 7 Cincinnati Veterans Affairs Medical Center, Cincinnati, OH and 8 Washington, DC Veterans Affairs Medical Center, Washington, DC.

SPECIFIC AIMS: To assess breast cancer risk in Women Veterans.

BACKGROUND/RATIONALE: Women are the fastest growing segment of patients numbering over 2 million and breast cancer incidence has more than tripled from 1995 to 2012 within the Veterans Health Administration (VHA). Preliminary data suggest that Women Veterans may be at an increased breast cancer risk based on unique service-related exposures (e.g., burn pits, depleted uranium) and Post Traumatic Stress Disorder (PTSD). Historically, breast cancer rates among African Americans (AA) are lower than those seen in the general population (8.2-13.3%).

METHODS: A pilot study was conducted at Bronx, NY and Washington, DC Veterans Affairs Medical Centers. Participants were enrolled at their regular visit to Women's Health Clinics or at breast cancer education and awareness events. 5-year and lifetime risks of developing invasive breast cancer were calculated using the Gail Breast Cancer Risk Assessment Tool (BCRAT). Demographics, PTSD status, eligibility for chemoprevention and genetic counseling using the Breast Cancer Genetics Referral Screening Tool (B-RST), were also determined.

ELIGIBILITY CRITERIA: Women Veterans age ≥ 35 years with no personal history of breast cancer.

RESULTS: A total of 99 Women Veterans with an average age of 54 years participated between 2015 and 2018; 60% African American (AA); 13% Hispanic; 14% non-Hispanic White and 13% as other. In total, 35% (35/99) were considered high risk with a 5-year BCRAT of >1.66% and of these, 51% were AA; 14% Hispanic and 17% were other. Prior breast biopsies were performed in only 22% (22/99) of our entire Veteran population; 57% (56/99) having a family history positive for breast cancer. Comparatively, in our high risk AA alone, 33% (6/18) had prior breast biopsies with 94% (17/18) having a positive family history. High risk patients were referred for chemoprevention; 5 (19%) accepted; and 13/35 (37%) patients were referred for genetic counseling. PTSD was present in 29% overall and in 31% of the high risk subgroup.

IMPLICATIONS: The VHA, which leads the nation in mammogram compliance, is an untapped potential resource for the study of breast cancer. To our knowledge, this is the only study with 60% AA Women Veterans. High participation rates among AA in this pilot study have uncovered the potential for further inquiry into this population, which is otherwise dramatically under-represented in research. Over half (51%) of AA in this pilot study had a high risk score, likely linked to a high rate of prior breast biopsies and family history. Limitations of this study include the small sample size, exclusively urban population, geography and self-selection for screening due to a higher level of concern for breast cancer. If Women Veterans are at higher risk of breast cancer, it has been assumed that this would be related to service-related exposures, PTSD and other factors. However this pilot study, which was not designed or powered to do more than raise questions, suggests the additional possibility of an innate or genetic risk, especially in AAs. Future directions include the evaluation of genetic and molecular mutations in high risk AA Women Veterans, possibly even a role for PTSD epigenetic changes and tumorigenesis.
Oral care evaluation to prevent oral mucositis in estrogen receptor positive metastatic breast cancer patients treated with everolimus (Oral Care-BC): A randomized controlled phase III trial

Naoki Niikura1, Katsuhiko Nakatukasa2, Takeshi Amamiya3, Ken-ichi Watanabe4, Hironobu Hata4, Yuichiro Kikawa4, Naoki Taniike5, Takashi Yamanaka6, Sachiyu Mitsunaga1, Kazuhiko Nakagami7, Moriyasu Adachi7, Naoto Kondo8, Koichi Horii9, Naoki Hayashi10, Mariko Naito11, Kosuke Kashiwabara12, Toshinari Yamashita8, Masahiro Umeda13, Hirofumi Mukai14 and Yoshihide Ota1.1Tokai University School of Medicine, Isehara, Kanagawa, Japan; 2Kyoto Prefectural University of Medicine, Kyoto, Japan; 3Kyoto Prefectural University of Medicine, Graduate School of Medical Science, Kyoto, Japan; 4Hokkaido Cancer Center, Sapporo, Hokkaido, Japan; 5Kobe City Medical Center General Hospital, Kobe, Hyogo, Japan; 6Kanagawa Cancer Center, Yokohama, Kanagawa, Japan; 7Shizuoka General Hospital, Shizuoka, Japan; 8Nagoya City University Graduate School of Medical Sciences, Nagoya, Aichi, Japan; 9Nagoya City University Hospital, Nagoya, Aichi, Japan; 10St. Luke's International Hospital, Chuo-ku, Tokyo, Japan; 11Graduate School of Biomedical and Health Sciences, Hiroshima University, Hiroshima, Japan; 12School of Public Health, the University of Tokyo, Bunkyo-ku, Tokyo, Japan; 13Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan and 14National Cancer Center Hospital East, Kashiwa, Chiba, Japan.

Introduction
Oral mucositis is a clinically significant complication of mucotoxic cancer therapy. The incidence of oral mucositis (any grade) as an adverse drug reaction of everolimus is 58%, while an analysis of Asian people has reported its occurrence as 81%. This study hypothesizes that the occurrence of oral mucositis will reduce with professional oral care (POC) administered prior to everolimus treatment.

Method:
This was a randomized, multi-center, open-label, phase III study, to evaluate the efficacy of POC in preventing mucositis induced by everolimus in postmenopausal, estrogen receptor (ER)-positive, metastatic breast cancer patients. Patients were randomized into POC and control groups (1:1 ratio). All patients received everolimus with exemestane and continued the everolimus until disease progression. In the POC group, patients were subjected to teeth surface cleaning, scaling and tongue cleaning, before initiating everolimus, and continued to receive weekly POC from dentist or oral surgeons throughout the 8 weeks of treatment. In the control group, patients brushed their own teeth and gargled with 0.9% sodium chloride solution or water. The primary end-point was to measure the incidence of all grades of oral mucositis. Target accrual was 200 patients with a 2-sided type I error rate of 5% and 80% power to detect 25% risk reduction. This trial has been registered at ClinicalTrials.gov, number NCT 02069093.

Result:
Between May 26, 2014 and Dec 28, 2017, we enrolled 174 women from 31 institutions; 168 were evaluable for efficacy but 5 were excluded (had not received the protocol treatment [n=4]; no efficacy data [n=1]). In 8 weeks, the incidence of grade 1 oral mucositis was significantly different between the POC group (76.5%, 62 of 81 patients) and control group (89.7%, 78 of 87 patients) (p=0.035). The incidence of grade 2 (severe) oral mucositis was also significantly different between the POC group (34.6%, 28 of 81 patients) and control group (54%, 47 of 87 patients) (p=0.015). As a result of oral mucositis, 18 (22.2%) patients in the POC group and 28 (32.2%) in the control group had to undergo everolimus dose reduction.

Conclusion:
POC reduced the incidence and severity of oral mucositis in patients receiving everolimus and exemestane. This could be a new standard in oral care for patients undergoing this treatment.

Meta-regression and meta-analysis of dexrazoxane for cardioprotection in all breast cancer stages in patients treated with anthracyclines

Ariane VS Macedo¹,², Angélica N Rodrigues¹, Rafael C Brant² and Antônio LP Ribeiro¹. ¹Federal University of Minas Gerais, Belo Horizonte, Minas Gerais, Brazil and ²Grupo Oncoclínicas do Brasil, Belo Horizonte, Minas Gerais, Brazil.

Background: Anthracyclines continue to be a valuable option in chemotherapy for breast cancer (BC), in spite of their well-documented cardiotoxicity. Anthracycline-induced cardiotoxicity depends on cumulative dose, and it actually begins with the first dose. Clinical studies have suggested that dexrazoxane could reduce this toxicity. Dexrazoxane is frequently used when higher anthracycline cumulative doses are needed, but is often omitted in the adjuvant setting. We aimed to analyse by an updated meta-analysis the cardioprotective effect of dexrazoxane in all BC stages in patients receiving anthracycline-based chemotherapy. In addition, we performed subgroup analyses and meta-regression to assess if the average anthracycline dose and the studies publication date would interfere in the cardiac event outcome.

Methods: We performed a systematic review and meta-analysis. The review was registered in PROSPERO database (CRD42017077462). We searched data from 1990 to August 2017 in Cochrane Central Register of Controlled Trials, Google Scholar, MEDLINE/Pubmed, LILACS, Web of Science, articles references and ASCO proceedings. Studies assessing congestive heart failure and cardiac event (cardiac function alterations without cardiac symptoms or hospitalization for cardiac reasons) as primary endpoints were included. Two reviewers independently performed the studies selection, risk of bias assessment and data extraction. Meta-analysis was done using random effect model for estimation of treatment effect. Heterogeneity was assessed by visual inspection of forest plots and by Q test. Subgroup analyses were carried out, according with the chemotherapy regimen (use of anthracycline in previous chemotherapy). In the meta-regression we used the random effects model.

Results: Our search resulted in 1603 articles, from which we included 7 studies providing 1545 participants. Meta-analysis showed an overall beneficial effect of dexrazoxane on reducing the risk of cardiac events (OR 0.262, CI 95%:0.169-0.407, p < 0.0001). In two of the seven studies which evaluated the cardiac event outcome, the patients were previously exposed to anthracyclines. In this patients’ subgroup, we found an odds ratio of 0.244 (CI 95%, 0.102 to 0.584). In the study subgroup that the patients didn't report previous exposure to anthracycline, the odds ratio was 0.266 (CI 95%, 0.149 to 0.478). The Q test to evaluate the difference between the subgroups showed a value of 0.026 with p = 0.871 suggesting there was no difference between the subgroups. The multiple meta-regression was performed, adding to the model the average dose and studies age variables, for a combined analysis. The statistical analysis of the impact of the two combined cofactors didn't show significative association (Q test = 2.36, df = 2 and p = 0.30).

Conclusions: Dexrazoxane reduced the occurrence of cardiac events when added to anthracycline based chemotherapy regimen. There was no evidence that the benefit of the reduction of cardiac events with the use of dexrazoxane was different according to the use of anthracycline in previous chemotherapy or by the used average dose of anthracycline. These findings may have significant implications for clinical practice.
Impact of scalp cooling device (SCD) in preventing alopecia in women undergoing chemotherapy for breast cancer

Ida Paris¹, Cristina Accetta², Luisa Carbognin¹, Danilo Di Giorgio³, Stefano Magno³, Daniela Terribile³, Gianluca Franceschini³, Martin Sanchez², Gabriella Ferrandina⁴, Tina Pasciuto⁴, Alberto Fulvi¹, Giovanni Scambia⁴ and Riccardo Masetti³.

Gemelli IRCCS, Roma, Italy; ³Multidisciplinary Breast Cancer, Fondazione Policlinico Universitario A. Gemelli IRCCS, Università Cattolica del Sacro Cuore., Roma, Italy and ⁴Gynecologic Oncology Unit, Fondazione Policlinico Universitario A. Gemelli IRCCS, Università Cattolica del Sacro Cuore, Roma, Italy.

Background.
Alopecia (A) is a common and emotionally traumatic adverse effect for breast cancer (BC) patients (pts) undergoing chemotherapy (CT). Food and Drug Administration (FDA) cleared the DigniCap® SCD, for patients with breast cancer in 2015. This device was designed to reduce hair loss during chemotherapy. However, the impact of SCD in pts undergoing anthracycline and taxane-based sequential regimen is not entirely established. Thus, the aim of this analysis was to prospectively explore the role of SCD in a cohort of pts including also this regimen.

Methods.
From February 2016 to June 2018 patients with early/locally advanced breast cancer treated with neoadjuvant/adjuvant CT including anthracycline, taxane or both in sequential regimen were enrolled. The estimate of hair-loss was evaluated by photographs of the head using the Dean scale during and one month after the end of chemotherapy. Alopecia was graduated according to Dean scale: G0 = no A; G1 < 25% A; G2 = 25–50% A; G3 = 50–75% A; G4 > 75%. A score of 0-2 (≤ 50% hair loss) was defined as treatment success. Tolerability was defined as the percentage of patients who completed all chemotherapy cycles using the SCD. All patients received the Patient Symptoms Survey (self-reported). A database for individual data and information was appropriately fulfilled. Descriptive statistics was adopted.

Results.
Overall 121 pts were enrolled; 118 pts were evaluable for efficacy of Dignicap® SCD. Median age was 44 years (range: 24-74 years). CT regimens included docetaxel/cyclophosphamide (37 pts), epirubicin (90 mg/m2) and cyclophosphamide (600 mg/m2 iv) three weekly followed by 12 courses of paclitaxel (80 mg/m2 iv weekly) (84 pts). Alopecia all grade was showed in 52.5% (n=62): G1 in 35 pts (29.6%) and G2 in 23 pts (19.5%). No hair loss in 42 pts (35.6 %). Treatment success was seen in 103 pts (87.3%). Toxicity included grade 1/2 headache in 56 pts (47.4%), cervical discomfort in 36 pts (30.5%), pain of skin in one pts (8.5%). Discontinuation of SCD was seen in 28 pts (23.7%) primarily for headache G3 (4 pts – 3.4%), hair loss G3 in 15 pts (12.7%), discomfort in 8 pts (6.8%), use of head cover in one pt (0.8%).

Conclusions.
This prospective observational study suggests that SCD is effective in preventing A in a relevant number of patients (87.3%), undergoing also anthracyclines followed by taxanes regimen in sequential schedule.
Association between body mass index (BMI) and response to duloxetine for aromatase inhibitor (AI)-associated musculoskeletal symptoms (AIMSS)

Norah Lynn Henry¹, Joseph M Unger², Cathee Till², Anne F Schott³, Katherine D Crew⁵, Danika L Lew³, Michael J Fisch⁴, Carol M Moinpour², James L Wade⁶ and Dawn L Hershman⁵. ¹University of Utah, Salt Lake City, UT; ²Fred Hutchinson Cancer Research Center, Seattle, WA; ³University of Michigan, Ann Arbor, MI; ⁴AIM Specialty Health, Chicago, IL; ⁵Columbia University, New York, NY and ⁶Heartland NCORP, Decatur, IL.

Background: AIMSS occurs often in women treated with AI therapy for early stage breast cancer and can negatively impact adherence and persistence with therapy. Duloxetine is a serotonin norepinephrine reuptake inhibitor used to treat mood disorders and chronic pain. In SWOG S1202, patients with AIMSS treated with duloxetine reported statistically significant improvement in pain by 12 weeks compared to placebo. Obesity is a predictor of increased likelihood of developing AIMSS, and a prior study of omega 3 fatty acid versus placebo for AIMSS showed a potential differential response to therapy by BMI. In this exploratory analysis of S1202, we investigated the association between baseline BMI and response to therapy.

Methods: In S1202, 299 postmenopausal women with stage I-III hormone receptor-positive breast cancer on AI therapy who developed new or worsening average pain of 4-10 on a numerical rating scale were enrolled, randomized 1:1 to duloxetine or placebo with randomization stratified by baseline pain (4-6 vs. 7-10) and prior taxane therapy (yes vs. no). Patients were treated for 12 weeks. Patient-reported outcomes including Brief Pain Inventory (BPI) were obtained at baseline and weeks 2, 6, 12, and 24. Patients were categorized into BMI<30 kg/m² (non-obese) or BMI≥30 kg/m² (obese). The pre-specified aim of this secondary analysis was to examine whether the effect of intervention on BPI average pain at 12 weeks differed between obese and non-obese patients. Multiple linear regression was used, adjusting for the stratification factors and the baseline score. We tested whether the interaction of BMI status and intervention effect was statistically significant at α=.05.

Results: 289 patients were eligible for the analysis, 54% of whom were obese. The cohorts were well balanced other than by race. The difference by intervention arm in the 12-week mean BPI scores between baseline and follow-up scores was substantially different for the obese versus non-obese cohorts. In the patients with BMI<30, the reduction in observed mean average pain score was similar in the duloxetine- and placebo-treated patients (-2.46 points vs. -2.34 points, p=.75). In contrast, in the patients with BMI≥30 the reduction in pain score was statistically significantly greater for the duloxetine-treated compared to the placebo-treated patients (-2.73 points vs. -1.64 points, p=.003; interaction p-value=.02). Differences in intervention effects between obese and non-obese groups were even stronger at 2-weeks (interaction p-value=.001) and 6-weeks (interaction p-value=.0001). Similar findings were evident for other pain-related patient-reported outcomes.

Conclusions: In the placebo-controlled S1202 trial, obese patients with AIMSS obtained more analgesic benefit from duloxetine. Additional studies are warranted to determine the biologic basis for these findings, such as a different mechanism underlying development of AIMSS or pain expression in patients with obesity, or other confounding variables related to analgesic response to duloxetine relative to placebo.

Support: NIH/NCI grants CA189974, CA189821, CA180820; and in part by Damon Runyon-Lilly Clinical Investigator Award #CI-53-10 [to NLH], and in part by Lilly USA, LLC.
Systematic evaluation of ovarian reserve in young breast cancer patients treated by sequential chemotherapy

Audrey Mailliez¹, Pascal Pigny², Emilie Bogart¹, Sara Diomande¹, Hermine Jeazet Tiotsia¹, Jacques Bonneterre¹, Marie Cecile Le Deley¹ and Christine Decanter³. ¹Centre Oscar Lambret, Lille, France; ²Centre de Biologie Pathologie, CHRU, Lille, France and ³Hôpital Jeanne de Flandre, CHRU, Lille, France.

Most women in reproductive age diagnosed with breast cancer receive (neo)adjuvant chemotherapy. Fertility preservation is part of the standard of care for these young women.

Patients and methods
We report preliminary results of a prospective multicentric cohort evaluating ovarian reserve during and after chemotherapy and fertility preservation in young (≤ 38 years old) in women aged ≤ 38 years, treated for a breast cancer with (neo)adjuvant anthracyclins and taxanes based chemotherapy, between July 2011 and December 2016. Fertility preservation was offered in patients (pts) who received adjuvant chemotherapy. The median duration of follow up was 2.6 years (4 months-5.3 years). The aim of this study was to evaluate the ovarian reserve assessed by antimullerian hormone and antral follicular count. The incidence of amenorrhea (defined by absence of menses ≥ 3 months), ovarian failure (absence of menses ≥ 12 months), chemotherapy induced menopause (absence of menses ≥ 24 months) was collected.

Results
One hundred and thirty-two pts were included in 10 centers. Data are available for 127 pts. For 4 pts, the scheduled chemotherapy was not received. One pt withdrew her consent. Chemotherapy was neoadjuvant for 43 pts and adjuvant for the 84 others. Fifty-eight asked for fertility preservation and received ovarian stimulation (all in adjuvant setting). Median age was 32 years (23-37). Eighty pts had a previous pregnancy. Three of them remained nulliparous. Among the 77 others, 36 had 1 child, 31 had 2 children and 10 pts 3 or more children respectively. At the time of diagnosis, 90% had regular menses and 75% had a contraception.

The median initial antral follicular count was 21.5 (Min 1- Max 100). The AMH level significantly decreased during chemotherapy with no secondary return to baseline value over the first 9 months after end of treatment: median of 20.9 pmol/l (0.5-223) before chemotherapy, 12.8 (0.5-120) at the second cycle of chemotherapy (C2), 3 (0.5-20) at C4, 0.5 (0.5-4.4) at C6, 0.5 (0.5-25.1) 3 months after the end of chemotherapy (M3), 0.5 (0.5-29) at M6, and 3 (0.5-29.8) at M9.

At last follow-up, 46% of pts experienced amenorrhea, 7% an ovarian failure and 3% a chemo-induced menopause. The highest incidence of amenorrhea (61%) was at M3. At M12, 7% of pts remained amenorrhoeic. The AMH initial level was not significantly lower in pts who experienced amenorrhea compared to those who did not (25.5 versus 35.1, p = 0.087). Ovarian stimulation and BRCA status did not impact risk of amenorrhea.

At 2 years, overall survival rate was 96% and progression free survival rate was 90% (6 deaths and 18 progression events).

Conclusion
(Neo)adjuvant sequential breast cancer chemotherapy is associated with a decrease of AMH level and amenorrhea. Our results suggest a significant risk of premature ovarian failure. Fertility preservation has to be proposed to these young patients.
Risk analysis for chemotherapy induced nausea and vomiting (CINV) in patients receiving FEC100 treatment

BACKGROUND:
Anthracycline-containing regimens are standard treatment options in adjuvant and neoadjuvant chemotherapy in breast cancer. Chemotherapy-induced nausea and vomiting (CINV) is experienced frequently in patients receiving these regimens, but the risk factors for CINV are unknown.

OBJECTIVE:
The aim of this study was to investigate risk factors for CINV in anthracycline-containing regimens retrospectively.

METHODS:
Data were collected from the JONIE study, which was conducted in order to estimate the efficacy of zoledronic acid in a neoadjuvant setting from March 2010 to June 2012 (UMIN000003261). A total of 180 patients were recruited, and we used CINV data from the first cycle of FEC100 treatment and patient backgrounds. As the protocol regulation allowed the use of antiemetic drugs, in the first cycle of the FEC100 regimen, patients received various types of antiemetic agents, which we classified into four groups: Dexamethasone (DEX)+5-HT3 receptor antagonist (5-HT3) + neurokinin-1 receptor antagonist (NK1) (DEX+5-HT3+NK1) group; Dexamethasone (DEX)+5-HT3 receptor antagonist (5-HT3) + dopamine receptor antagonist (DRA) (DEX+5-HT3+DRA) group; and Dexamethasone (DEX)+5-HT3 receptor antagonist (5-HT3) + dopamine receptor antagonist (DRA) (DEX+5-HT3+DRA) group. Risk factors were selected from patient backgrounds and the combinations of antiemetic drugs. In patient backgrounds, the body mass index (BMI) was stratified into 3 categories: Less than 18.5 (underweight group); equal to or more than 18.5 but less than 25 (standard BMI group); and equal to or more than 25 (overweight group). In a univariate analysis of nausea, the body mass index (BMI) was the only significant factor (P<0.05). On the other hand, BMI and the combination of antiemetic drugs were significant factors in vomiting. (P<0.05 and 0.005, respectively). In a multivariate analysis of nausea, the P value for BMI was 0.02. The odds ratio for the underweight group was 7.745 (confidence interval: 2.171 to 27.634) compared with the standard BMI group. In a multivariate analysis of vomiting, BMI and the combination of antiemetic drugs were significant risk factors (P=0.025 and 0.023, respectively). The odds ratio for the underweight group was 3.481 (confidence interval: 1.183 to 10.241) compared with the standard BMI group. Furthermore, the odds ratios in the DEX+5-HT3+DRA and DEX+5-HT3 groups were 5.005 (confidence interval: 1.543 to 16.239) and 4.178 (confidence interval: 1.428 to 12.222), respectively, compared with the DEX+5-HT3+NK1 group, which was consistent with the CINV guidelines in 2011.

CONCLUSIONS:
This study revealed that BMI was the most important risk factor for nausea, and that BMI and the combination of antiemetic drugs were risk factors for vomiting. Underweight-patients tend to have CINV in anthracycline-containing regimen. The DEX+5-HT3+NK1
group was the best antiemetic drug combination. These results show that following the CINV guideline treatment is mandatory in order to prevent CINV.
Assay for personalized prediction of chemotherapy-induced delayed nausea

Dillon D McCourt¹, Kinjal Parikh², Angeleah Dadivas¹, Amy L Brady¹, John Kennedy³, Zonera A Ali², Erik L Zeger², Aarti Shevade², Paul B Gilman² and U Margaretha Wallon³. ¹Philadelphia College of Osteopathic Medicine, Philadelphia, PA; ²Lankenau Medical Center, Wynnewood, PA and ³Lankenau Institute for Medical Research, Wynnewood, PA.

**Background**: Chemotherapy-induced nausea and vomiting (CINV) is a distressing side effect according to patients. CINV can negatively affect nutritional habits, ability to work and motivation to follow treatment regimens. Assessment of CINV is an essential component of care for patients receiving chemotherapy. Multiple factors influence the incidence of CINV with the chemotherapy regimen, both type and dosage, being the primary risk factor. It is generally assumed that the strongest patient-related factors are younger age and female sex. However, reports in the literature have demonstrated that using these factors clinicians underestimate the prevalence of CINV, especially delayed nausea. Thus, there is a need for risk assessment tools to accurately identify patients requiring anti-emetic regimens to improve quality of life of patients and their families.

Most chemotherapeutic agents cause bursts of reactive oxygen species (ROS) resulting in cellular damage and release of substances that can activate receptors in the chemoreceptor trigger zone. Glutathione (GSH), a key antioxidant, is responsible for maintaining redox homeostasis by neutralizing ROS elicited from chemotherapy. Therefore, we hypothesized that a patient's risk of CINV may reflect individual variations in the efficiency to scavenge free radicals after chemotherapy.

**Methods**: In our Institutional Review Board approved study, we have enrolled over 300 patients and completed assessment of 133 patients. These patients were treated with highly or moderately emetogenic chemotherapies for lung, colon, or breast cancer. Blood samples were drawn from chemotherapy naïve patients and used to determine the glutathione recycling capacity. The assay detects the conversion of a bioactive probe, hydroxyethyl disulfide, into mercaptoethanol, which once normalized to red blood cell count, indicates glutathione recycling capacity (ChemoTox). Nausea severity was reported using the Rotterdam Symptom Check-List at each treatment cycle. Self-reported symptoms were compared to notes in medical records and anti-emetic prescription history.

**Results**: We previously published the correlation between low ChemoTox and risk of delayed nausea for patients receiving platinum-based therapy for lung and colon cancer (N=64; correctly classified 88.5%; AUC 0.77). In this second evaluation, using SAS/STAT v.14.1 classification trees, we show the results from testing this prediction tool for breast cancer patients that typically are treated with anthracycline- or taxane-based chemotherapies. An early evaluation of anthracycline-based therapies (N=37) demonstrated a weak association between experienced nausea and ChemoTox (correctly classified 69.2%; AUC 0.64). In contrast, patients treated with taxane-based therapies (N=32) demonstrated a similar correlation between ChemoTox and severity of nausea as previously seen for platinum therapies. Also, a similar accuracy in identifying patients at risk of moderate-severe nausea was identified (correctly classified 77.3%; AUC 0.79).

**Conclusion**: The results from our prospective study suggests that a reduced ability to recycle GSH in the blood may offer an objective prediction of delayed nausea, possibly allowing for optimal anti-emetic regimen to improve the quality-of-life for breast cancer patients.
Sleep disturbance and quality of life among breast cancer survivors

Shauna McManus¹, Alexandra K Zaleta¹, Melissa F Miller¹, Julie Olson¹, M Claire Saxton² and Kevin Stein¹. ¹Cancer Support Community, Research and Training Institute, Philadelphia, PA and ²Cancer Support Community, Washington, DC.

Introduction: Breast cancer survivors are at risk for substantial sleep disturbance, which can negatively affect quality of life. Sleep disturbance can be exacerbated by co-occurring emotional concerns such as depressive symptoms and anxiety. Prior research has largely focused on linkages between sleep disturbance and emotional concerns among individuals with early stage disease. To dive deeper, we examined sleep disturbance and its correlates among breast cancer survivors with and without metastatic disease.

Methods: 631 female breast cancer survivors (168 ever experiencing metastatic disease [MBC]; 463 never metastatic [BC]) enrolled in the Cancer Support Community’s online Cancer Experience Registry, provided socio-demographic information, and reported cancer-related distress (CancerSupportSource®, a 25-item measure with depression and anxiety risk screening subscales) and levels of pain interference (PI) and sleep disturbance (PROMIS-29 subscales). We examined associations between risk for depression/anxiety, PI, and worse sleep disturbance with multivariate regression, adjusting for metastatic disease, treatment history, and number of comorbidities.

Results: Participants were 84% non-Hispanic White; mean age=54.8 years, SD=12.2; mean time since diagnosis=4.4 years, SD=5.5. 72% ever received chemotherapy; 60% radiation therapy; 56% hormone therapy; 91% had surgery for their cancer. 47% reported moderate to very serious concern about sleep problems; concern about sleep did not differ by metastatic history. 20% of participants reported a level of sleep disturbance that was significantly worse (>1SD) than the U.S. population average and 18% reported PI that was significantly worse (>1SD) than the U.S. population average; these did not differ by metastatic history. Using CancerSupportSource anxiety and depression risk screening subscales, 47% of participants were identified as at risk for clinically significant levels of anxiety, and 35% at risk for clinically significant levels of depression. Participants with MBC were more likely to be at risk for clinically significant levels of anxiety ($\chi^2=7.98$, $p<.01$). Depression risk did not differ between MBC and BC survivors. Greater sleep disturbance was associated with having ever received radiation therapy ($r=.11$, $p<.01$), number of reported comorbidities ($r=.37$, $p<.001$), greater PI ($r=.46$, $p<.001$), and greater risk for clinically significant depression ($r=.38$, $p<.001$) and anxiety ($r=.35$, $p<.001$). In multivariate analysis, risk for clinically significant levels of depression (semipartial $r=.12$, $p<.005$), anxiety (semipartial $r=.05$, $p<.05$), and greater PI (semipartial $r=.24$, $p<.001$) remained associated with greater sleep disturbance after controlling for treatment history, metastatic status, and number of comorbidities, ($R^2=.28$, $F(4,588)=56.26$, $p<.001$).

Conclusion: Being at risk for clinically significant levels of depression and anxiety and experiencing greater pain interference are associated with worse sleep disturbance among breast cancer survivors across the illness trajectory. Health care providers are encouraged to discuss with patients how they can address sleep disturbance concerns, including referrals to integrative therapies that address the constellation of affective, pain, and sleep symptoms.
Efficacy of NEPA as antiemetic prophylaxis in breast cancer patients receiving highly or moderately emetogenic chemotherapy – Interim results of a German prospective, non-interventional study

Joerg Schilling¹, Carsten Hielscher², Claus Hanusch³, Christian Kurbacher⁴, Steffi Busch⁵ and Meinolf Karthaus⁶.
¹Gynaeko-onkologische Gemeinschaftspraxis, Berlin, Germany; ²g.SUND Gynaekologie Kompetenzzentrum, Stralsund, Germany; ³Rotkreuzklinikum Muenchen Frauenklinik, Munich, Germany; ⁴Gynaekologische Zentrum Bonn, Bonn, Germany; ⁵Praxis für Frauenheilkunde, Muehlhausen, Germany and ⁶Staedtisches Klinikum Muenchen Neuperlach, Munich, Germany.

Background
The oral fixed dose combination of netupitant and palonosetron NEPA has been approved for the prevention of acute and delayed chemotherapy-induced nausea and vomiting (CINV) in cancer patients receiving cisplatin-based highly emetogenic (HEC) or moderately emetogenic chemotherapy (MEC). The primary objective of the prospective, non-interventional study (NIS) AkyPRO is the evaluation of quality of life in adults receiving MEC or HEC and NEPA for CINV prevention. Secondary endpoints are efficacy and safety of NEPA. Here we present an interim analysis of NEPA efficacy in the subgroup of breast cancer patients, who represent the largest subgroup (66%) of enrolled patients. Since September 2015, 2427 patients have been enrolled, of whom 986 are breast cancer patients.

Methods
The NIS has been designed to evaluate NEPA in 2,500 cancer patients receiving single day or two day MEC or HEC. QoL is recorded by FLIE questionnaires. Efficacy (complete response (CR, no vomiting, no rescue medication)), additional medication, and adverse events are recorded in patient diaries over three consecutive chemotherapy cycles. Additionally, physicians report their efficacy assessments of NEPA online, using an eCRF.

Results
At the cut-off date November 11, 2017, 2427 patients had been enrolled in the study. For the interim analysis 986 breast cancer patients were evaluated who had been fully documented in the eCRF at the cut-off date.
95% had an ECOG performance status of 0 or 1. 51% received adjuvant, 44% neoadjuvant, and 5% palliative chemotherapy. 80% of patients received HEC, mostly (79%) anthracycline/cyclophosphamide (AC) combinations. Of the women receiving MEC, the majority were treated with carboplatin-based regimens (9%). 7% of patients received other MEC regimens.
81.4-82.8 % of patients reported CR in cycles 1-3 and more than 93% of patients reported no emesis during the 3 treatment cycles covered in the patient diaries. No significant nausea was reported by 62.7-64.2% of patients.
Physicians rated the efficacy of the antiemetic prophylaxis with NEPA using the 4 categories very good, good, satisfactory, and poor. In cycles 1 and 2, more than 89% of physicians rated the efficacy of NEPA very good or good. In cycle 3, 90.6% rated it very good or good. In addition to reporting CR, nausea and emesis episodes in their patient diaries, patients used the same 4 categories to assess the efficacy of NEPA at the end of each treatment cycle. Efficacy assessments of physicians and patients were very similar, with 87% of patients choosing very good or good in cycle 1 compared to 89% of physicians.
NEPA was well tolerated. Low-grade constipation (14.9%) and insomnia (8.3%) were the most frequent treatment-related adverse event.

Conclusion
In this real life study, NEPA was effective in the prevention of CINV in the subgroup of breast cancer patients receiving HEC or MEC. The efficacy assessments by patients and physicians were comparable, with approximately 90% good or very good efficacy for 3 consecutive cycles. More than 93% of patients reported no emesis and more than 81% reported CR during the 5 days post-chemotherapy during all 3 cycles. The study is ongoing.
Cimicifuga racemosa extract prevents menopausal syndrome in LHRHa treatment of breast cancer: A prospective randomized research

Xingfei Yu1, Chen Wang1, Chenlu Liang1, Haojun Xuan1 and Hongjian Yang1. 1Zhejiang Cancer Hospital, Hangzhou, Zhejiang Province, China.

BACKGROUND Menopausal syndrome (MPS) is common in pre/peri-menopausal breast cancer patient receiving luteinizing-hormone releasing hormone analogue (LHRHa). According to the results of TEXT & SOFT study, it could affect patients' life quality seriously and even caused 8%~23% treatment break. Cimicifuga racemosa (Remifemin) is previously proved effective for MPS in nature menopause patients. We aim to design a prospective randomized research for investigating the effect of Remifemin on MPS which caused by LHRHa in breast cancer (NCT03339882).

METHODS The pre/peri-menopausal patients diagnosed as early breast cancer planning for LHRHa were identified and randomly divided into two groups after surgery and chemotherapy if necessary: the Remifemin group (Remifemin 20mg twice a day for 12 weeks) and the control group. The primary endpoint is Kupperman menopause index (KMI). The estradiol (E2), follicle-stimulating hormone (FSH), luteinizing hormone (LH) levels in blood were also evaluated.

RESULTS From January 2017 to December 2017, totally 85 patients (42 in Remifemin group and 43 in control group) were enrolled in Zhejiang Cancer Hospital and there were no significant differences in baseline characteristics including age, BMI, tumor stage, ER, PR, HER2, KMI and hormone levels between two groups (Table 1). At the time of 4, 8, 12 weeks after treatment, the KMI of Remifemin group were all significantly lower than control group (Table 2, P<0.01) while no significant difference in E2, FSH and LH levels between the two groups (Table 2, P>0.05). There was no significant difference in endometrial thickness, ovarian cyst and Uterine fibroids except cervical cyst (P=0.02).

CONCLUSION The use of Remifemin is oncological safe and reliable in preventing MPS which caused by LHRHa in breast cancer.

The clinical characteristics of two groups

Effect of wearable wellness brain sensing mindfulness-based technology in newly diagnosed surgical breast cancer patients: A randomized intervention

Sandhya Pruthi¹, Denise M Millstine¹, Anjali Bhagra¹ and Minh-Doan Nguyen¹. ¹Mayo Clinic, Rochester, MN.

Introduction: There is insufficient knowledge about the feasibility and effect of mind-body intervention on QOL and stress at initial diagnosis and shortly after undergoing breast cancer surgical treatment. The pre-operative and post-operative period can be stressful, distressing and anxiety provoking for many women. Mind-body interventions such as meditation, relaxation and mindfulness can offset distress and is an option to cope with the stresses of treatment. We investigated the role of wearable mindfulness based technology in patients newly diagnosed breast cancer patients.

Methods: This randomized study compared the Muse EEG mindfulness sensing headset device (n=16) to a stress reduction education control group (n=13). Primary outcomes included quality of life (QOL), stress, and fatigue via validated, standardized scales/subscales: Functional Assessment of Cancer Therapies – General (FACT-G), Multidimensional Fatigue Symptom Inventory – Short Form (MFSI-SI), and the Perceived Stress Scale (PSS). Participants from an academic cancer center were randomized to the wearable device or stress education material prior to surgery. Participants completed questionnaires at initial diagnosis and at specific time points during the breast cancer surgical journey: pre-surgery, post-surgery (2 weeks), and at 3 months. Usage was directly from Muse and via written log. Was It Worth It (WIWI) survey was conducted at 3 months.

Results: Mindfulness via the headset devise was feasible and worthwhile (71.4% intervention group). The scales of QOL, fatigue, and stress improved in both groups at 3 months compared to baseline (MFSI-E, MFSI-M, MFSI-V, FACT-EWB, and PSS). Participants randomized to the mindfulness headset device had improved fatigue and QOL at 2 weeks post-operatively (MFSI-E, MFSI-V, MFSI-T, FACT-PWB, FACT-EWB) and in total MFSI at 3 months. The results were not significantly different between groups. High mindfulness headset utilizers (>30 sessions) compared to below average utilizers differed at the 3 month visit in fatigue and QOL (MFSI-G, MFSI-P, FACT-PWB, and FACT-Total).

Conclusion: Our study demonstrated that the use of wearable mindfulness sensing headset device was feasible, simple to use, low cost, and integrated into the surgical breast cancer journey. Overall, among breast cancer patients undergoing surgery there was improvement in QOL, fatigue, and stress with mind-body interventions around surgery compared to baseline. Participants randomized to the wearable mindfulness headset device trended toward outcomes sooner (2 week follow-up) and with high utilization. Further research is needed to determine significance of these outcomes and long term impact in care of cancer survivors.
Depomedroxyprogesterone therapy for hot flashes in survivors of ER-expressing breast cancer: Impact on recurrence and survival

Natalie Ertz-Archambault¹, Lana Rogoff¹, Heidi Kosiorek¹, Brenda Ernst², Karen Anderson¹, Barbara Pockaj¹, Richard Gray¹ and Donald Northfelt¹. ¹Mayo Clinic Arizona, Phoenix, AZ and ²Mayo Clinic Florida, Jacksonville, FL.

Background
Survivors of ER-expressing operable breast cancer (ER+BC) generally do not receive hormone replacement therapy for menopausal symptoms due to concern about provoking recurrence of disease. Single dose depomedroxyprogesterone acetate (MPA) 400 mg IM has previously been shown (Loprinzi CL, et al. J Clin Oncol 2006;24:1409) to be the most effective non-estrogen therapy available for menopausal hot flashes (HF) but long-term evidence of safety in survivors of ER+BC is lacking.

Methods
Consecutive patients previously diagnosed with ER+BC who received MPA for HF between January 2007 and December 2012 were retrospectively identified in the breast cancer patient database at Mayo Clinic Arizona. Medical records were audited for breast cancer outcomes in these cases and in contemporaneous control patients with ER+BC who did not receive MPA, matched for age, stage of disease, and year of diagnosis. Statistical comparisons of local-regional recurrence and event-free survival were performed.

Results
92 patients who received MPA were identified and matched 1:1 with contemporaneous controls. Median follow-up duration was 5.7 years in cases and 4.5 years in controls. Estimated local-regional recurrence free survival at 10 years was 85% (95% CI, 72-100%) in cases and 95% (95% CI, 86-100%) in controls. Matched pairs hazard ratio was 1.0 (95% CI, 0.06-16.0) for local-regional recurrence free survival. Estimated event-free survival at 10 years was 81% (95% CI, 69-97%) in cases and 76% (95% CI, 64-92%) in controls. Matched pairs hazard ratio was 0.38 (95% CI, 0.10-1.41) for event-free survival. The majority (77%) of case patients experienced satisfactory relief of hot flashes from MPA injection.

Conclusion
In this retrospective case-control study we were unable to identify a detrimental effect of MPA therapy for HF in survivors of ER+BC. MPA may be acceptable for management of HF in this population.
Efficacy and quality of life analysis of palonosetron vs ondansetron for high and moderate emetogenic chemotherapy for breast cancer

Claudia Arce-Salinas¹, Zuratzi Deneken-Hernandez², Diana Flores-Diaz¹, Juna Pablo Gonzalez-Serrano¹, Juan Antonio Matus-Santos¹, Erika Ruiz-Garcia¹, German Calderillo-Ruiz¹, Omar Macedo¹, Julieta Santamaría-Galicia¹, Jose Luis Aguilar-Ponce¹ and Nancy Reynoso-Noverón¹. ¹Instituto Nacional de Cancerología, Mexico, CDMX, Mexico and ²FUCAM-IEM, Mexico, CDMX, Mexico.

Background: Nausea and vomiting are common complications on the chemotherapy (CINV) and can affect the quality of life of the patients. There are various antiemetic regiments that varies in both cost and effectiveness. The aim of this trial is to evaluate the efficacy in acute and delayed CINV of ondansetron vs palonosetron.

Patients and methods: In his was a randomized, open label trial, we included breast cancer patients' candidate to (AC, TC, TCH regimens); arm A received palonosetron, dexamethasone and fosaprepitant and arm B ondansetron, dexamethasone, fosaprepitant; patients who had received previously any chemotherapy or radiotherapy were excluded. Presence of CINV were investigated, as well the ER visits due for CINV and QoL (EORTC QLQ 30 and EORTC B-23) were analyzed during the first cycle of treatment. Local ethics committee approved the trial.

Results: 262 patients were included, 87% received AC and 13% TC; acute control was achieved in 87% and 94% respectively, p=ns and delayed control was achieved in 76% and 86% p=ns, toxicity was similar in both arms. QoL analysis showed no differences in family interaction, social life and financial troubles. ER visits due to severe symptoms were similar p=ns

Conclusions: Palonosetron or ondansetron are equally effective in prevention acute and delayed CINV and they also maintain similar quality of life.
Chemotherapy-induced peripheral neuropathy in breast cancer survivors: Comparison of objective and subjective measures

Ting Bao, Alice Kwon, Lauren Piulson, Patricia Chen, Qing Li, Sujata Patil, Andrew Seidman, Victoria Blinder, Linda Vahdat, Wanqing Iris Zhi and Jun J Mao. Memorial Sloan Kettering Cancer Center, New York, NY.

Background: Chemotherapy-induced peripheral neuropathy (CIPN) is a common, potentially debilitating, and dose-limiting side effect experienced by breast cancer survivors. CIPN encompasses symptoms such as pain, numbness, and tingling, which can be measured subjectively by patient-reported outcomes (PRO), or objectively by quantitative sensory testing (QST); however, little is known how QST correlates with symptom profiles measured by PRO.

Methods: We conducted a cross-sectional analysis using baseline data of two ongoing clinical trials of breast cancer survivors who experienced moderate to severe CIPN defined by pain, numbness, or tingling ratings of four or greater on a numeric rating scale (NRS) after chemotherapy completion for at least three months. PRO measures of CIPN symptoms included Neuropathic Pain Scale (NPS) and Functional Assessment of Cancer Therapy-Gynecologic Oncology Group/Neurotoxicity subscale (FACT/GOG-Ntx). QST included tactile threshold (TT) measured by Von Frey's filaments, and vibration threshold (VT) measured by biothesiometer. We ran a Spearman correlation to assess the relationship between the subjective measures (NPS and FACT/GOG-Ntx) and objective measures (TT and VT QST).

Results: We included 52 sets of baseline data on 50 unique patients; two patients were enrolled in both trials at different times. Mean age was 61 years (SD 10) and 66% were white. The mean NRS pain score was 3.9 (SD 2.8), numbness 5.7 (SD 2.2), and tingling 4.3 (SD 2.8) on a 0-10 scale. The mean NPS total score was 39.2 (SD 23.1) on a 0-100 scale, and FACT/GOG-Ntx was 26.2 (SD 6.8) on a 0-44 scale. High scores on NRS and NPS and low scores on FACT/GOG-Ntx signify more severe CIPN symptoms. See Table 1 for a summary of the correlation between two questions on FACT/GOG-Ntx on tingling/numbness in hands and feet, and NPS total score with QST. A moderate correlation was observed between FACT/GOG-Ntx and QST results, suggesting patient-reported hand and foot numbness or tingling is associated with decreased hand and foot tactile and vibration perception. NPS was positively correlated with tactile perception for the hand and foot, but not with vibration perception.

Table 1. Correlation between objective and subjective measures of CIPN

<table>
<thead>
<tr>
<th></th>
<th>Tactile QST</th>
<th>Vibration QST</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Hand</td>
<td>Feet</td>
</tr>
<tr>
<td>FACT/GOG-Ntx</td>
<td>-0.33 (P=0.018)</td>
<td>-0.28 (P=0.045)</td>
</tr>
<tr>
<td>NPS</td>
<td>0.34 (P=0.015)</td>
<td>0.32 (P=0.022)</td>
</tr>
</tbody>
</table>

Conclusions: A mild to moderate correlation was observed between subjective and objective measurements of CIPN. As CIPN presents a diverse range of symptoms, better quantifying the subjective and objective measures of CIPN can help incorporate these tools in observational and intervention trials. Understanding the correlation between PRO and QST can help establish QST as a reliable objective measurement of CIPN symptoms, and enable targeted interventions to alleviate CIPN symptoms.
Efficacy and safety of acupuncture for the hot flashes in breast cancer patients taking adjuvant tamoxifen: A multicenter study in Korean women

HyeRyeon Choi¹, Young-ju Jeong¹, Sung-Hwan Park¹, Min-Ah Kwak², Kyung-Soon Kim², Yuri Lee² and SeoYoung Park³.
¹Catholic University of Daegu School of Medicine, Daegu, Korea; ²Daegu Haany University, College of Korean Medicien, Daegu, Korea and ³Comprehensive and Integrative Medicine Institute, Daegu, Korea.

Background: Tamoxifen is widely used in premenopausal patients with estrogen receptor positive (ER+) breast cancer. Among the side-effects of tamoxifen, hot flashes is a common and challenging one. Previous pilot study suggested the effectiveness of acupuncture for relief of symptoms. This study was performed to evaluate the efficacy and safety of acupuncture for treatment of hot flashes in Korean women breast cancer patients taking tamoxifen as adjuvant endocrine therapy.

Methods: Thirty (30) breast cancer patients taking tamoxifen and reported moderate to severe hot flashes were enrolled from two institutes. Patients were randomly assigned into acupuncture group (n=15) and control group (n=15). The acupuncture group received acupuncture 3 times a week for 4 consecutive weeks, at 5 predefined points (GV 20, M-HN-3, HT 8, KI 10 and LV 2) for 20 ± 5 minutes at each session. Control group received no treatment. The score of hot flash visual analogue scale (VAS) and total hot flash score, EORTC QLQ-C30 and QLQ-BR 23 questionnaire were recorded before treatment, once every treatment week and 4 weeks after treatment for both groups.

Results: Acupuncture group showed significantly reduced severity of hot flashes during treatment assessed with either VAS and total hot flash score (p=0.000 and p=0.008, respectively). Also, acupuncture group showed improvement of global health status and physical functioning score assessed with EORTC QLQ-C30 (p=0.004 and p=0.027, respectively). Four weeks after the treatment, these trends were retained. No adverse events were notified.

Conclusion: Acupuncture may have feasibility and safety for alleviate hot flashes of Korean women breast cancer patients taking tamoxifen as an adjuvant endocrine therapy. Long-term follow up results and further study with a larger sample size is required.
Effects of depression, anxiety, and sexual functioning on quality of life among young breast cancer patients in Mexico

Cynthia Villarreal-Garza1,2,3, Alejandra Platas1,2, Melina Miaja1,3, Edna A Lopez-Martinez1,3, Jose F Muñoz-Lozano1,3, Alan Fonseca1, Claudia Pineda1, Regina Barragan-Carrillo1,3, Bertha A Martinez-Cannon1,3, Judy-Anne W Chapman4, Paul E Goss5, Juan E Bargallo-Rocha1,2, Alejandro Mohar1,2 and Andrea Castro-Sanchez1,6. 1Joven & Fuerte: Programa para la Atencion e Investigacion de Mujeres Jovenes con Cancer de Mama, Mexico City, Mexico; 2Instituto Nacional de Cancerologia, Mexico City, Mexico; 3Breast Cancer Center, Tecnologico de Monterrey, Monterrey, Mexico; 4(Retired) Canadian Cancer Trials Group, Queen's University, Kingston, Canada; 5Global Cancer Institute, Boston and 6Catedras CONACYT, Instituto Nacional de Cancerologia, Mexico City, Mexico.

Background: Despite the disproportionately high-rates of breast cancer (BC) in young women in Mexico, cancer-control efforts have been predominantly aimed at improving oncological treatment, bypassing survivorship issues and supportive care for this group. The “Joven & Fuerte” cohort, the first supportive care and research program for young BC patients in Latin America, aims to describe and assess the burden of BC in young Mexican women. In this study, we focused on evaluating the association between quality of life (QoL) and anxiety, depression, and sexual functioning in young women with BC (≤ 40 years).

Methods: This study included non-metastatic and non-recurrent patients belonging to the cohort's pilot phase. QoL was assessed with the EORTC QLQ-C30 global score. Patients were classified in the domains of anxiety and depression with the Hospital Anxiety and Depression Scale (HADS) as either probable case, doubtful case, or not a case. Sexual functioning was assessed with the Female Sexual Function Index (FSFI) and the sexual functioning and enjoyment domains of the EORTC QLQ-BR23. Assessments were performed at baseline, 6 months, 1 year, and 2 years. Pearson chi-square and analysis of variance (ANOVA) were used for analysis. Nominal unadjusted significance is reported with p<0.05.

Results: 73 out of 96 (76%) pilot phase patients met the inclusion criteria and had complete assessments up to 2 years follow-up. Global QoL was significantly worse for cases with anxiety and depression at baseline (means for non-cases, doubtful cases and cases, respectively: for anxiety, 81.09, 69.54, and 61.54, p<.001; and for depression, 75.63, 64.17, and 55.00, p=0.01) and depression at 6 months (76.55, 66.67, and 35.42, respectively, p<.001). Classification of case level anxiety was associated with FSFI morbidity during the first year (baseline, p=0.03; 6 months, p=0.09; 1 year, p=0.04). There was no significant association between case level depression and FSFI morbidity in the first 2 years. Neither anxiety nor depression was generally associated with significantly different BR23 sexual functioning or sexual enjoyment; however, a sporadic association was observed between anxiety and BR23 sexual functioning at 6 months (p=0.04).

Conclusion: This study confirmed an association between anxiety and/or depression and worse QoL at diagnosis of BC and after 6 months. Additionally, worse sexual function was significantly associated with the classification of case level anxiety. These findings support the current recommendation that physicians should regularly assess patients’ psychosocial health and sexual functioning and provide prompt referral to corresponding supportive care services. Additional efforts must be conducted in low-resource settings, where sexual health and psychosocial care are not considered routine cancer treatment. Dedicated programs that promote multidisciplinary and supportive care services, such as “Joven & Fuerte”, should be incorporated into institutional health-care protocols to systematically address patients’ emerging needs and improve QoL.
Measuring severe anxiety in patients with metastatic breast cancer: Living up to the PROMIS

Celine Marquez1, Yun Li1, Chiung-Yu Huang1, Hope Rugo1, Mike Rabow1, Michelle Melisko1 and Laura Esserman1. 1University of California, San Francisco, San Francisco, CA.

Purpose/Objective(s):
Symptom burden in the advanced cancer patient can be substantial. PROMIS (Patient Reported Outcome Measurement Information System) is a powerful PRO symptom assessment tool that is increasingly being utilized at the point of care through patient-facing electronic health record (EHR) systems. However, the PROMIS threshold (T-score) for detecting severe anxiety has not been previously validated for patients with advanced breast cancer. The sensitivity/specificity of current expert derive threshold T-score of >/=75 in this specific population is not known. In this study, we compared PROMIS scores with the PRO-CTCAE anxiety instrument—a standard PRO tool used in the setting of clinical trials that assesses anxiety frequency, severity, and interference with usual activities—to examine the best T-score to use for PROMIS to guide management in advanced breast cancer care.

Materials/Methods:
A total of 84 unique visits of 74 English speaking patients on active cancer treatment for metastatic breast cancer were assessed using electronic PROMIS CAT (Computer Adaptive Test) and PRO-CTCAE at the UCSF Carol Buck Breast Cancer Center. Assessment forms were displayed on a touch screen tablet and completed by the patient at check-in for weekly treatment visits. PRO-CTCAE anxiety questions were graded on a scale of 1 (none) to 5 (disabling). Any score of grade >/=4 (severe to disabling) for frequency, severity or interference was defined as severe anxiety.

Results:
There was a strong correlation of PROMIS T-score and maximum PRO-CTCAE grade (highest grade of frequency, severity, or interference); Spearman correlation coefficient = 0.77 (P= <0.001). No patients reached the expert derived severe threshold of PROMIS T-score 75. Highest PROMIS T-score was 69 (range, 33-69). 11 patients reported severe or disabling anxiety by PRO-CTCAE at one visit. Area under the ROC analysis identified a cutoff that maximizes Youden's index at 55.05—sensitivity = 100% (95% CI) and specificity = 63% (95% CI).

Conclusion:
Electronic systems with integrated patient reported outcomes (PROs) along with validated thresholds to identify severe anxiety will allow for systematic identification of symptoms at point of care and the opportunity to respond rapidly to those symptoms most distressing to patients.
E-DomSanté study on the improvement of care in oncology through digital technology

Nathalie Quénel-Tueux, Valentyne Allam, Mikaël Desroches, Odile Duguey-Cachet, Christian Fillatreau, Pauline Beaufrière, Véronique Trézéguet, Sylvie Cassauba, Nicolas Portolan, Christian Caubet, Jérôme Rodrigues, Noëlle Saint-Upéry, Aude Gourgues, Clément Oukhemanou, Frédéric Savino, Maxime Maurel, Thierry Burbaud, Mathieu Jacques, David Lamurey, Pierre-Emmanuel Buyse, Mélanie Volpato-Coilier, Eugénie Michardière and Stéphanie Hoppe. 1Institut Bergonié, Bordeaux, France; 2GRADeS ESEA Nouvelle Aquitaine, Bordeaux, France; 3Domicalis, Saint Jean d'Illac, France; 4Telecom Design Vital Base, Canéjan, France; 5Orange Health Care, Paris, France; 6ACETIAM, Valbone, France; 7Agence Régionale de Santé Nouvelle Aquitaine, Bordeaux, France and 8Conseil Régional Nouvelle Aquitaine, Bordeaux, France.

**Background:** The effectiveness of remote follow-up of cancer patients through weekly medical questionnaires filled in on their smartphone has been reported in international studies. These studies demonstrated an improvement in quality of life (QoL) and survival of several months. The e-DomSanté study proposes the combined use of innovative technological tools for the improvement of patient care.

**Patients and methods:** This 2-year pilot study was carried out with patients followed-up for metastatic breast cancer who lived far from their treatment center. They were offered, in addition to their usual follow-up, weekly medical questionnaires (10 items) on an interactive tablet and a connected watch that registered their falls, bedtime and their general activity. All this data arrived on a secure portal. In the event of an alert, telemedicine was organized by remote consultation with exchange on a secure platform, in parallel, between the center's carers and the treating physician, nurse, pharmacist or the Territorial Support Unit. The evaluation criteria used included telemedicine and patients' QoL (FACT-B questionnaires) as well as their satisfaction with their care.

**Results:** The average age of the 15 patients included in the study was 65 years (range, 36-82 years) with one third of patients who had never used a computer or tablet. Those patients as well as elderly patients (≥ 75 years old) adapted very well to the technology simply with reinforced education and modification of the ergonomics of tablets and questionnaires. The requests for remote consultation were mainly due to 1) symptoms of deteriorating disease detected in advance, 2) toxicities relating to the treatment making it possible to adapt the therapy quickly, 3) the support oncological care (pain, depression or taken into terminal care at home) and 4) exhausted relatives. The QoL of all patients was stable or even improved despite progression of their metastatic disease in most cases. Practically all patients were satisfied (less fatigue due to less travel, high responsiveness of carers, security and confidence, less stress) with just a few criticisms (stress generated by the technology, no space for comments in the questionnaires and the restrictive nature of wearing the watch).

**Conclusions:** The e-DomSanté study confirms the contribution of digital technology in improving cancer care. This system avoids unnecessary consultations that are tiring for the patient and costly for society (transportation and hospitalization). It also avoids acute admissions through the emergency room. This method leads to an improvement in the QoL of patients and their satisfaction with their care. A second, much larger, multicenter randomized trial assessing patients’ survival, QoL of patients and their relatives and medico-economic assessment will commence soon.
Patient reported supportive care needs in a dedicated advanced breast cancer center

Savannah J Geske¹, Timothy J Pluard¹, Chetanna Amazu¹ and Rachel Holden¹. ¹Saint Luke’s Cancer Institute, Kansas City, MO.

Background: As of January 1st, 2017 nearly 154,794 women in the US will be living with metastatic breast cancer (MBC) and rates are expected to increase. Additionally, 58.3% of individuals with MBC, and their caregivers, believe that people with MBC have unique informational, emotional and physical needs that are unmet. However, there are still few research studies examining these needs.

Methods: In October of 2016, the Koontz Center for Advanced Breast Cancer was established in Kansas City, MO. Supportive services assume a large role in this center to assist in caring for the whole person and improving quality of life. During the initial consult, the patient meets with the medical oncologist, psychologist, social worker, nutritionist, exercise physiologist and chaplain. All patients complete forms assessing multiple domains that may influence the patient's treatment and outcomes. We use the PROMIS (Patient-Reported Outcome Measurement Information System) measures to assess sleep, physical function, fatigue and pain interference, the Daily Spiritual Experience Scale (DSES) to assess spiritual concerns, the DSM-5 Self-Rated Level 1 Cross-Cutting Symptom Measure-Adult to assess mental health concerns and Koontz Center forms to assess social work and nutritional concerns. The following data is from assessments collected through May of 2018.

Results: Eighty-two individuals were included in the analysis. The mean age was 60.1 (SD=10.6) and 98% (n=80) were female. A majority were white, non-Hispanic (88%; n=71). Sleep related impairment was mild for 27 (33.8%) individuals, moderate for 22 (27.5%) and severe for 3 (3.8%). For physical function, 12 (14.8%) individuals had mild, 32 (39.5%) moderate and 19 (23.5%) severe impairment. Twelve (15%) individuals had mild, 25 (31.3%) moderate and 6 (7.5%) severe symptoms of fatigue. For pain interference, 12 (15%) individuals had mild, 24 (29.6%) moderate and 9 (11.1%) severe symptoms. The average DSES score was 12.6 (SD=6.8) out of 36 with lower scores indicating stronger spiritual satisfaction. The top three mental health concerns were anxiety (n=47; 58.8%), depression (n=40; 50%) and somatic symptoms (n=38; 47.5%). Seventeen percent (n=14) reported concern over weight and 30% (n=24) reported losing weight over the past two weeks. The top three areas individuals reported needing assistance in were finding financial resources (n=16; 20.5%), help at home (n=11; 14.1%) and insurance questions (n=10; 12.8%). The top four areas individuals reported needing support in were information on support groups (n=20; 25.6%), managing stress (n=20; 25.6%), coping with cancer diagnosis (n=14; 17.9%) and communicating with children about cancer (n=14; 17.9%). Also, 38% (n=28) endorsed wanting information about an advanced directive. Changes across age and symptom complexes were also noted and will be presented.

Conclusion: The data indicate that there are a wide variety of physical, spiritual, nutritional, social and psychological concerns for those coping with a MBC diagnosis. Future treatment of those with MBC should integrate supportive services to address these symptoms.
Analysis of cognitive function in elderly HER2-positive breast cancer patients receiving either trastuzumab monotherapy or trastuzumab plus chemotherapy as a postoperative adjuvant treatment: A cognitive function sub-study of a randomized, open-label, phase 3 clinical trial (RESPECT trial)

Masato Takahashi¹, Masataka Sawaki², Yasuhiro Hagiwara³, Yukari Uemura⁴, Takuya Kawahara³, Kojiro Shimozuma⁵, Yasuo Ohashi⁶, Tsyuoshi Saito⁷, Shinichi Baba⁸, Kokoro Kobayashi⁹, Hirofumi Mukai¹⁰ and Naruto Taira¹¹. ¹NHO Hokkaido Cancer Center, Sapporo, Japan; ²Aichi Cancer Center Hospital, Nagoya, Japan; ³Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; ⁴Clinical Research Support Center, The University of Tokyo Hospital, Tokyo, Japan; ⁵College of Life Sciences, Ritsumeikan University, Kusatsu, Japan; ⁶Chuo University, Tokyo, Japan; ⁷Japanese Red Cross Saitama Hospital, Saitama, Japan; ⁸Sagara Hospital, Kagoshima, Japan; ⁹The Cancer Institute Hospital of the Japanese Foundation for Cancer Research, Tokyo, Japan; ¹⁰National Cancer Center Hospital East, Kashiwa, Japan and ¹¹Okayama University Hospital, Okayama, Japan.

OBJECTIVE: The effect of trastuzumab(Tmab) or chemotherapy on cognitive function has not been fully understood, especially in elderly breast cancer patients. The RESPECT trial compared 1-year(yr) Tmab monotherapy with Tmab plus standard chemotherapy as adjuvant therapy in elderly patients with HER2-positive breast cancer. The primary objective was to verify the noninferiority of 1-yr Tmab monotherapy compared to Tmab plus chemotherapy in terms of disease-free survival, and the planned analysis showed that the difference of restricted mean survival time between two groups at 3 yrs was 0.45 months (Sawaki at ASCO2018). The goal of this report was to assess the impact of the treatment groups on longitudinal cognitive function.

PATIENTS AND METHODS: The study was performed with patients from 99 hospitals in Japan. Elderly women with HER2-positive, stage I-IIIA invasive breast cancer surgery treated with clear resection margins were randomly assigned to either receive 1-yr Tmab or 1-yr Tmab plus standard chemotherapy. 15 institutions participated in the cognitive sub-study. Cognitive function was assessed using the Mini-Mental State Examination (MMSE) at baseline and at 1 and 3 yrs after treatment. The primary outcome was the amount of change in the MMSE score from the baseline. A linear mixed-effects model was used for comparisons of change in the MMSE score between groups, controlling for time and baseline score. Secondary outcomes were the proportion of both suspected mild dementia (MMSE≤27) and dementia (MMSE≤23) at each time point.

RESULTS: Between October 2009 and October 2014, 275 patients were enrolled in the RESPECT trial, and 57 patients were enrolled in the cognitive function sub-study with 2 patients subsequently excluded. The 55-patient sub-study comprised 29 patients assigned to the Tmab monotherapy group and 26 patients assigned to the Tmab plus chemotherapy group. Primary analysis revealed that change in the MMSE score was not significantly different between the two groups (difference −0.6 at 1 yr and −0.9 at 3 yrs; p=0.136), whereas the baseline score was the only significant factor that had an effect on the amount of change in the MMSE score (p<0.001). The proportions of suspected mild dementia at baseline, and at 1 yr and 3 yrs were 15.4, 32.0, and 41.7% in the Tmab monotherapy group, and 45.8, 17.6, and 28.6% in the Tmab plus chemotherapy group. The proportions of suspected mild dementia at baseline were significantly higher in the Tmab plus chemotherapy group (p=0.04). The proportions of suspected dementia at baseline, and at 1 yr and 3 yrs were 0%, 0%, and 4.2% in the Tmab monotherapy group, and 4.2%, 0%, and 4.8% in the Tmab plus chemotherapy group. There were no significant differences in the proportions of suspected dementia between the treatment groups at each time point.

CONCLUSION: Postoperative chemotherapy for elderly breast cancer patients was considered to have little effect on the onset of dementia during the follow-up period of 3 yrs. Further long-term observation is necessary to obtain a significant conclusion.
Aromatase inhibitors are significantly better tolerated by early stage breast cancer patients 75 or older and with significantly lower early discontinuation rate

Bareia Chaudhry\textsuperscript{1}, Lea Baer\textsuperscript{1}, Andrzej Kudelka\textsuperscript{1}, Jules Cohen\textsuperscript{1} and Alison T Stopeck\textsuperscript{1}. \textsuperscript{1}Stony Brook University Hospital, Stony Brook, NY.

Introduction:
Breast cancer is the most common cancer in women. In postmenopausal women with early stage estrogen receptor positive breast cancer, aromatase inhibitors (AI) are a common treatment option. AI's are reported to lead to a high early discontinuation rate in younger post-menopausal women due to poor tolerance. The most common side effects reported to lead to early discontinuation are arthralgia, hot flashes, fatigue, and night sweats. The reported tolerance to AI therapy in women age 75 or older is not well documented. Our study looks at women, ages 75 and older, diagnosed with early stage breast cancer who were placed on adjuvant AI therapy and focuses on tolerability, incidence of common side effects, rate of treatment changes, and on discontinuation rates.

Objective:
This study evaluates the tolerability, treatment side effects and the discontinuation rate of AI in women over the age of 75 with early stage breast cancer.

Methods:
Our study is a retrospective chart review of 58 patients' ages 75 to 95 with early stage breast cancer treated with adjuvant AI. Charts of patients were reviewed and duration of treatment, patient reported side effects, treatment changes, and discontinuation rate were recorded.

Results:
Data analysis showed that 36/55 (65.5\%) of patients did not report significant side effects to AI. 6/55 (10.9\%) patients required therapy changes due to side effects. 5/6 required one treatment change and 1/6 required multiple treatment changes. In 5/6 therapy was changed to another AI. Only 2/55 (3.6\%) of patients discontinued therapy. In both patients who discontinued AI, therapy was discontinued due to medical complications unrelated to AI therapy. Average time to discontinuation was 11 months. The most common reported side effects were arthralgia 9/55 (16.4\%), fatigue 3/55 (5.5\%), hot flashes 4/55 (7.3\%), rash 3/55 (5.5\%) and hair thinning 3/55 (5.5\%). The most common reported side effect which led to treatment change was arthralgia 4/6 (66.7\%). With a median follow up time of 24 months, breast cancer specific mortality was 1/55 (1.8\%).

Conclusion:
Our study evaluated the tolerance of AI in older women diagnosed with early stage breast cancer. 36/55 (65.5\%) of elderly patients reported no significant side effects suggesting that AI's are well tolerated in this population and the known side effects
are significantly less common than previously reported in a younger cohort in whom arthralgia as well as vasomotor symptoms affect as many as 30% of women. This improved tolerance led to a significantly lower early discontinuation rate than previously reported in the younger cohort: discontinuation rate of 3.6% by 24 months in the 75 or older population versus 20% by 24 months in the younger cohort of post-menopausal women treated with AI.

Patient care in breast cancer: Unmet and fulfilled needs

Hélène Simon, Jérôme Viguier, Hervé Naman, Chantal Touboul, Christine Lhomel, Gérard Ganem, François Eisinger and Jean-François Morère. 1CHRU Brest Hôpital Morvan, Brest, France; 2Hôpital Bretonneau, Tours, France; 3Centre Azuréen de Cancérologie, Mougins, France; 4Kantar Health, Paris, France; 5Roche, Boulogne-Billancourt, France; 6Clinique Victor Hugo, Le Mans, France; 7Institut Paoli-Calmettes, Marseille, France and 8Hôpital Paul Brousse, Villejuif, France.

Background

Comprehensive cancer care uses complementary approaches alongside specific anticancer therapy. Using a dedicated questionnaire, the Calista 2 national survey sought to assess the importance of supportive care and activities among breast cancer (BC) patients, how often these services are made available, the uptake rate, and the proportion of unmet needs.

Methods

Of the 82 physicians who accepted to take part in the survey, 29 recruited 257 patients with BC of whom 210 answered the patient-reported questionnaire. Patients meeting the inclusion criteria were adult females already on specific therapy for early or advanced BC. The patient-reported questionnaires covered drug management of pain, fatigue, adverse events (AE), sleep disorders, social and psychological support, physical activities, and complementary and alternative medicines. Items were rated on a scale of 0 – 10. Questionnaires were collected between September 2016 and October 2017.

Results

After exclusion of non-valid patient questionnaires, 197 were analyzed. The mean age of these patients was 56.8 years (SD 12.6); 53% had early stage disease and 41% advanced stage disease. Patients perceived the management of AE and pain, and self-image improvement techniques as the three most important items (8.0, 7.5, 6.7, respectively), followed by physical activity (6.3) and the management of fatigue (6.0), while preservation of fertility (2.3), spiritual support (2.5), counselling with regards to employment (3.2), and art therapy (3.3) were the least important. Most facilities were available at the point of care. Physicians frequently suggested management AE and pain (83% and 73%, respectively), self-image improvement techniques (73%) and psychological support for the patient (70%). Management of fatigue was however far less frequently proposed (30%). Management of AE (75%) and pain (60%), and self-image improvement (50%) were the most widely used support techniques. Only 19% of patients who were offered support in the management of fatigue declared actually using it. The management of fatigue nevertheless represented one of the three main unmet needs (for 27% of patients), together with complementary medicines (37%) and relaxation (29%).

Conclusion

These key findings highlight the fact that support for the management of AE and pain, together with self-image improvement techniques, are important for patients, are available, suggested and used. Although management of fatigue is available, it is rarely suggested by physicians and is therefore seen by patients as an unmet need. Patients also expressed the need for complementary medicines and relaxation techniques; these are however less frequently available at the point of care and seldom proposed.
Aromatase inhibitors and bone health in women 75 and older treated for early stage breast cancer

Lea Baer1, Bareia Chaudhry1, Andrzej Kudelka1, Jules Cohen1 and Alison T Stopeck1. 1Stony Brook University Hospital, Stony Brook, NY.

Introduction:
Breast cancer is the most common cancer in women. In estrogen receptor positive breast cancers aromatase inhibitors (AI) are a common treatment option. AIs are associated with a reduction in bone mineral density, and patients with osteopenia at baseline have a higher risk of developing subsequent osteoporosis while on AI therapy. Women age 75 and older are a fast growing subset of breast cancer patients and commonly have osteopenia or osteoporosis at time of breast cancer diagnosis. Studies of long-term effects of AI on bone density in these older women who are at higher risk of osteoporosis and musculoskeletal events are lacking at this time.

Objective:
To evaluate the objective change in bone density in women over the age of 75 diagnosed with early stage breast cancer and treated with AI.

Methods:
A retrospective chart review of 49 patients ages 75 to 95 diagnosed with early stage breast cancer and treated with AI. Pretreatment DEXA scan results were recorded as well as prevalence of bone targeted therapy at the time of breast cancer diagnosis. Incidence of bone targeted therapy initiated subsequent to cancer diagnosis and changes in T score on follow up DEXA scans were collected as well. Incidence of musculoskeletal events and osteonecrosis of the jaw were recorded.

Results:
40/49 (81.6%) of study women were found to have osteopenia (23/49 [46.9%]) or osteoporosis (17/49 [34.7%]) on pre-treatment DEXA scans. Only 16/49 (32.7%) of patients were on bone-targeted treatment prior to breast cancer diagnosis. Of the patients with baseline osteoporosis, only 4/17 (23.5%) were on bone targeted treatment prior to breast cancer diagnosis. 25/49 (51%) of women were initiated on bone targeted therapy subsequent to breast cancer diagnosis and following review of pretreatment DEXA scan results. 5/49 (10.2%) of women were started on bisphosphonates and 7/49 (14.3%) were started on Denosumab. On the first subsequent DEXA scan at a median follow up of 2 years, 14/21(66.7%) of women were noted to have stable DEXA findings (defined as change in T score less than 0.5). 7/21 (33.3%) had a worsening T score on repeat DEXA. Of those patients with worsening T score, 3/7 (42.9%) changed categories (either from normal density to osteopenia or from osteopenia to osteoporosis. 3/49 (6%) of patients sustained a fracture while on AI therapy. There were no reported events of osteonecrosis of the jaw.

<table>
<thead>
<tr>

</tr>
<tr>
<td>Baseline Osteoporosis</td>
<td>4 (n=6)</td>
<td>2 (n=6)</td>
<td>2 (n=17)</td>
</tr>
</tbody>
</table>

Conclusion:
Many elderly women are found to have osteopenia or osteoporosis at the time of breast cancer diagnosis and AI initiation. Most elderly patients had stable findings on subsequent bone density testing. Women with known osteoporosis initiated on bone-targeted therapy and AI did not have significant worsening in bone health. With appropriate treatment and monitoring elderly
women with baseline decreased bone density can be treated safely with aromatase inhibitors.
The importance of social support and self-esteem in quality of life in patients with breast cancer

Sabrina RP Chagas¹, Carlos R Chagas¹, Barbara PC Barros², Mariana F Constancio¹ and Dayanne SGB Assunção³. ¹PUC, Rio de Janeiro, Brazil; ²Hospital Universitário Gaffré e Guinle, Rio de Janeiro, Brazil and ³Viver eu Quero, Petrópolis, Brazil.

BACKGROUND:
Among the changes that have occurred in the practice of oncology in the last decade is the recognition that the patient well-being is important for the treatment. Another one was to have a greater focus on Quality of Life (QoL) and its questionnaires to evaluate this well-being.

Self-esteem is a factor that can be promoted through integrative oncology, through support groups and other forms of social support (such as meditation, yoga, massage, recreation, etc.). It is believed that promoting self-esteem is of great value for the improvement of patients' Quality of Life.

Integrative oncology coordinates the delivery of evidence-based complementary therapies with conventional cancer care. Complementary therapies encompass a broad range of mind and body practices, natural products, and lifestyle modifications, and are commonly used by patients with breast cancer and survivors of breast cancer.

METHODS:
A prospective cohort study conducted at three institutions to compare the patients' responses to the Rosenberg Self-Esteem Scale (RSS - 12) questionnaire, before and after watching two videos of SOCIAL SUPPORT, where women received care for the promotion of increase of SELF-ESTEEM.

The study included 109 patients with breast cancer in different stages of the disease, and it was carried out between December 2017 and June 2018. For all the patients the Free and Informed Consent Term was applied.

RESULTS:
18% of the patients were between 30-40 years old, 28% between 40-50, 28% between 50-60 and 26% had more than 60 years. 55% were in neoadjuvant or adjuvant treatment, while the rest were in palliative treatment. 94% of the patients reported having family support during treatment and 48% of the patients were married.

Of the 10 questions in the questionnaire, four presented a positive change in more than 35% after applying the questionnaire. The four questions are those of numbers 4, 8, 9 and 10 and refer to: 4) ability to do things with the same quality as the general population; 8) feeling of self-respect; 9) feeling useless and 10) feeling a good person at all. It is important to emphasize that question 8 presented a positive change in 53% of respondents.

In the rest of the questions, most of the other questions remained unchanged in more than 30% of the time.

CONCLUSION:
It can be suggested that projects carried out for the promotion of social support must be carried out continuously so that the well-being is promoted in a continuous and permanent way, thus leading to an increase in the quality of life of patients in general.
Prevalence, predictive factors, and clinical outcomes of anthracycline induced cardiac dysfunction among patients with breast cancer in Japan, where the normal body weight (BMI ≤ 25) is dominant

Koji Matsumoto1, Akiko Nonaka1, Takatsugu Ogata1, Misato Ogata1, Hideki Sakai1, Meiko Nishimura1, Takuma Onoe1, Misawo Soyama1, Kazuki Hashimoto1, Kaori Tane1, Koichi Hirokaga1 and Shintaro Takao1. 1Hyogo Cancer Center, Akashi, Hyogo, Japan.

Objective: Cardiac dysfunction (CD) is a major clinical problem for survivors of breast cancer. ASCO released a guideline for prevention and monitoring CD in survivors of adult cancer in 2017. Exposure to anthracycline (A) and trastuzumab are both risk factor for CD, as well as obesity is a part of multiple risk factors in the guideline. Meta-analysis shown obesity itself increases risk of A induced CD (A-CD). Prevalence of obesity and CD among non-oncology patients vary in countries, as many Western countries have obesity dominant population. Then little is known about clinical characteristics of A-CD in survivors of adult cancer among normal weight dominant countries, especially in Asia. This study was conducted to understand characteristics of A-CD among patients with breast cancer in Japan.

Method: This study used electrical charts, breast oncology database, and cardiology database to find prevalence, predictive factors, and clinical outcomes of A-CD in Hyogo Cancer Center. The definition of CD is based on diagnosis by the cardiologist. Major Cardiac Events (MACE) is defined as cardiac death or emergency admission due to CD. Obesity is defined as BMI ≥ 30, normal body weight is defined as BMI ≤ 25, and elderly is defined as age ≥ 60 years old, same as in ASCO guideline. Patients gave written informed consent. IRB approved this study.

Result: From Apr. 2006, to Mar. 2017, 855 patients received A for the treatment of breast cancer. Median body weight was 55 Kg, median BMI was 23, and 93.4 % of patients are non-obese. Half of patients (46.9 %) are elderly. Almost a quarter (24 %) of patients received trastuzumab. At the median follow up 60 months, 20 patients (2.3 %) experienced CD, one patient (0.11 %) passed away due to CD, and four patients were admitted as emergency, then five patients (0.58 %) experienced MACE. Median time to onset of CD after the last dose of A is seven months. Among patients with CD, 18 patients (90 %) recovered their ejection fraction (EF), and the median time to recover of EF was two months. Predictive factors for CD include usage of trastuzumab (15 patients), elderly (eight patients), high dose anthracycline (four patients), and multiple cardiac risk factors at base line (four patients). Among patients treated without trastuzumab, only five (0.76 %) patients experienced CD, but four of them experienced MACE.

Conclusion: Prevalence of A-CD in the normal weight dominant population was lower than reported in obesity dominant population, especially in patients treated without trastuzumab. In this population, clinical outcome such as prevalence of MACE may vary depending on the usage of trastuzumab. Further study is warranted to set an optimal strategy for the prevention and monitoring of A-CD in non-obese dominant population.
Preliminary evaluation of a mind-body intervention to improve body and/or self-image: A phase II randomized trial

Debra Barton¹, Trevor Brooks¹, Alison Cieslak¹, Gary Elkins², Patricia Clark¹, Mohamad Baydoun¹, Asa Smith¹ and Catherine VanPoznak¹. ¹University of Michigan, Ann Arbor, MI and ²Baylor University, Waco, TX.

Background: The number of cancer survivors is growing and expected to be 18.9 million by 2024. Addressing survivorship issues, such as sexual health, are a critical part of health promotion. Women diagnosed with breast or gynecologic cancer can experience distressing changes in their self and/or body image, which affects their sexual health. This study evaluates hypnosis compared to progressive muscle relaxation (PMR) to improve self/body image in order to improve sexuality.

Methods: Women with a history of breast or gynecologic cancer, who also report negative body image changes, were randomized in a 2:1 fashion to a 6-week intervention of hypnotic relaxation or PMR. Both intervention arms consisted of three 30-minute sessions delivered face-to-face by a trained therapist, one every two weeks, along with home practice using a CD. The primary outcome was impact of treatment on body image using the Impact of Treatment Scale (ITS). Secondary outcomes included mood (Positive/Negative Affect Scale-PANAS), sexual satisfaction (PROMIS satisfaction), and perceived change (Global Impression of Change Scale -GCIS). Outcomes were measured at baseline and 6 weeks except for the GCIS measured only at 6 weeks. A series of independent samples t-tests were used to compare changes in outcome measures between arms. The intention-to-treat principle was applied.

Results: The final randomized sample consisted of 87 women. There was no statistically significant difference (p=.15) in the change in ITS between groups at 6 weeks, with both groups significantly improving (within group effect size Cohen’s d .49 - .75). There were non-significant differences between groups on secondary outcomes. Change from baseline for positive affect (PANAS) was 1.7 in the hypnosis group and 3.8 in the PMR group while negative affect change was very similar being about 2.8 in both groups. Change from baseline for the PROMIS general sexual satisfaction scale was 1.5 in the hypnosis group and 1.3 in the PMR group. On the GCIS at 6 weeks, 42% of the hypnosis group reported moderate to very much improvement on self/body image (GCIS) while only 32% of the PMR group reported this level of improvement; and 36% of the hypnosis group versus 11% of the PMR group reported moderate to very much improvement in their sexuality.

Implications: The stress relieving strategies applied in this study may contribute substantially to decreasing the distress of the cancer experience related to altered self/body image and sexuality. The variable improvement across domains suggests that hypnosis and PMR may work in different ways, mechanistically. Further mechanistic studies of interventions to optimally promote survivorship health are warranted.
A qualitative exploration of self-developed and peer-recommended techniques used by women with breast cancer to improve sexual functioning during and after treatment

Christiana D von Hippel1,2, Shoshana M Rosenberg2,3, Melissa B Jenkins4, Marisa C Weiss4 and Ann H Partridge2,3. 1UC Berkeley School of Public Health, Berkeley, CA; 2Dana-Farber Cancer Institute, Boston, MA; 3Harvard Medical School, Boston, MA and 4Breastcancer.org, Ardmore, PA.

Background: Coping with sexual dysfunction during and after breast cancer treatment is a persistent challenge for many women, even if clinicians offer standard sexual rehabilitative therapies (e.g. lubricants, counseling). This study sought to explore how women with breast cancer supplement clinician recommendations with self-developed and peer-recommended techniques for improving sexual function, what those techniques are, and how well they work.

Methods: We conducted a cross-sectional, online survey of 501 adult women with stage I-IV breast cancer who were members of the Breastcancer.org community. Open-ended survey items asked women to describe any techniques used to improve sexual function during and after breast cancer treatment beyond those recommended by clinicians. Closed-ended items asked women to assess the source and perceived efficacy of their techniques. We used qualitative content analysis to extract themes that described women's techniques and calculated frequencies in StataMP 15 to quantify sources and efficacy levels.

Results: Participants were, on average, age 53 (range 30-79) and 10 years from diagnosis. Most were partnered (90%), heterosexual (96%), with stage I/II disease (73%). 174/501 (35%) women reported using a sexual self-management technique they developed themselves or that was recommended by someone other than a clinician. Emergent themes in techniques included: 1) pain reduction: trial-and-error to find an effective lubricant or moisturizer (e.g. coconut oil), changing sex positions, choosing oral sex over intercourse 2) intimacy enhancement: open partner communication, planning sex 3) arousal enhancement: masturbation, erotica, vibrator use 4) emotional coping: adopting an attitude of persistence vs. acceptance of loss of sex life, encouraging partners to use sexual surrogates. 77 women developed the technique themselves, 54 with partners, 37 heard about it from survivors, 36 read about it online. 45% of women rated their techniques as moderately or more effective when used in addition to or instead of standard therapies offered by clinicians.

Conclusion: In a survey of an Internet-based community of women treated for breast cancer, women reported a variety of successful techniques for increasing intimacy and arousal, reducing vaginal pain, and coping emotionally with changes in sexual life after breast cancer. More women reported developing these techniques on their own or with partners vs. learning them from others. Given that standard therapies are often insufficient to manage sexual dysfunction during and after breast cancer treatment, clinicians should address sexual function during follow-up care and encourage women's safe experimentation with techniques for improving sexual function. Clinicians can refer patients to platforms like Breastcancer.org for peer-to-peer support and information exchange. Existing self-developed and peer-recommended techniques should be evaluated for safety, quality, and generalizability. Future research can then assess the effectiveness of particularly novel techniques as a complement to standard, clinician-developed therapies for the broader population of women with breast cancer experiencing sexual dysfunction.
Endothelial dysfunction in breast cancer survivors on aromatase inhibitors (AIs) over time

Anne H Blaes¹, Ashley Petersen¹, Heather Beckwith¹, David Potter¹, Natalia Florea¹, Douglas Yee¹, Rachel Vogel¹ and Daniel Duprez¹. ¹University of Minnesota, Minneapolis, MN.

Endothelial dysfunction in breast cancer survivors on aromatase inhibitors (AIs) over time

Background: AIs reduce breast cancer-related mortality however they may increase cardiovascular (CV) risk. Our previously published cross-sectional study suggested women on AIs were more likely to have endothelial dysfunction when measured by EndoPAT ratio as compared to healthy postmenopausal women. Reductions in EndoPAT ratio (<1.67) and small artery elasticity (SAE) and increases in highly sensitive C-reactive protein (CRP) are associated with worsening endothelial dysfunction and increased cardiovascular events. We present data from a longitudinal pilot study looking at endothelial dysfunction over time in women on AIs.

Methods: Fourteen women with locally advanced breast cancer prescribed an AI underwent vascular testing at baseline (pre-AI) and at 6 months. Subjects with tobacco use, hypertension or hyperlipidemia were excluded. Consented subjects underwent biomarker analysis and radial artery pulse wave analysis using the HDI/Pulse Wave CR-2000 CV Profiling System and pulse contour analysis using the Endo-PAT2000 system. Biomarkers were obtained using a fasting blood draw to evaluate the following lipids and inflammatory markers: serum ultrasensitive estradiol, serum glucose, total cholesterol (TC), low-density lipoprotein cholesterol (LDL), high-density lipoprotein cholesterol (HDL), and triglycerides (TG), CRP, plasminogen-activator 1 (PA1), and tissue-type plasminogen activator (tPA). Changes between baseline and follow-up using Wilcoxon signed-rank tests were analyzed.

Results: Mean baseline age was 59 years and median body mass index was 26.5 kg/m². Median systolic blood pressure and total cholesterol were 120/70 mm/Hg and 228 mg/dL, respectively. Baseline ultrasensitive estradiol levels were 7 pg/mL and hsCRP was 2.45 mg/dL. Prior to AI therapy, endoPAT ratio was 2.18 (1.19, 2.43). After six months, EndoPAT ratio declined to a median 1.12 (0.85, 1.86) (p=0.045). There were no statistically significant changes in serum glucose, TC, LDL, HDL, hsCRP, PA1 and tPA. HsCRP remained elevated at median 2.98 mg/L. At six months, estradiol levels decreased to a median of 2 pg/mL (p=0.052), however, there appeared to be no linear association between changes in EndoPAT and estradiol (p=0.91).

Conclusion: Breast cancer survivors on AIs have endothelial dysfunction, a predictor of adverse CV disease. These changes develop while on AIs. Underlying pathophysiology requires further evaluation.

Prospective 36-month follow-up to determine changes in body mass index and weight among Chinese breast cancer survivors

Winnie Yeo, Yuan Y Lei, Ashley CK Cheng, Carol CH Kwok, Ka L Cheung, Roselle Lee, Iris CK Lee and Suzanne Ho. Chinese University of Hong Kong, Hong Kong, China and Princess Margaret Hospital, Hong Kong, China.

Background: Anticancer treatment for breast cancer has been associated with weight gain but such observation has mainly been reported in western patients. More recent data in Asian patients have inconsistent findings. Factors including socio-demographic, clinical and lifestyle may be associated with post-diagnosis weight gain. In this prospective cohort study of women with breast cancer, the objectives were to determine the body mass index (BMI) and weight changes over 36 months after initial diagnosis and the factors associated with such changes.

Methods: Chinese women with newly diagnosed early-stage breast cancer were recruited. Individual woman had her weight measured at breast cancer diagnosis (W0), at study entry (W1) and at 36-month follow-up (W2). Body height was measured at W0. We evaluated change in weight and body mass index (BMI) before and after breast cancer diagnosis. Socio-demographic, clinical and lifestyle factors were assessed to identify potential associated factors with weight changes.

Results: A total of 1133 women with breast cancer had detailed weight measurements at the 3 time-points of assessment. The mean age at diagnosis was 52 years. Fifty-four percent were premenopausal at W1. The proportion of patients with stage 0-I, II and III diseases were 35%, 46% and 19%, respectively.

The proportions of patients who were overweight and obese at the three assessment time-points were 21.2% and 28.5% at W0, 19.7% and 26.6% at W1, and 21.7% and 30.9% at W2 assessment, respectively. When compared to W0, the proportions of women who gained weight within 2-5kg at W1 and W2 were 2.4% and 20.6% respectively, that with weight gain of >5kg at W1 and W2 were 0.5% and 10.0% respectively; 6.1% and 19.6% of women had weight loss >2kg at W1 and W2 respectively.

Compared to W0, the median value of weight change was -0.5 kg (range: -11.4, 18.3) at W1 and 0.6 kg (range: -19.6, 20.5) at W2. On multivariate analysis, only BMI at diagnosis were significantly associated with weight change between assessments at diagnosis and W2; the median (range) for weight changes for women who were underweight, normal, overweight and obese were respectively 0.9 (-4.8, 7.6), 0.6 (-13.2, 20.5), 0.5 (-11.5, 13.0) and 0.5 (-19.6, 12.6) kg, p <.001.

Conclusions: In this prospective study of Chinese women with a history of breast cancer who were followed-up over a 36-months’ period, the proportions of women with overweight and obese statuses were relatively stable; weight gain was uncommon among Hong Kong women with breast cancer during the same period. These findings are in contrast with studies conducted in the West, where weight gains were more commonly reported.

Association of CBR3 polymorphisms with an early change in cardiac function as assessed by left ventricular global longitudinal strain in breast cancer patients treated with doxorubicin

Jennifer K Lang¹, Adolfo Lombrana Quinones¹, Rachael Hageman Blair¹, Amy P Early², Ellis G Levine², Mateusz Opyrchal², Javier G Blanco¹ and Tracey O'Connor². ¹University at Buffalo, Buffalo, NY and ²Roswell Park Comprehensive Cancer Center, Buffalo, NY.

Progress made in early cancer diagnosis and therapy has translated into increased longevity for patients with breast cancer. As survival has increased, the potential cardiotoxicity of cancer chemotherapy regimens has become an important issue for survivorship. Doxorubicin-induced cardiotoxicity has been demonstrated at a cumulative dose of ≤300mg/m², with histopathological changes seen in endomyocardial biopsy tissue from patients receiving as little as 240mg/m² of doxorubicin. Individual risk stratification and early detection of chemotherapy-induced cardiotoxicity are crucial to prevent irreversible cardiac dysfunction. There is accumulating evidence for the utility of echocardiographic indices such as left ventricular global longitudinal strain (GLS) in the detection of early chemotherapy induced cardiac injury. We have previously highlighted a predictive role of genetic polymorphisms in the carbonyl reductase 3 gene \textit{CBR3} in anthracycline-related cardiomyopathy following childhood cancer. Consistent with our prior work, we hypothesized that breast cancer patients homozygous for the \textit{CBR3} V244M G allele would exhibit worsening GLS following DOX treatment when compared with patients homozygous for the A allele. We recruited 138 patients with breast cancer receiving treatment with DOX (total cumulative dose: 240mg/m²). 72 patients received an echocardiogram analyzing global longitudinal strain by speckle tracking at baseline (t₀ month) and at 6 months (t₆ month) of follow up after DOX treatment. Patients were genotyped for variants associated with anthracycline-related toxicity. In agreement with our previous findings and hypothesis, our interim analysis suggested that patients homozygous for the \textit{CBR3} V244M G allele (CBR3 V244) exhibited GL changes at 6 months after DOX treatment compared to individuals homozygous for the A allele (\textit{CBR3} M244) (-1.2 ±3.5 vs 1±1.6; mean±SEM, p=0.8 by Mann-Whitney test). Although the differences between \textit{CBR3} genotype groups are not significant at p<0.05, the direction and magnitude of changes in ventricular GL are well in line with various reports describing early detection of cardiotoxicity in similarly treated breast cancer patients. This study outlines a potential role for screening \textit{CBR3} polymorphisms in patients prior to DOX therapy and highlights a need for further investigation into the pharmacogenomics of chemotherapy-induced cardiotoxicity.
Proposal for integrating the pathologic assessment of lymphovascular invasion and extranodal tumor extension in breast cancer-related lymphedema clinical management

Nicola Fusco1,2, Chiara Corti1, Gianluca Lopez1, Anna Michelotti1,2, Luca Despini2, Donatella Gambini2, Daniele Lorenzini1, Elena Guerini-Rocco1,3, Stefania Maggi4, Marianna Noale4 and Marco Invernizzi1. 1University of Milan, Milan, MI, Italy; 2Fondazione IRCCS Ca’ Granda - Ospedale Maggiore Policlinico, Milan, MI, Italy; 3European Institute of Oncology, Milan, MI, Italy; 4National Research Council (CNR), Neuroscience Institute Aging Branch,, Padua, PD, Italy and 5Physical and Rehabilitative Medicine, University of Eastern Piedmont "A. Avogadro", Novara, NO, Italy.

Breast cancer related lymphoedema (BCRL) occurs in a substantial proportion of breast cancer survivors and is a major contributor to disability, representing a long-term threat to these patients. Given the extremely high incidence of breast cancer worldwide, and the increasing number of long-term survivors, the reduction of BCRL burden represents an urgent clinical need in women's healthcare. However, there are no validated predictive biomarkers, diagnostic tools, and strong evidence-supported therapeutic strategies for BCRL management. Here, we provide a comprehensive clinicopathological characterization of a large series of women with node-positive breast cancers and identify new bona fide predictors of BCRL occurrence.

332 cases of surgically-treated node-positive breast cancers were retrospectively collected (2-10.2 years of follow-up). Among them, 62 patients developed BCRL. To identify demographic and clinicopathologic features related to BCRL, Fisher’s exact test or Chi-squared test were carried out for categorical variables; the Wilcoxon rank-sum was employed for continuous variables. Factors associated with BCRL occurrence were assessed using a Cox proportional hazards regression model. En-bloc dissection of the axillary lymph nodes but not the type of breast surgery impacted on BCRL development. Most of BCRL patients had a Luminal A-like neoplasm. The median number of lymph nodes involved by metastatic deposits was significantly higher in BCRL compared to the control group (p=0.04). Both peritumoral lymphovascular invasion (LVI) and extranodal extension (ENE) of the metastasis had a negative impact on BCRL-free survival (p=0.01). Specifically, patients with LVI and left side localization harbored 4-fold higher risk of developing BCRL, while right axillary nodes metastases with ENE increased the probability of BCRL compared to ENE-negative patients.

Here, we document that LVI and ENE have a strong predictive value for BCRL occurrence. Furthermore, we confirm that the full excision of the axillary nodes is one of the major determinants of BCRL, regardless of the extent of the surgical procedure involving the breast. In conclusion, our results suggest that the pathologic data on LVI and ENE should be integrated with information on the laterality of the tumor and the type of surgical procedure. This new integrative approach could be extremely beneficial to improve BCRL risk stratification.
Regimen-specific rates of chemotherapy-related amenorrhea in breast cancer survivors

Kelly C Gast1, Elizabeth J Cathcart-Rake1, Aaron Norman1, Leah Eshragī2, Nwamaka Obidegwu2, Kathleen Yost1, Hazel B Nichols3, Shoshana Rosenberg4, H Irene Su5, Elizabeth Stewart1, Fergus Couch1, Celine Vachon1 and Kathryn J Ruddy1. 1Mayo Clinic, Rochester, MN; 2Dr. Susan Love Research Foundation, Encino, CA; 3University of North Carolina, Chapel Hill, NC; 4Dana Farber Cancer Institute, Boston, MA and 5University of California San Diego, San Diego, CA.

Background: Chemotherapy can damage the ovaries and cause amenorrhea, a surrogate for infertility. Young women often wish to understand and minimize their risk of chemotherapy-related amenorrhea (CRA). However, the incidence of CRA with regimens that do not include either an anthracycline or cyclophosphamide is poorly studied. For patients with HER-2 positive disease, these anthracycline and cyclophosphamide-sparing regimens (e.g., docetaxel-carboplatin) are common (in combination with Her-2 directed therapy) in both the neoadjuvant and adjuvant settings.

Methods: Women diagnosed with breast cancer under age 50 and within the past 10 years were recruited through a Dr. Susan Love Research Foundation Army of Women e-mail blast. Those who provided their contact information were mailed a consent form and medical record authorization form. Participants then received a web-based survey that inquired about receipt of and type of chemotherapy (including date of last dose) and date of last menstrual period (LMP). Patient-reported LMP was compared to date of final chemotherapy dose to determine if the LMP occurred before (defined as “CRA”) or after the last chemotherapy dose. When available, medical record data was used in place of survey data regarding type of chemotherapy used. Exclusion criteria included: LMP prior to diagnosis date, receipt of multiple chemotherapy regimens or no chemotherapy regimens, receipt of ovarian suppression medications (which interfere with interpretation of menstrual data), surgical menopause prior to or at the same time as diagnosis, a cancer diagnosis more than 10 years prior, incomplete menstrual data on the survey, report of an unknown chemotherapy regimen, and no date available for the last chemotherapy dose without an LMP within a month prior to survey completion. Fisher Exact test was used to compare CRA rates between regimens. Rates after two anthracycline-sparing regimens (taxane/cyclophosphamide; taxane/carboplatin) were compared to rates after anthracycline/cyclophosphamide/taxane.

Results: 273 women consented to participate in this study, 258 of whom filled out the web survey. 151 of them were eligible for this analysis with a median age at diagnosis of 41 (range 24-49) and a median time from last chemotherapy dose to survey of 62.5 months (range 2-138). CRA occurred in 51.2% of the 86 participants who received an anthracycline, cyclophosphamide, and a taxane, in 41.9% of the 43 participants who received only a taxane and cyclophosphamide (p=0.35), and in 13.3% of the 15 participants who received carboplatin with a taxane (p=0.01). When the 11 patients who were <12 months since last chemotherapy were excluded, CRA rates changed minimally. Age did not differ by regimen, but median time since chemotherapy was shorter in the taxane/carboplatin group (35 months vs. 68 months). Trastuzumab with or without pertuzumab was administered in 100% of patients who received carboplatin/taxane, in 23.3% of patients who received taxane and cyclophosphamide, and in 22.1% of patients who received anthracycline/cyclophosphamide/taxane.

Conclusions: This study suggests that carboplatin/taxane may be substantially less gonadotoxic than cyclophosphamide-based (neo)adjuvant regimens. Further research is necessary to confirm these findings.
Background:
Women in rural areas are less likely to engage in physical activity (PA) compared with their urban counterparts. It can be even more challenging for BC patients due to the sequelae of their cancer and treatment. A quality improvement project in our cancer center evaluating leisure time activity among BC patients identified that about half the responders were sedentary or insufficiently active. Only one third were aware of the recommendation to achieve 150 active minutes per week while more than half reported not meeting the goal. Lack of motivation was quoted as the main reason for not meeting the goal by one-third of the responders. Goal setting has been an integral part of cardiac rehabilitation and behavior change techniques. It has shown to increase participation and motivation. We performed a combined analysis of collaborative interventions in NNE to identify if effective goal setting can overcome the barriers to PA among BC survivors.

Methods:
5 IRB-approved interventions promoting PA among BC patients across 3 states were included. Studies were stratified according to the stages of treatment, the types of intervention and whether goal-setting was used. Pooled effects were calculated using Comprehensive Meta-Analysis software and R package metafor (v.2.0.0) with the maximum-likelihood configuration. Subgroup analyses were conducted based on the goal-setting criteria.

Results:
The 5 studies examining 4 exercise interventions are shown in the table below.

D12030 included patients on chemotherapy with the aim to increase activity by 10MET/week, while the W12051, UVM, D1032 and D12110 studies included patients who were post-chemotherapy. Home-based programs were used in W12051 and D12030.
Goal-setting was used in all the studies except for the UVM study which used a supervised program with self-reporting. Weighing by percentage of patients completing the program, the pooled change in PA was 56.6% (95% CI=24.2-89.1%). Pooled PA for the goal-setting subgroup was nearly twice as high as the without-goal-setting subgroup (74.3% and 39.5%, respectively).

**Conclusion:**
Cancer centers with large catchment areas need to design creative approaches to encourage PA among the BC survivors. With the lack of motivation as the most common barrier to achieving the recommended PA, goal-directed programs can be helpful by creating attainable targets as well as providing emotional and psychological support. In addition, geographical barriers need to be addressed through interventions like internet-based programs, personal tracking devices, and small-group social activities.
Introduction: Adherence to endocrine therapy is a long recognized problem despite efficacy of these drugs with reported compliance rates of 89% in first year and 50% in fourth year. Most of our knowledge of noncompliance is observational and retrospective. This final analysis of the Bubble Study reports the compliance rate of adjuvant endocrine therapy among women with early stage breast cancer using “bubble” packaging. We previously reported adherence rates of 97% with bubble packaging. This updated analysis includes disease free survival (DFS) and overall survival (OS) at 5 years.

Methods: The Bubble study is a non-blinded, prospective observational cohort study, which enrolled 86 patients between August 2012 and April 2014. Demographic and clinical data were collected prospectively including age, race, insurance, duration of therapy, stage, treatment, comorbidities, recurrence and survival. Duration of therapy was divided into 3 cohorts: <12 months, 12-36 months, and 37-60 months. All patients received routine prescriptions in a “bubble” pack or daily blister pack. Patients returned all used bubble packs at follow up appointments for review and kept a diary of missed doses for analysis. DFS and OS data were obtained at 78 months. Compliance was defined as >90% adherence. We calculated institutional DFS and OS for breast cancer patients treated within a similar timeframe from the tumor registry.

Results: 53 patients were included in the analysis. The remaining patients withdrew from the study prior to data collection or were deemed ineligible. The overall compliance rate was 97%; however, only 72% of enrolled patients were continued in the analysis. None of the variables examined (race, age, insurance status and stage) had an impact on compliance. Only duration of endocrine therapy had a marginal effect on compliance (p value = 0.06). The latest cohort (duration of therapy 37-60 months) was least likely to be compliant at 89.53%. Our 5-year DFS is 92% and 5-year OS is 96%. There is no statistically significant difference in DFS and OS between patients with compliance>90% and <90%. For ER+ breast cancer patients treated during similar timeframe at our institution outside the trial, 5-year DFS is 94% and 5-year OS is 90%.

Conclusion: There was no difference in OS or DFS based on compliance to oral anti-estrogens. Given the high overall compliance rate in this small patient population, the lack of OS and DFS difference is not surprising. However, the compliance rate of bubble packaging (>90%) is higher than expected based on current literature. Although this may suggest improved compliance with bubble packaging, more studies are necessary to confirm this given small sample size and high trial dropout rate. Trial withdrawal likely altered analysis of adherence rates as it selects for a largely compliant group of patients. This bias may also explain the lack of difference in compliance rate among race, insurance status and/ or age, which contradicts our current knowledge of high-risk groups. There was a trend towards lower DFS in the bubble cohort, but overall better survival when comparing to institutional rate. Studies are ongoing to confirm bubble packaging adherence rates and compare this to established strategies to improve adherence.
Initial report of a prospective, pilot study of patient-reported upper extremity dysfunction in women undergoing radiation for breast cancer

Erin Healy¹, Xueliang Pan², Sasha Beyer¹, Iman Washington¹, Jose Bazan¹ and Julia White¹. ¹The Ohio State University Medical Center, Columbus, OH and ²The Ohio State University, Columbus, OH.

Objectives: Upper extremity dysfunction (UED) is a known side effect of breast cancer treatment. It is unclear, however, to what degree radiation contributes to this morbidity. We aimed to characterize the level of UED using patient-reported outcomes (PROs) prior to, during, and after treatment with radiation for breast cancer. Our secondary aims were to evaluate the association of UED with pain scores.

Methods: This is a single-institution, prospective, longitudinal cohort study of patients treated with radiation for breast cancer. The validated patient-reported outcome measure, Quick Disabilities of the Arm, Shoulder and Hand (QD) was used to capture UED prior to radiation, at the end of radiation, and 1 month following the completion of radiation. Pain scores were also collected at these intervals using the numeric pain reporting scale (NPRS) from 0 (no pain) to 10 (worst pain).

Results: Forty-four patients were enrolled on this study and 43 (97.7%) had completed radiation at the time of analysis. Thirteen patients (29.5%) were treated with mastectomy, axillary lymph node dissection and regional nodal irradiation in the supine position. The other 31 (70.5%) patients underwent lumpectomy and sentinel lymph node biopsy. Of these patients, 26 (83.9%) were treated in the prone position and 30 (96.8%) received whole breast irradiation. Median time from surgery to radiation was 69 days (range 35 – 212 days), 76 days for mastectomy and 68 days for lumpectomy. Median time from start to end of radiation was 38 days for mastectomy and 28 days for lumpectomy. Pre-treatment median QD score prior to radiation was 12.5 (11.4 for lumpectomy, 15.9 for mastectomy), 9.1 at the end of radiation (9.1 for lumpectomy, 18.2 for mastectomy), and 2.4 at 1 month after radiation (2.3 for lumpectomy, 2.5 for mastectomy). Median NPRS scores at pre-treatment, post-treatment and 1 month follow-up were 1, 1, and 1 for lumpectomy and 0, 1, 0 for mastectomy patients, respectively.

Conclusion: In this initial pilot study with 1 month of follow up, patient-reported UED as demonstrated by QD scores were higher pre-radiation and decreased by one month after. This likely reflects recuperation after surgical procedure. Median average pain scores were low at all time points. Further evaluation of UED over time to characterize the long-term effect of radiation and correlation with quality of life and other clinical factors is planned.
Quality of life, fear of recurrence, impact of cancer, and dietary habits in breast cancer patients during the early survivorship period - Initial data from the pilot Cas-PET (Cancer Survivorship Patient Engagement Toolkit) study

Paula Y Rosenblatt¹³, Mary McQuaige³, Kenneth Miller¹³, Eun-Shim Nahm² and Lindsey Hertsenberg². ¹University of Maryland School of Medicine, Baltimore, MD; ²University of Maryland School of Nursing, Baltimore, MD and ³University of Maryland Marlene and Stuart Greenebaum Comprehensive Cancer Center, Baltimore, MD.

Introduction – With heightened public awareness, earlier detection, and better treatment, the number of breast cancer survivors continues to grow. Many of these cancer survivors have physical, psychological, social, spiritual, and financial challenges that require coordinated, comprehensive care. Patient involvement programs that focus on education and health promotion may help breast cancer survivors to manage their symptoms and take better control of their health. At the University of Maryland, a collaborative group developed the Cancer Survivorship Patient Engagement Toolkit (CaS-PET). CaS-PET includes the following components: survivorship care plans, online support program (learning modules and discussion board), and ongoing communication between providers and patients using a patient portal. The main aim of the study is to test the preliminary impact of the CaS-PET using a small sample.

Methods – After IRB approval, 30 cancer survivors at the University of Maryland Marlene and Stuart Greenebaum Comprehensive Cancer Center who were within 6 months of completion of active treatment were enrolled in a prospective pilot study that used a single group pre-post design. The outcome measures included changes in quality of life, fear of recurrence, impact of cancer, dietary and exercise behaviors, and selected cancer symptoms. In addition, participants' demographic characteristics, as well as Internet and patient portal experiences were also assessed at baseline. Currently, baseline surveys are completed and the 3-month follow-up data collection is ongoing.

Results – Among the total of 30 patients, 15 (50%) were breast cancer survivors. The median age was 57.2±13 years and all were female. Ten survivors were African American (66.7%). Most survivors received combination of surgery, chemotherapy, and radiation treatments. At baseline, the mean scores for the positive impact and negative impact of cancer were 3.69 (range, 1-5, higher means more positive) and 2.57 (1-5, higher means more negative) respectively. Among various physical and mental cancer symptoms, breast cancer patients frequently experience lack of energy, pain, bloating, sadness, and constipation. The mean score for fear of recurrence was 14.16 ±6.4 (range of 6-24, higher means more fear). The average scores for fat and fruit/vegetable consumption were 17.7+6.0 and 7.6+4.1, respectively, which indicated a diet high in fat and calories and low in fruit and vegetables.

Discussion – This baseline assessment shows breast cancer survivors experience significant residual symptoms following completion of active therapy. Many patients are fearful of recurrence and struggle with other negative impacts of cancer. However, patients have also found positives in their experiences. Participants have expressed enjoyment and benefit of the CaS-PET study. Full outcomes will be available in early September 2019.
Quality of life, unmet needs and social support of patients with breast cancer during adjuvant endocrine therapy in Mexico

Lizette Gálvez-Hernández¹, Israel Páez-Gerardo¹, Raúl Ramírez-Medina¹, Verónica Neri-Flores², Enrique Bargallo-Rocha¹, Cynthia Villarreal-Garza¹, Nereida Esparza¹, Diana Flores-Díaz¹, Alejandro Mohar¹ and Paula Cabrera-Galeana¹.¹Breast Cancer Unit, Instituto Nacional de Cancerología, CDMX, Mexico; ²Facultad de Psicología, Universidad Nacional Autónoma de México, CDMX, Mexico and ³Centro de Cáncer de Mama del Hospital Zambrano Hellion, Tecnológico de Monterrey, San Pedro Garza García, NL., Mexico.

Background: As survival increases in patients with breast cancer (BC), long-term care is required. Studies have shown that the psychosocial situation of this patients changes according to age and the types of treatment they received. Quality of life (QoL), unmet needs (UN), and social support (SS) have been significantly related to the way they live their survivorship. However, it is still unclear how these variables are affected by adjuvant endocrine therapy (AET) in Mexican patients with BC, to address and provide appropriate interventions. Objective: To describe the level of quality of life, unmet needs and social support, and to evaluate their relationship with the type of AET. Method: 200 patients with BC under AET were enrolled in a cross-sectional and correlational design. We administered QoL (EORTC-30 and BR-23), UN (SCNS-SF32), SS (MOS-SSS14), validated and standardized instruments in Mexican population. Premenopausal patients with ovarian function suppression were excluded. Non-parametric analyzes of U Mann Whitney and Spearman's correlation were used. Results: Mean age of the 186 patients evaluated was 54.52 (SD=10.65) years. Most of patients had elementary school (32.8%), were married (49.5%), housewives (60.2%), and catholics (86%). 54.8% underwent tamoxifen, 25.8% exemestane, 12.9% letrozol, 6.5% anastrozol. Mean time of AET were 2.59 years and 3.53 years since diagnosis. They reported a good level of global QoL (mean= 80 points, 0-100); however, they experienced insomnia (25.44 points), financial difficulties (24.19), fatigue (23.77), constipation (21.68) and pain (18.54); besides, adequate body image perception (91.6 points). The most UN were on information and the health system 31.13 (0-100 score), sexual (29.23) and psychological (28.21). The most frequent SS type was affection (88.46 points) and emotional-informational (79.56 points). Patients under anastrozole in comparison with exemestane, tamoxifen and letrozol reported significantly more nausea-vomiting (p=0.028; p=0.041; p=0.002 respectively), insomnia (p=0.008; p=.014; p=0.032, respectively), and appetite loss (p=0.049; p=0.049; p=0.04, respectively). We found that patients with anastrozol perceived significantly less SS than other types of AET (p=<0.005). It highlights that patients who received letrozol perceived significantly better future perspective (QoL). Our data also shows that the higher QoL level and the fewer reported symptoms the lower the UN. Conclusions: These results are consistent with previous studies in terms of information and psychological UN, and its relationship with QoL. Despite the small percent of patients treated with anastrozole in our study, they had more side effects than other aromatase inhibitors. In addition, it shows that postmenopausal survivors patients with BC still have sexual UN. This study is the first on Mexico exploring differences in perception of QoL, UN and SS according AET type. We concluded that the health care professionals who attend postmenopausal survivors patients with BC in the real clinical practice, should be aware of that long-term intervention includes care to sexual and psychological UN in the same importance as to the adverse events of treatment.
Risk factors for trastuzumab cardiotoxicity in a cohort of Mexican population

Marytere Herrera-Martínez¹, Pabel A Miranda-Aguirre¹, Luis A Cota-Apodaca¹, Verónica Martínez-Bustos¹, Brenda Carbajal-Saldaña¹, Zuratzi C Deneken-Hernandez¹, Consuelo Díaz-Romero¹, Maria del Mar Y Namba-Bando¹, Carlos A Dominguez-Reyes¹, Juan A Tenorio-Torres¹, Felipe Villegas-Carlos¹ and Bruno Crocco-Quiros¹. ¹Fundación Contra el Cáncer de Mama, Mexico City, Mexico.

BACKGROUND: Advances in chemotherapy and target therapy have made treatment of breast cancer (BC) more effective; however, survivors of BC suffer an increased burden of cardiotoxicity. The aim of this study is to determine the risk factors in a Mexican patients (pt)

METHODS: Observational study of a cohort of pt with locally BC and Her2 (+++) treated with trastuzumab (TZ). According to clinical stage, they underwent to surgery or neoadjuvant chemotherapy, scheme was at the decision of the physician. The main schemes: AC-T, EC-T, FAC-T, FEC-T, Paclitaxel, intravenous (IV) or subcutaneous TZ. The doses were according to NCCN guidelines and the route of administration of TZ was decision of the oncologist. Ventriculography was performed basally, at 4, 8, 12 cycles and at the end of treatment. If the pt presented a decrease in the ejection fraction>10% with/without symptoms, they received cardioprotection (metoprolol+atorvastatin). It was the oncologist decision to suspend chemotherapy as well as TZ.

RESULTS: 97 pt were included from Jan 2017 to Jan 2018, 35% presented cardiotoxicity. The only variables that presented a statistically significant for cardiotoxicity risk were normal weight, neoadjuvant treatment and IV TZ (table 1,2). Only 32.4% of the pt tolerated full doses of cardioprotective drugs. 13% of the pt with cardiotoxicity presented symptoms and 52.9% of the pt did not complete trastuzumab for 1 year

Abreviation: * U Mann-Whitney. The rest were analized with X2 / AC-T: Adriamicin/Cyclophosphamide - Paclitaxel, EC-T: Epirrubicin/Cyclophosphamide - Paclitaxel, FAC-T: Fluorouracil/Cyclophosphamide-Paclitaxel

**DISCUSSION:** This study shows that normal weight and IV TZ is significantly associated with the risk of cardiotoxicity. The observation of our pt will continue to observe this phenomenon in detail.
Exercise and nutrition intervention on breast cancer survivors in Taiwan with BMI 25 or more to decrease BMI and maintain at an appropriate level - A preliminary report

Chia-Ming Hsieh\textsuperscript{1}, Ning-Chiang Yang\textsuperscript{1}, An-Ko Yang\textsuperscript{1} and Chi Tseng\textsuperscript{1}. \textsuperscript{1}Taiwan Adventist Hospital, Taipei, Taiwan.

It has been reported that lifestyle changes after completion of breast cancer treatment may decrease recurrence rate. Lifestyle was formed since childhood, and modified and sustained throughout lifetime. Usually, lifestyle changes are difficult without specific motivation.

Materials and Methods
Breast cancer survivors, aged from 20 to 80 years old with stage I, II, III, who have received surgery and completed courses of chemotherapy within 4 years, were candidates for the study.

According to the American Athletic Association sports guidelines, aerobic, muscular and extension exercises are taught by a sports instructor to the participants, and the participants were asked to exercise at home, 150 minutes a week, 30 minutes each time. Participants were instructed to calculate the calories they needed (25 calories/kg/day). Food selection and diet plan must meet the calories they have calculated, and a diet log was recorded.

The study of one-year diet and exercise intervention study was designed. Group meeting was started at the beginning and then held every 3 months. Measurements of body weight, height, body fat, BMI, waist circumference, muscle mass, and basal metabolic rate were performed; WHO quality of life and brief pain inventory (BPI) were also collected.

Results
A total of 32 breast cancer survivors were recruited, and 20 participants had completed one-year follow-up. Two of the participants withdrew from the study due to personal reasons, and the remaining 18 were included in the statistical analysis.

Body weight, BMI, and body fat decreased after interventions in diet and exercise and reached a significant lower level (p-value = 0.001, 0.002 and 0.01, respectively). In the linear regression model, it could be seen that body weight has a negative correlation with time; the body weight and BMI gradually decreased during the one-year period (\(\beta = -0.327, \text{p-value}=0.005\); \(\beta = -0.362, \text{p-value}=0.002\), respectively). There was no statistically significant change in waist circumference, muscle mass and basal metabolic rate.

BPI at baseline, 17 reported among 20 participants (80\%) and decreased to 11\% (2/18) at after one-year follow-up.

In the quality of life questionnaire, after the score calculation, the single factor repeated measurement analysis (calculated under the statistical power \(\alpha=0.05\)) was used. There was no significant difference and change between the scores after the interventional measures. In the bivariate regression analysis, it was also seen that QOL had not changed due to weight loss, and there was no correlation between the two.

Discussion
This study results demonstrated that lifestyle adjustment can be motivated, and lifestyle can be changed by exercise and diet intervention; however, statistically, quality of life did not change with weight loss.
Mechanical properties of the shoulder and pectoralis major in women undergoing breast conserving therapy with axillary dissection and regional nodal radiotherapy versus sentinel node biopsy and radiotherapy to the breast alone

David B Lipps1, Joshua M Leonardis1, Shira Lehmann1, Robert T Dess1, Gwendolyn McGinnis3, Jonathan B Strauss2, James A Hayman1, Lori J Pierce1 and Reshma Jagsi1. 1University of Michigan, Ann Arbor, MI; 2Northwestern University, Chicago, IL and 3Oregon Health & Science University, Portland, OR.

Background: Breast conserving surgery (BCS) and radiotherapy (RT) reduce the risk of breast cancer recurrence, but can cause various functional deficits in breast cancer survivors. Side effects to the shoulder can include pain, stiffness, and restricted mobility, which are difficult to objectively assess in the clinic.

Methods: The mechanical integrity of the shoulder and the pectoralis major (PM) was assessed in patients at least 1 year post-treatment with BCS and RT. Nine patients with node-negative breast cancer were treated with 2 RT fields to the breast alone after BCS and sentinel node biopsy (Group 1). Nine patients with node-positive breast cancer were treated with ≥3 RT fields to the breast and draining lymphatics after BCS and axillary lymph node dissection (ALND) (Group 2). Nodal RT was delivered to the supraclavicular and infraclavicular (level III axillary) nodes in 9/9 patients, the internal mammary nodes in 6/9 patients, and the full axilla (levels I, II, and III) in 1/9 patient. Nine age-matched healthy controls (mean age 54) with no history of breast cancer or shoulder injury were also examined. The mechanical integrity of the shoulder was objectively quantified using robot-assisted biomechanical measures of shoulder stiffness. The shear elastic modulus, or ‘stiffness’, of the clavicular and sternocostal fiber regions of PM was assessed using ultrasound shear wave elastography. Participants were examined while they were relaxed or actively contracting force with their shoulder muscles. Linear mixed effect models with Bonferroni-corrected multiple comparisons were used to determine if shoulder stiffness or PM shear elastic modulus differed between the two breast cancer groups and controls.

Results: Patients in Groups 1 (mean age 54) and 2 (mean age 57) were an average (SD) 754(111) and 988(163) days since initiating RT (p=0.003). Shoulder stiffness did not differ between the 2 groups and healthy controls (F_{2,27}=0.76, p=0.48). There was a significant group difference in PM shear elastic modulus (F_{2,27}=8.33, p=0.0015), with Group 2 patients exhibiting an average greater stiffness of 14-21% in the sternocostal and 12-28% in the clavicular regions of the PM versus Group 1 patients (p<0.001) and healthy controls (p =0.021). There was no difference between patients treated with Group 1 and controls (p=0.29).

Conclusions: Although power is limited due to small sample size, this study provides the first evidence that the mechanical integrity of the shoulder remains intact in patients who receive ALND combined with a supraclavicular field (generally without full axillary radiotherapy). The observation of altered PM function without subsequent changes to shoulder stiffness in patients treated with ALND and ≥3 RT fields suggests these patients likely develop new neuromuscular strategies to stabilize the shoulder joint to compensate for the PM. Future work is needed to appreciate whether certain muscle strategies are associated with poorer quality of life in breast cancer survivors, and to prospectively monitor the impact of breast cancer treatments on PM mechanical properties.
Quality of life of patients with pregnancy-associated breast cancer

Vesna Bjelic-Radisic1,2, Bernadette Hartmann1, Julia Reisinger1, Elisabeth Trapp1, Christoph Benedicic1, Philipp Klaritsch1, Elisabeth Dunst1, Iva Brcic3 and Karl Tamussino1. 1Medical University Graz, Graz, Austria; 2Helios Universitätsklinik, Wuppertal, Germany and 3Medical University Graz, Institut for Pathology, Graz, Austria.

Background: Breast cancer (BC) is the most common cancer diagnosed during pregnancy and occurs between one in 3000 to one in 10 000 pregnancies. The first international guidelines for the diagnosis and therapy of pregnancy associated BC (PABC) has been developed in 2003. The 5 year survival rate is similar to the non-pregnant women with the same stage of disease. In contrast to the data about the oncological outcome of patients with PABC, the literature about quality of life (QoL) of those patients is lacking. The aim of the study was to investigate the QoL of patients with PABC.

Materials and methods: Patients with PABC diagnosed and treated at our department in the period between 2000 and 2016 were included in the study. Clinical and demographic data were collected from the data base. The QoL was assessed using the EORTC QLQ-C30, the EORTC QLQ-BR 45 and the EORTC SHQ-22. The QoL results were compared with reference data (EORTC Reference Values) of BC patients. Statistical analysis was performed using descriptive statistics and t-test to test the significance.

Results: In the analysed period, twenty-one patients with PABC were found. In 16 patients BC had been diagnosed during the pregnancy and in 5 patients during the first year after delivery. Mean age at the time of diagnosis was 34.24 (SD±3.3), mean pregnancy week 21.14 (SD±10.28), and 8 months (SD±5.0) for patients with the diagnosis in the first year after the delivery. All patients underwent surgery, as well as chemotherapy. In addition, 10 patients received hormonal therapy and 12 irradiation. 16 patients lived at the time of the QoL assessment and received the QoL questionnaire per mail. After the mean follow up of 5.2 years, there were no statistically significant differences in EORTC QLQ C30 scales between our population and reference data except for constipation which a better score in our population. Clinical relevant differences were found in scales: physical functioning, role functioning and symptom dyspnea with the better score in our population. Our patients reported clinical relevant more financial difficulties. In the disease specific questionnaire EORTC BC 45, patients with PABC showed statistically significantly worse score in the following scales: body image, upset by hair loss, side effects of the systemic therapy and future perspective. 40% of the patients had a decreased libido and 37% of patients reported that therapy negatively impaired sexual activity. 25% of patients reported that they fill less feminine because of the disease.

Conclusion: The results revealed that QoL in patients with PABC is more impaired compared to the overall QoL reference data of BC patients. Despite the small number of patients, the results indicate that PABC patients are a vulnerable group, especially regarding outer appearance (body image, upset by hair loss, fill les feminine). The QLQ BR 45 showed more sensitivity to assess the impact on QoL of these patients than EORTC QLQ C30 and underlines the necessity to use disease-specific questionnaires in specific patient populations.
Final results of the ASG1-3 study, a randomized phase III study comparing a standard dose chemotherapy with epirubicin/cyclophosphamide and paclitaxel with a dose dense regimen with epirubicin and paclitaxel.

Background
Dose dense chemotherapy (DDT) has shown improvements of disease-free survival (DFS) and overall survival for primary breast cancer patients with a high risk of relapse. There are much less data about the effect of DDT in patients with intermediate risk of recurrence (1-3 positive axillary lymph nodes). Aim of this prospectively randomized trial was to investigate the superiority of a DDT schedule over a standard chemotherapy (ST) in primary breast cancer patients with 1-3 positive axillary lymph nodes.

Methods
The ASG1-3 study is a prospectively randomized, open label phase III study of the Adjuvant Study Group of the NOGGO association. Patients were eligible for the trial, if they had a primary invasive breast cancer (pT1-3) with 1-3 positive axillary lymph nodes and no evidence of distant metastases. Patients were randomized to an adjuvant therapy with either 4 cycles epirubicin (90mg/m² body surface area, BSA) and cyclophosphamide (600mg/m² BSA) q3w, followed by 4 cycles of paclitaxel (175mg/m² BSA) referred to as ST or to a therapy with 4 cycles of epirubicin (120 mg/m² BSA) q2w and primary G-CSF support followed by 4 cycles of paclitaxel (175mg/m² BSA) q2w and primary G-CSF support referred to as DDT. Trastuzumab was not given in this study. The study was designed to show an increase of 70% DFS (ST) to 80% DFS (DDT) 5 years after randomization. Comparisons were conducted using Kaplan Meier estimates, log rank tests and Cox regression analyses. In an exploratory way, subgroup analyses were performed for HER2, hormone receptor status and grading using Cox regression models with interaction terms.

Results
A total of 936 patients were eligible for survival analysis, of which 465 were randomized to ST and 471 to DDT from 2001 to 2004. Patient characteristics were mainly well balanced, with patients being 52.5/52.1 years old, 71.9/78.1% being hormone receptor positive, 24.4/24.6% being HER2 positive and 38.6/38.8% having a tumor grade of 3 in the ST arm and DDT arm respectively. 53 events occurred after ST and 46 after DDT. Adjusted hazard ratio (HR) was 0.87 (95%CI: 0.57-1.35; p=0.54). 5 year DFS rates were 85% (ST) vs. 87% (DDT). Hematological toxicities were the most common grade 3 or 4 adverse events. Grade 3/4 neutropenia occurred in 57.2 vs. 28.0%, grade 3/4 anemia in 15.3% vs. 17.1% and grade 3/4 pain symptoms were seen in 13.2 vs. 12.4% of the patients in the ST arm vs. DDT arm respectively. Other grade 3/4 toxicities were less frequent than 10%.
Subgroup analysis showed a significant interaction (p<0.001) between HER2 status and randomization arm with regard to DFS. In HER2 negative patients the HR was 1.53 (95%CI: 0.91-2.59), whereas in HER2 positive patients the HR was 0.22 (95%CI: 0.09-0.55). Patients with HER2 positive disease and DDT had a similar prognosis like HER2 negative patients.

**Conclusion**
In the overall population a statistically significant improvement of DFS could not be shown for the DDT arm. In patients with HER2 positive breast cancer DDT chemotherapy improved the disease-free survival to a prognosis which was similar to patients with HER2 negative disease.
Real world outcomes of adjuvant FECD, ddACT and ACT for the treatment of early stage breast cancer - A multicenter retrospective analysis

Nathalie LeVasseur¹, Zachary Veitch²,³, Rekha M Diopee⁴, Lovedeep Gondara⁴, Winson Cheung², Omar Khan², Rachel Cossetti¹, Karen A Gelmon¹, Karen King¹, Sasha Lupichuk², Stephen K Chia¹, Patricia Tang⁴ and Christine Simmons¹. ¹British Columbia Cancer Agency, Vancouver, BC, Canada; ²Tom Baker Cancer Centre, Calgary, AB, Canada; ³Princess Margaret Cancer Centre, Toronto, ON, Canada; ⁴Breast Cancer Outcomes Unit, British Columbia Cancer Agency, Vancouver, BC, Canada and ⁵Cross Cancer Institute, Edmonton, AB, Canada.

Background: Adjuvant chemotherapy combining anthracyclines and taxanes for early stage breast cancer (ESBC) have demonstrated disease-free survival (DFS) and overall survival (OS) benefits. Among the 3rd generation regimens, 2 options have been favoured: FEC-Docetaxel (FECD) and AC-Paclitaxel (ACT). ACT may be delivered with dose-dense (ddACT) or weekly taxane scheduling (ddACWT), compared to traditional every 3-weekly (q3ACT) scheduling. Despite literature supporting both FECD and (dd)ACT regimens in the management of ESBC, no direct prospective trial has evaluated their comparative effectiveness.

Methods: A retrospective review of the BC Cancer Breast Cancer Outcomes Unit (BCOU) and the Alberta Health Services (AHS) databases was performed to identify patients with HER2 negative, stage 1-3 ESBC, who received adjuvant chemotherapy between 2007-2014. The primary endpoint was OS and the secondary endpoint was RFS, defined as freedom from local (invasive), regional or distant recurrence or breast cancer death. Outcome comparisons were made between FECD, ddACT/ddACWT and q3ACT using the Kaplan Meier method. Treatment arms were compared using a log-rank test for univariate analysis. A multivariate analysis was also conducted for OS comprising age, stage, grade, receptor status and type of chemotherapy received (FECD vs combined ACT group).

Results: A total of 4047 patients met inclusion criteria, including 2685 FECD, 1259 ddACT and 103 ACT. Median age was 53 (24-77) in the FECD group vs 52 (26-68) in the ddACT/ddACWT group and 58 (43-78) in the q3ACT group. The majority had stage 2 disease, 51.3%, 53.5% and 50.5% in the FECD, ddACT/ddACWT and q3ACT groups, respectively. Most were HR+, 84.5% in the FECD group vs 66.9% in both the ddACT/ddACWT and q3ACT groups. In the FECD group, 42.8% had a grade 2 tumour and 48.2% a grade 3 tumour vs 35.4% and 56.4% in the ddACT/ddACWT group and 35.0% and 58.3% in the q3ACT group. Lymphovascular invasion (LVI) was present in 40.7% of patients who received FECD vs 39.7% for ddACT/ddACWT and 26.2% for ACT. 5-year OS, for the FECD group was 90.3% (95%CI 89.1,91.4) vs 87.0% (95%CI 84.3,89.2) for the ddACT/ddACWT and 84.9% (95%CI 84.3,89.2) for the q3ACT group, p=0.0907. 5-year RFS was 85.5% (95% 84.0-86.8) with FECD vs 84.4% (95% 81.9,86.6) for ddACT/ddACWT and 87.7% (95%CI 79.2,92.8) with q3ACT,p=0.4200. In multivariate analysis: age, stage and grade were significantly associated with OS whereas type of chemotherapy received (FECD vs ACT) was not (p=0.165). Finally, OS rates were compared across provinces and no significant differences were identified, 87.0% vs 88.0% (p=0.6294). Subgroup analyses by receptor type, comparing HR+ and TNBC are ongoing.

Conclusions: The use of FECD as compared to ACT based chemotherapy did not reveal significant differences in OS or RFS in this population-based study. Further, chemotherapy regimen was not associated with differences in overall survival, as compared to other well recognized prognostic factors. While the results were obtained from a retrospective analysis, conclusive prospective data is lacking. These results may therefore reassure physicians and patients alike on a comparable efficacy of these regimens in a real-life setting.
Grade of leukopenia predicts treatment effect in early breast cancer in patients treated with tailored epirubicin/cyclophosphamide chemotherapy

Henrik Lindman¹, Paula Poikonen-Saksela², Johan Ahlgren³, Michael Andersson⁴, Jonas Bergh⁵ and Carl Blomqvist⁶. ¹Uppsala University, Uppsala, Sweden; ²Comprehensive Cancer Center, Helsinki University Hospital and University of Helsinki, Helsinki, Finland; ³Regional Cancer Centrum Uppsala-Örebro, Uppsala, Sweden; ⁴Rigshospitalet, Copenhagen, Denmark; ⁵Radiumhemmet, Karolinska Institutet, Karolinska University Hospital, Stockholm, Sweden and ⁶Örebro University Hospital, Örebro, Sweden.

Background: Body surface based dosing of chemotherapy is unreliable due to marked inter-individual variations in pharmacokinetics/dynamics. Multiple retrospective studies have demonstrated that hematological toxicity could be a surrogate marker for efficacy of chemotherapy. The SBG 2000-1 trial was the first adjuvant randomized trial designed to compare the same drugs and number of courses of individually dosed chemotherapy based on grade of toxicity vs. standard dosed chemotherapy in early breast cancer. The aim was to study the relations between dose of chemotherapy, leukopenia nadir grade and prognosis.

Methods: Women (n=1452) in Sweden and Denmark with early breast cancer aged 18-60 years, received the first cycle at a standard dose of FEC (fluorouracil 600 mg/m², epirubicin 60 mg/m², cyclophosphamide 600 mg/m²). Patients (n=1052) with nadir leukopenia grade 0-2 after first cycle were randomized between either 6 tailored FEC with increased doses of epirubicin and cyclophosphamide aimed at achieving grade 3 leukopenia or treatment with 6 standard FEC. Patients with nadir leukopenia grade 3-4 represented a second control group (registered group) treated with 6 standard FEC. Dose escalation did not significantly improve 10 year distant disease-free survival (HR 0.87, p=0.32, Eur J Cancer 13:79-86, 2018). In this report grade of leukopenia at course 3 (after final escalation) was assessed as a prognostic marker in a Cox regression model adjusted for chemotherapy doses.

Results: Eight-year distant disease-free survival (DDFS) was 73%, 77%, 78% and 83% for patients with leucocyte nadir grade 0, 1, 2 and 3-4 and overall survival (OS) 77%, 81%, 81% and 86% respectively. Cox regression analysis of leucocyte grade and DDFS showed a statistically significant hazard ratio (HR) of 0.84 (CI 0.74-0.96, p=0.008) per grade of leukopenia, with non-significant trend for OS (HR 0.88, CI 0.76-1.02, p=0.066). The correlations with DDFS and cumulative dose of epirubicin and cyclophosphamide were not significant with hazard ratios of 0.96 (0.91-1.014 p=0.15) and 1.002 (1.00-1.005 p=0.21) per mg cumulative dose per meter squared. Patients with grade 3 tumors had a significantly stronger impact of leukopenia on DDFS (HR 0.76, 95% CI 0.65-0.90 p<0.001) and a test of interaction between the prognostic effect of grade and leukopenia was significant (p=0.026).

Conclusions: The grade of leukopenia predicts the individual treatment effect better than chemotherapy doses. The results of this prospective trial are in agreement with previous retrospective studies indicating that chemotherapy induced leukopenia is predictive for outcome in early breast cancer. Dose dependent toxicity should be monitored for optimal adjustment of the dosage of chemotherapy.
Efficacy of adjuvant 5-Fluorouracil in residual HER2-negative breast cancer following neoadjuvant chemotherapy

Nicci Owusu-Brackett¹, Stephen Scott¹, Erkan Yuca¹, Kurt W Evans¹, Coya Tapia² and Funda Meric-Bernstam¹. 'MD Anderson Cancer Center, Houston, TX.

Background: Patients with residual disease following neoadjuvant chemotherapy have an increased risk of relapse. Recently the CREATE-X trial demonstrated that adjuvant capecitabine (oral prodrug of 5′deoxy-5-fluorouridine), prolonged disease-free survival and overall survival among patients with HER2-negative breast cancer who had residual invasive disease after neoadjuvant chemotherapy containing anthracycline, taxane, or both. Therefore, we sought to evaluate the antitumor efficacy of 5-fluorouracil (5-FU) in patient-derived xenografts (PDXs) from residual tumors resistant to neoadjuvant chemotherapy.

Methods: Antitumor efficacy of 5-FU was assessed in vivo in three PDXs varying in hormone receptor status (0, 4% and 11% respectively), generated from residual tumors of primary breast cancer patients treated with neoadjuvant chemotherapy containing anthracycline, and taxanes. In addition, significance of timing of therapy was also assessed, comparing efficacy of initiating treatment upon implantation (immediate start cohort; mimicking treating residual disease with adjuvant therapy), with initiating treatment upon establishment of PDX (standard start cohort).

Results: 5-FU was efficacious in established PDX models that are triple negative (0% ER; p< 0.0001), low ER positive (4% ER, p=0.0213) and ER-positive (11% ER; p= 0.0390), decreasing growth compared to the cohort. However, there was no statistically significant difference between the immediate start cohort and standard start cohort. Western blot analysis of the treatment-naïve derived mouse tumors recognized RB as a predictive biomarker for 5-FU response.

Conclusion: 5-FU has anti-tumor activity in residual HER2-negative PDX models resistant to taxanes, and anthracyclines in the neoadjuvant setting.
Efficacy and safety of eflapegrastim confirmed in reducing severe neutropenia in breast cancer patients treated with myelosuppressive chemotherapy in the second Phase 3 randomized controlled multinational trial compared to pegfilgrastim (RECOVER trial)

Lee Schwartzberg¹, Gajanan Bhat², Klara Mezei³, Istvan Lang⁴, Yong Wha Moon⁵, Lasika Senviratne⁶, Shanta Chawla², Patrick Cobb⁷ and Zane Yang². ¹West Cancer Center, Germantown, TN; ²Spectrum Pharmaceuticals, Irvine, CA; ³Szabolcs-Szatmár-Bereg Megyei Korhaz ak Egyetemi Oktási Korház, Onkológiai Osztálly, Nyíregyháza, Hungary; ⁴Országos Onkológiai Intezet, “B” Belgyogyászati Onkológiai Osztaly, Budapest, Hungary; ⁵Cha Bundang Medical Center, Seongnam, Republic of Korea; ⁶Los Angeles Hematology and Oncology Medical Group, Los Angeles, CA and ⁷St Vincent Frontier Cancer Center, Billings, MT.

Background:
Eflapegrastim is a novel investigational biologic comprised of recombinant human G-CSF covalently linked to the human immunoglobulin G4FC fragment using proprietary LAPSCOVERY™ technology with potentially unique distribution to areas rich in FcRn receptors. RECOVER is the second Phase 3 study to investigate the non-inferiority (NI) of eflapegrastim to pegfilgrastim in patients receiving chemotherapy for breast cancer. The first Phase 3 study, ADVANCE, has demonstrated the non-inferiority of eflapegrastim comparing to pegfilgrastim in the duration of severe neutropenia (DSN) in breast cancer patients receiving docetaxel and cyclophosphamide (TC) and was previously published at ASCO 2018 meeting.

TrialDesign:
Patients with Stage I to Stage IIIA breast cancer from centers in the USA, Canada, Poland, Hungary, South Korea and India were treated on Day 1 of each of four 21-day cycles with adjuvant or neo-adjuvant TC. On Day 2 of each cycle, patients received a single subcutaneous dose of either eflapegrastim 13.2 mg/0.6 mL (equivalent to 3.6 mg G-CSF) or pegfilgrastim (6 mg) in a 1:1 ratio. Patients had CBCs drawn on Day 1 prior to chemotherapy and Days 4-15 daily or until recovery of neutropenia in Cycle 1. CBC was also collected on Days 1, 4, 7, 10 and 15 in Cycles 2-4. The primary endpoint was to demonstrate the non-inferiority (NI) of eflapegrastim comparing to pegfilgrastim in the duration of severe neutropenia (DSN) in breast cancer patients receiving docetaxel and cyclophosphamide (TC) and was previously published at ASCO 2018 meeting.

Results:
In a total of 237 intent-to-treat patients (randomized to 118 eflapegrastim; 119 pegfilgrastim), median age was 59 years (range 29 to 88 years); mean (SD) DSN was 0.31 (0.688) days for eflapegrastim and 0.39 (0.949) days for pegfilgrastim, demonstrating the non-inferiority (95% CI of ΔDSN: [-0.292, 0.129]; p<0.0001). Non-inferiority of eflapegrastim for DSN was maintained across all 4 cycles. There were no statistically significant differences in secondary endpoints: time to ANC recovery, depth of ANC nadir and incidence of FN at Cycle 1. The common Grade 3/4 adverse events observed in ≥5% of patients were similar across both arms and were mainly hematologic including neutropenia, lymphopenia, anemia and leukopenia. Grade 3/4 bone pain and febrile neutropenia rates were similar across both arms and were less than 5%.

Conclusions:
Eflapegrastim, a novel long acting G-CSF demonstrated non-inferiority to pegfilgrastim in the reduction of DSN in breast cancer patients treated with TC and has validated the results from the first Phase 3 ADVANCE study. Eflapegrastim was safe and well-tolerated with a similar safety profile to pegfilgrastim.
Exploring the real-life incidence of toxicities amongst obese breast cancer patients receiving adjuvant chemotherapy dosed based on absolute body weight

Laura L Tam¹, Benjamin Mcguigan¹, Anita Connor¹, Suzanne Allan¹ and Jasotha Sanmugarajah¹. ¹Gold Coast University Hospital, Gold Coast, Queensland, Australia.

Background:
Obesity is an established risk factor for developing breast cancer and is also a negative prognostic indicator for higher recurrence risk.¹ Adjuvant chemotherapy reduces the likelihood of metastatic recurrence and improves disease-free and overall survival.² However, the practice of optimal dosing of adjuvant breast cancer chemotherapy amongst obese patients remains contentious with concerns regarding excessive toxicity if obese patients are dosed based on actual body weight (ABW).²-⁴ A 2014 study reported that obese patients were five times more likely to have dose reductions in cycle 1 than non-obese patients.⁵ Inadequate dosing amongst obese breast cancer patients may have deleterious implications on ultimate prognosis.²-⁴ This study aimed to investigate whether chemotherapy dosing using ABW in obese breast cancer patients is associated with comparable incidences of toxicity.

Methods:
A retrospective cross-sectional study was conducted amongst 257 patients (aged ≥18) treated in the adjuvant setting with doxorubicin-cyclophosphamide-paclitaxel (AC-P) or docetaxel-cyclophosphamide (TC) with/without trastuzumab between 2014 and 2017. Obesity was classified as a body mass index (BMI) of ≥30, with morbid obesity defined as a BMI ≥35. Chemotherapy dosing based on body surface area calculated using ABW was considered the standard protocol with any variations from this dosing method for cycle 1 being recorded. Subsequent dose adjustments were also noted. The primary outcome was tolerability of chemotherapy regimens dosed using ABW with outcome measures of toxicity defined as the incidence of febrile neutropaenia, the incidence of grade 3 or 4 non-haematological toxicities and the number of hospitalisations during the treatment course.

Results:
257 patients were eligible (1 male, 256 females). Median age was 55 (range, 31-78). AC-P was the most commonly used regimen (48.6%), followed by TC (40.1%). Obesity and morbid obesity were noted amongst 17.9% and 15.6% of patients respectively; with 63.8% with a BMI ≥25. Chemotherapy dosing was largely based on ABW, with only 4.3% of patients dosed based on ABW or had their dosing body surface area capped at 2.0m². In patients with a BMI ≥25, 25% had febrile neutropaenia compared to 21.8% in those with normal BMI (p=0.58). Incidence of febrile neutropaenia during treatment by BMI – underweight: 33.3% (p=0.61); normal: 24.1%; overweight: 24.4% (p=0.97); obese: 17.4% (p=0.37); morbidly obese: 25%(p=0.92). Grade 3-4 non-haematological toxicities had comparable incidences between the normal BMI group as opposed to the overweight/obese group (23.0% vs 18.9% respectively, p=0.44). Hospitalisations by BMI - underweight: 50% (p=0.85); normal BMI: 46%; overweight: 42.3% (p=0.64); obese: 54.3%(p=0.36); morbidly obese: 57.5%(p=0.23).

Conclusion:
This study demonstrates that obese breast cancer patients do not experience higher toxicities when their adjuvant chemotherapy is dosed based on ABW. This supports current guidelines for dosing amongst obese patients.
Effect of adjuvant chemotherapy for patients with ER-positive/HER2-negative breast cancer assessed by the propensity score matching: Significance of nuclear grade and nodal status

Natsuko Tanaka, Kaoru Ogura, Mari Kamimura, Akinori Hattori, Hiroaki Inoue, Hiroko Yukawa, Shiho Sakaguchi, Aya Matsuoka, Asaka Kodera and Akira Hirano. Tokyo Women’s Medical University Medical Center East, Tokyo, Japan.

Purpose: Although a survival benefit with chemotherapy (CT) is obtained over all among patients with estrogen receptor-positive (ER+) breast cancer, the degree of benefit differs among the subtypes. The 21-gene Recurrence Score assay is a validated prognostic/predictive tool for early ER+ breast cancer. However, genomic assays have not been approved in Japan and most other countries, except in some developed countries. Based on the St. Gallen 2015, 1-3 positive nodes are not an absolute indication for CT among patients with ER+/HER2-negative breast cancer. In contrast, it is better for CT to be performed except for low-risk groups, based on genomic tests according to the St. Gallen 2017. In fact, no prospective study has proven the survival benefit of CT specifically for luminal-A breast cancer. Therefore, we analyzed the survival benefit of CT for ER+/HER2-negative breast cancer by propensity score matching (PSM).

Patients and methods: Between 2000 and 2015, 895 patients with stage I-III ER+/HER2-negative breast cancer who had undergone surgery in our hospital were examined. Patients with bilateral breast cancer, ER<10%, and preoperative treatment were excluded. The primary end point was the 5-year recurrence-free survival (RFS) and overall survival (OS) in patients matched by propensity score that estimated by a logistic regression model that included factors likely to influence the decision of whether or not to administer CT (tumor size, nuclear grade [NG], progesterone receptor status and nodal status).

Results: In the entire cohort, the median age was 59 (28-95) years; 223 patients (24.9%) were node positive and 126 patients (14.1%) had NG3 disease. Overall, all patients received endocrine therapy, and 24.1% received additional CT. After a median follow-up of 68.8 months, the 5-year RFS rate was 94.3% in CT-untreated patients (non-CT group) and 90.1% in CT-treated patients (CT group; hazard ratio [HR] for recurrence, 1.47; 95% confidence interval [CI], 0.90-2.33; p=0.106). The 5-year OS rate was 97.5% in the non-CT group and 95.6% in the CT group (HR for death, 1.80; 95% CI, 0.99-3.21; p=0.047). Using PSM, 236 patients were selected (1:1 matching between non-CT and CT groups). After matching, the 5-year RFS rate was higher in the CT group than in the non-CT group (96.8% vs. 82.7%; HR for recurrence, 0.29; 95% CI, 0.11-0.68; p=0.003), and the 5-year OS rate was higher in the CT group than in the non-CT group (100% vs. 91.9%; HR for death, 0.06; 95% CI, 0.003-0.35; p<0.001). Among PSM patients, with node-negative/NG3 and 1-3 node positive/NG2 disease, the 5-year RFS rate was significantly higher in the CT group than in the non-CT group (p=0.041 and p=0.006, respectively).

Conclusion: No significant benefit of CT was observed when considering the entire cohort because of the treatment bias. When clinical and tumor features were matched by propensity score, the addition of CT significantly improved both RFS and OS of ER+/HER2-negative breast cancer patients, especially for patients with node-negative/NG3 and 1-3 node positive/NG2 disease.
A prospective non-randomized clinical trial of adjuvant carboplatin chemotherapy in triple negative breast cancer

Caroline Hamm1,2, Swati Kulkarni1,2, Rasna Gupta1,2, John Mathews1, Kay Amin1, Abdulkadir Hussein1 and Lisa Porter2. 1Schulich School of Medicine, Windsor, ON, Canada and 2University of Windsor, Windsor, ON, Canada.

Background: The addition of carboplatin in the neoadjuvant setting has demonstrated improved outcomes in patients with triple negative breast cancer (TNBC). Carboplatin in the adjuvant setting has not been demonstrated to be an accepted regimen to date. This trial addresses this issue.

Methods: The primary objectives of this study were to assess the toxicity of an adjuvant carboplatin-containing regimen for early stage TNBC patients, and to correlate outcomes with molecular markers including Spy-1. Secondary objectives included determination of progression free (PFS) and overall survival (OS), and comparing these to our institutional historical controls. Patients received the backbone of a dose dense anthracycline, taxane, cyclophosphamide (DD ACT), with the addition of carboplatin.

Results: Ninety patients with stage I to III patients with triple negative breast cancer were accrued to this trial between Jan 2011 and June 2017. We discovered that DD ACT with carboplatin with an AUC of 5 given on the second and last paclitaxel was well tolerated. Chemotherapy delays were minimized when the parameters for administration of the carboplatin was to allow chemotherapy to proceed if the platelet count was >/= 70,000 x10^9/L and dose adjustment of paclitaxel was allowed based on neuropathy. There were no grade 4 adverse events. 4% of patients had grade 3 peripheral neuropathy (PN), 28% had grade 2 PN and 45% had grade 1 PN. Results of molecular profiles will be reported. Univariate analysis are reported, and were found to be very promising. Using log-rank statistic, a trend to improvement in overall survival was found when compared to historical controls (p=0.089). Median follow-up is 24 months. Longer follow-up is necessary to determine PFS and overall survival benefit. Conclusion: If considering an adjuvant regimen for triple negative breast cancer patients DDAC/TC with the carboplatin administered with an AUC of 5 on the second and fourth taxol of DDACT is a well-tolerated regimen.

Long-term follow-up of two randomized controlled trials (N-SAS-BC01 trial and CUBC trial) comparing oral tegafur-uracil (UFT) versus classical cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) as adjuvant therapy in early breast cancer

Kan Yonemori1, Shozo Ohsumi2, Shintaro Takao3, Yutaka Tokuda4, Yoshihori Ito5, Kazuhiro Nakagami6, Masato Takahashi7, Katsuhide Yoshidome8, Takahiro Nakayama9, Yasunobu Yamaguchi10, Yasuo Ohashi11, Hideo Inaji12 and Toru Watanabe13.

Background: Two randomized controlled trials comparing the efficacy of oral tegafur-uracil (UFT) (2 years) with that of classical cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) (6 courses) were conducted in patients with resected early breast cancer. UFT is an oral fluoropyrimidine that combines tegafur, a prodrug of 5-fluorouracil, with uracil in a 1:4 molar ratio. One study was the N-SAS-BC01 trial (Watanabe et al, J Clin Oncol 2009), which was conducted in patients with high-risk node-negative breast cancer (n=733). The other was the CUBC trial (Park et al, Br J Cancer 2009), which was performed in patients with node-positive breast cancer (n=377). We reported the pooled analysis of these two randomized control trials using individual patient data (Ohashi et al, Breast Cancer Res Treat 2010). This pooled analysis showed that UFT was non-inferior to CMF in terms of inhibiting recurrence of estrogen receptor (ER)-positive early breast cancer. In addition, an exploratory subgroup analysis showed that UFT may be more effective in ER-positive patients who were 50 years or older. The present study was conducted to investigate the long-term efficacy of UFT or CMF in patients with early breast cancer.

Methods: Long-term follow-up data for disease recurrence and survival were collected. Hazard ratios (HR) were determined using the Cox model stratified by study and adjusted for clinical characteristics, namely age, tumor size, nodal status, histological type, ER, and progesterone receptor (PgR). Survival curves were estimated by the Kaplan-Meier method. Hochberg multiplicity adjustment was applied in the previous pooled analysis, and non-inferiority of UFT versus CMF was shown in terms of relapse-free survival (RFS) in the ER-positive patient group. We investigated the non-inferiority of UFT in the same patient group with updated data. Restricted mean survival time (RMST) was calculated to consider the relative efficacy of UFT. This study is registered with JapicCTI-163321.

Results: In total, 1,057 patients were analyzed (CMF, n=528; UFT n=529). The median follow-up time was 11.1 years (12.1 years in the N-SAS-BC 01 trial and 8.3 years in the CUBC trial). Table 1 shows the 10-year RFS and overall survival (OS) in all patients and ER-positive patients.

Comparison of overall and recurrence-free survival between four and six cycles of adjuvant docetaxel and cyclophosphamide in early stage breast cancer

Inderjit Mehmii, Charles E Wighti and Jordan L Hilli. 1West Virginia University Medicine, Morgantown, WV.

Background: The ABC trials and the WSG Plan B trial demonstrated that certain early stage breast cancer patients can be appropriately treated with docetaxel and cyclophosphamide (TC) rather than doxorubicin and cyclophosphamide (AC); however both of these trials utilized six cycles of TC as the comparator. TC is given for 4 cycles based on the US Oncology 9735 trial. To our knowledge, there is no available data that has compared adverse events or outcomes of four versus six cycles of TC.

Methods: This was a single-center, retrospective study evaluating recurrence-free survival, overall survival, and occurrence of toxicities between four and six cycles of docetaxel and cyclophosphamide adjuvant chemotherapy for early stage breast cancer at West Virginia University Cancer Institute.

Results: 112 patients were included; 81 received four cycles and 31 received six. Recurrence free survival rates of patients that received four and six cycles of chemotherapy were 94% and 90%, respectively, at three years (P=0.68). Overall survival at three years was 99% versus 97% (P=0.49), respectively. The incidence of peripheral neuropathy requiring treatment was 42% in patients that received six cycles and 19% in patients that received four (P=0.015).

Conclusion: The addition of two cycles of docetaxel and cyclophosphamide adjuvant chemotherapy for early stage breast cancer provides no additional recurrence-free or overall survival benefit but does increase the incidence of peripheral neuropathy requiring treatment.

Optimal omission of anthracycline in adjuvant chemotherapy of HER2 positive breast cancer

Rurina Watanuki, Tetsu Hayashida, Kawai Yuko, Masayuki Kikuchi, Ayako Nakashoji, Takamichi Yokoe, Tomoka Toyota, Tomoko Seki, Maiko Takahashi and Yuko Kitagawa. Keio University School of Medicine, Tokyo, Japan.

Background In adjuvant settings of HER2 positive cancer, trastuzumab has been shown to be effective in combination with anthracycline-based chemotherapy followed by taxane-based chemotherapy. However, the role of anthracyclines for the treatment of breast cancer has remained in controversy, due to the increased risk of cardiotoxicity and secondary carcinogenesis. Recently, additional anthracycline-free treatment regimens have also been reported. In a single-arm multicenter trial of 406 patients treated with paclitaxel plus trastuzumab for <3cm, lymph node negative, HER2 positive breast cancer, Tolaney et al reported a 98.7% rate of survival free from invasive disease at 3 years of follow-up (NEJM 2015). NCCN guideline 2018 suggests paclitaxel plus trastuzumab to be considered for patients with low-risk T1, N0, M0, HER2 positive breast cancer. However, there is a lack of definitive evidence for anthracycline-free regimens in adjuvant chemotherapy of HER2 positive cancer. We performed a single-center retrospective cohort study to assess the characteristics of patients we can safely omit anthracyclines in the adjuvant settings for HER2 positive breast cancer.

Patients and methods 238 women were diagnosed with HER2 positive breast cancer and treated with neoadjuvant and/or adjuvant chemotherapy between January 1, 2008 and December 31, 2015 at Keio University Hospital. They were divided in two cohorts: an “anthracycline” cohort of 112 anthracycline-treated women and a “no anthracycline” cohort of 126 anthracycline-untreated women.

Results Three years disease free survival (DFS) was 91.3% (95% CI, 84.0%–95.4%) and 93.1% (95% CI, 86.1%–96.7%) in the no anthracycline and anthracycline cohorts, respectively. There were no significant differences between the two cohorts (P=0.692). Among the cT1N0 subset, no significant differences were observed between two cohorts in 3 years DFS (P=0.612). However, the patient characteristics of the cT2 subset were not balanced enough to compare the two cohorts. Of the 238 patients, 122 received neoadjuvant chemotherapy and 36 (29.5%) of them achieved pathological complete response (pCR). Among the pCR group, only one patient in each cohort had recurrence.

Discussion We suggest that we can safely omit anthracyclines in cT1N0 HER2 positive breast cancer patients and also in patients who achieved pCR by neoadjuvant chemotherapy. However, we need a larger number of cases to assess the possibility of omission in cT2 HER2 positive breast cancer. Current clinical trials indicate the addition of pertuzumab to trastuzumab for neoadjuvant and adjuvant chemotherapy in HER2 positive breast cancer leads to a good pCR rate and increase the efficacy of anti HER2 block therapy. We expect that the additional use of pertuzumab with trastuzumab will widen the possibility of anthracycline-free adjuvant chemotherapy in HER2 positive cancer.
Final results of NorBreast-231, a randomized phase II study evaluating weekly oral vinorelbine versus weekly paclitaxel as first-line chemotherapy in patients with advanced breast cancer

Matti S Aapro¹, Roberto Hegg², Manuel Ruiz Borrego³, Elzbieta Staroslawska⁴, Serafin Morales⁵, Saverio Cinieri⁶, Ruffo De Freitas Junior⁷, Laura Garcia Estevez⁸, Eva Szombara⁹, Helene Hervieu¹⁰, Melanie Groc¹⁰ and Gustavo R Villanova¹⁰. ¹Breast Center, Genolier Cancer Center, Genolier, Switzerland; ²Hospital Perola Byington, Sao Paulo, Brazil; ³Hospital Virgen del Rocio, Seville, Spain; ⁴Oncology Center, Lublin, Poland; ⁵Hospital Arnau de Vilanova, Lleida, Spain; ⁶Ospedale A. Perrino, Brindisi, Italy; ⁷Hospital Universitario Araujo Jorge, Goiania, Brazil; ⁸Hospital San Chinarro, Madrid, Spain; ⁹Marie Curie Oncology Center, Warsaw, Poland and ¹⁰Pierre Fabre Medicament, Boulogne-Billancourt, France.

Background: Single-agent chemotherapy (CT) is the standard treatment option in endocrine receptor (ER)-positive advanced breast cancer (ABC) after failure of endocrine therapy (ET) or in patients (pts) without visceral crisis. Both weekly paclitaxel (WP) and oral vinorelbine (OV) are among the recommended treatment options in this setting. The aim of this study was to evaluate the efficacy and safety profiles of OV and WP in a face to face study.

Material and methods: Pts with ER-positive, HER2-negative ABC, with an age ≥18 years and with a documented locally recurrent or metastatic involvement previously untreated by CT were eligible. Pts were randomized to receive, as first-line CT, 3 weekly-cycles of either: ARM A: weekly OV, given as a 80 mg/m² dose (following a first cycle at 60 mg/m², dose escalation to 80 in the absence of grade 3 or 4 toxicity at cycle 1); ARM B: WP 80 mg/m² per week. Primary endpoint was disease control rate (DCR). Pts were stratified according to prior taxane CT and visceral metastases.

Results: 131 pts have been treated (OV: 66, WP: 65). Baseline pts characteristics (Arms OV/WP): median age 58/61 years; median number of prior ET: 2/2; prior (neo) adjuvant CT 74/72%; prior anthracycline 67/62%; prior taxane: 41/42%; >3 metastatic sites 42/48%; visceral metastases 79/79%. Median number of cycles (range): 6(1-55)/7(1-44); dose escalation of OV was performed in 75% of pts. Safety: most common non-hematological related G3/4 adverse events per pt were fatigue 8/2%, peripheral neuropathy 0/5%, nausea 3/0%, diarrhoea 3/2%, vomiting 3/0%, constipation 3/2%, alopecia (G2) 2/34%, no toxic deaths; febrile neutropenia was present in 2/0% of pts. Quality of life: over time, no major differences between both arms have been observed. Efficacy: DCR in the intent-to-treat population was [95%CI] 75.8 [63.6-85.5] /75.4 [63.1-85.2]%; overall response rate 20/40%; median progression-free survival: 5.5/6.4 months. Median overall survival was: OV 27.6/WP 22.3 months.

Conclusion: Both OV and WP reached similar DCR rates of 75%. Each regimen presented a specific tolerance profile, with, in particular, a lower incidence of alopecia and peripheral neuropathy with OV. OV and WP are valid first-line CT options for ER-positive/HER2-negative pts with ABC.
A phase 2 study of low dose metronomic eribulin in metastatic breast cancer

Pavani Chalasani¹, Alex J Liu¹, Jonathan A Khanjian², Madelyn Peha³, Barbara J Buening², Vijayakrishna K Gadi³, Jennifer M Specht³, Lupe Salazar³ and Hannah M Linden³. ¹The University of Arizona Cancer Center, Tucson, AZ; ²Seattle Cancer Care Alliance, Seattle, WA and ³University of Washington, Seattle, WA.

Background: Eribulin mesylate is a non-taxane microtubule dynamics inhibitor approved by FDA in treatment of metastatic breast cancer (MBC) based on improvements in overall survival in the pivotal EMBRACE trial. Eribulin is approved at 1.4mg/m² administered D1,8 of q21d cycle. However, this dose and schedule may have significant myelosuppression and peripheral neuropathy requiring dose reductions and treatment delays for some patients. We hypothesized that a low dose metronomic schedule will allow responding patients to remain on treatment, resulting in longer TTP (time to progression) and decreased incidence of toxicities and treatment-related discontinuations.

Methods: A multi-site prospective open-label phase II trial of metronomic dosing of eribulin in patients with MBC has completed accrual of 60 patients, outcomes will be updated at presentation. Patients whose disease had progressed following 1-6 prior regimens with prior exposure to a taxane, ECOG performance status of 0 – 2, measurable disease per RECIST 1.1, with normal marrow and organ function were eligible. Eribulin was administered at 0.9mg/m² weekly for 3 out of 4 weeks. For patients with HER2 positive disease, concurrent trastuzumab administration was allowed. Concurrent denosumab or bisphosphonates were allowed for patients with bone disease.

Results: 60 patients were enrolled, average age 58 (range 34-83). Majority were postmenopausal Caucasian females, but the study included African American, Hispanic, native American, male patients. The majority of tumors were ER+, infiltrating ductal, but the study included 13 HER2+, and 12 TN tumors, with 5 ILC, and 5 mixed ILC/IDC. Nearly half of the enrolled patients had clinical benefit from the regimen, remaining on therapy for 6 months or longer, with stable disease or response; 50% had progression PD at 3 months 32% had stable disease and 18% had a partial or complete response (1, long term). Overall Survival, OS, for the entire group of heavily pre-treated patients was 1.2 years, with TN and HER2 positive patients faring better than ER+ in this small study. One HER2+ patient remains in long-term remission, off chemotherapy.

The regimen was extremely well tolerated. The majority of the patients experienced grade 0 or 1 toxicity for alopecia (48/60) and peripheral neuropathy (7 with grade 2 neuropathy, 5 pre-existing, 2 with grade 3 neuropathy). There were few dose reductions (n=15), thrombocytopenia (11 grade 1 only), or use of G-CSF (14).

Conclusions: Metronomic weekly low dose eribulin appears to be an active and tolerable regimen with less myelosuppression, alopecia and peripheral neuropathy than is seen with approved dose, allowing longer duration of use and disease control, with similar outcomes compared to the standard dose regimen. Outcomes will be updated at presentation.
Outcomes in patients (pts) with metastatic triple-negative breast cancer (mTNBC) treated in second line (2L) in the US real-world setting

Patricia Luhn1, Carol O’Hear1, Thanh GN Ton1, Angela Hsieh1, Jingbo Yi2, Ching-Wei Chang1, Roel Funke1 and Allison Kurian3.
1Genentech, Inc, South San Francisco, CA; 2Genesis Research, Hoboken, NJ and 3Stanford University School of Medicine, Stanford, CA.

Background: mTNBC represents an area of high unmet need, yet studies assessing real-world outcomes in pts treated in 2L are limited. We describe treatment patterns and outcomes in mTNBC pts receiving 2L treatment primarily in community cancer care clinics in the USA.

Methods: Pts aged ≥18 y with a confirmed diagnosis of mTNBC between 1 Jan 2011 and 28 Feb 2017 and who received 2L therapy were identified from the Flatiron Health electronic health record-derived database. Overall survival (OS) and time to next treatment (TTNT) were assessed as primary outcomes using Kaplan–Meier methods in both the overall population and subgroups of pts receiving the most commonly used agents (capecitabine, taxane, gemcitabine).

Results: Most of the 623 pts analyzed were White (62.9%) and received care in community clinics (94.9%). The most commonly used previous first-line (1L) regimens in this 2L pt population were: capecitabine (14.0%), cyclophosphamide/doxorubicin (11.6%), carboplatin/gemcitabine (9.3%), paclitaxel (7.1%), and nab-paclitaxel (7.1%); the remaining 51.0% of pts received 95 different 1L regimens. The most common 2L treatments were monotherapy regimens: capecitabine (10.9%), paclitaxel (9.3%), eribulin (9.0%), nab-paclitaxel (8.2%), and gemcitabine (7.7%); the remaining 54.9% of pts received 120 different 2L regimens. Selected demographic, clinical, and treatment characteristics and outcomes after median follow-up of 8.5 (interquartile range [IQR] 4.5–15.7) mo are shown below.

TFI=treatment-free interval. *Any regimen containing each agent (monotherapy or combination); subgroups not mutually exclusive. †Defined as the interval between last (neo)adjuvant therapy and metastatic diagnosis; percentages calculated using pts with recurrent disease and non-missing TFI as the denominator. ‡From start of 2L

Conclusions: There was no clear 2L treatment standard used for mTNBC and median OS was short (10.2 mo overall). Notably, pts receiving 2L gemcitabine- vs taxane-containing therapy experienced shorter median OS and lower 1-y OS rates, although
imbances in prior therapy, disease biology, and demographic and prognostic factors between these subgroups may have contributed to the observed differences. 2L treatment for mTNBC remains an area of high unmet medical need.
Phase II study of eribulin in combination with gemcitabine for the treatment of patients with locally advanced or metastatic triple negative breast cancer (ERIGE Trial). Clinical and pharmacogenetic results on behalf of the Gruppo Oncologico Italiano di Ricerca Clinica (GOIRC)

**Background:** There are no well-established chemotherapy regimens for metastatic triple negative breast cancer. The combination of a microtubule inhibitor (eribulin) with a nucleoside analog (gemcitabine) may synergistically induce tumor cell death, especially in tumors like triple negative breast cancers (TNBC) characterized by high cell proliferation, aggressive tumor behavior, and chemo-resistance.

**Materials and Methods:** This is an open-label, national multicenter phase II study evaluating the combination of eribulin (0.88 mg/m²) plus gemcitabine (1000 mg/m²) on day 1 and 8, q21 as either first- or second-line treatment of locally advanced or metastatic TNBC. The primary endpoint was the objective response rate (ORR) for evaluable patients (pts). The study was designed according to the Simon's two stage optimal design. We chose the lower activity (p0) of 0.20 and target activity level (p1) of 0.35. A prospective, molecular correlative study has been being carried out on germinal DNA of study population to assess the role of BRCA mutations and single nucleotide polymorphisms (SNPs) in predicting efficacy and toxicity of the combination regimen.

**Results:** From July 2013 to September 2016, 83 evaluable pts (37 in the first stage, 46 in the second one) were enrolled. They received a median number of 6 cycles of treatment (range 1-24). The ORR (CR+PR) was 37.35% (90% CI: 28.47-46.93) and the clinical benefit rate (CR+PR+SD ≥ 24wks) was 48.78% (90% CI: 39.24%-58.39%). The most common grade 3-4 adverse events (> 10% of patients) were neutropenia and liver toxicity. With a median follow-up of 28.8 months, the median progression-free survival (PFS) and overall survival (OS) were 5.1 months (95% CI: 4.2-7.0) and 14.7 months (95% CI: 10.2-20.0), respectively. BRCA1/2 deleterious mutations were observed in 15 (22%) out of 68 genotyped pts. Women with BRCA1/2 mutations were associated with worse ORR, PFS and OS than those with BRCA1/2 wild-type. A panel of SNPs in genes of study drug metabolism pathways was evaluated. Among these, CYP3A4 392A >G and FGD4 2044236G>A SNPs were associated with greater liver toxicity by logistic regression analysis. Furthermore, CDA*2 79A>C, RRM1 2455 A>G, and CYP2C8 416G>A SNPs were associated with poorer overall survival by Cox proportional hazards model.

**Conclusions:** The combination of eribulin and gemcitabine shows promising activity and a moderate toxicity profile in metastatic TNBC. BRCA status and pharmacogenetics tests may help identify pts with high probability of response with negligible toxicity.
Long-term treatment patterns and OS in metastatic breast cancer by intrinsic subtypes in a clinical setting in Sweden

Henrik Lindman¹, Fanny Sjöberg¹, Fredrik Wiklund² and Helene Nordahl Christensen³. ¹Uppsala University Hospital, Uppsala, Sweden; ²Statisticon AB, Uppsala, Sweden and ³AstraZeneca, Södertälje, Sweden.

Background
Breast cancer is the most common female cancer in Sweden, and patients diagnosed with early stage have a good curative prognosis. However, once metastases are detected, the disease is incurable. There is lack of detailed knowledge on the current management of metastatic breast cancer (MBC), especially treatment lines beyond second or third line. The aim was to describe long-term treatment sequences and OS for metastatic breast cancer patients by intrinsic subtypes in a clinical setting in Sweden.

Method
In this observational cohort study, women with MBC treated between 2009-2017 were identified in the RealQ® clinical database (Uppsala University Hospital, Sweden). Clinical characteristics, complete MBC treatment regimens, and overall survival (OS) were obtained. Patients were classified into intrinsic subtypes as determined by gene expression profiling i.e., luminal A, luminal B, HER2 subtype, and basal-like (also called triple negative breast cancer [TNBC]). OS was defined from date of first metastatic diagnosis until date of death, migration or end of study. Survival rates were estimated using the Kaplan-Meier method. Subgroup analyses among deceased patients were conducted for all treatment lines and combinations. Treatment exposure rates for each treatment category were calculated using the following formula: exposure rate = person-years for the treatment category/total person-years × 100.

Results
The full analysis set comprised 371 MBC patients (mean age 67 years, 88% with performance status 0 or 1) of which 350 patients could be subtyped: 118 (34%) Luminal A, 119 (34%) Luminal B, 68 (19%) HER2, and 45 (13%) TNBC. Median follow-up was 27 months and median OS was 32.5 months; 5-year survival rates for Luminal A, Luminal B, HER2, and TNBC were 27%, 29%, 36%, and 7%, respectively. In total 245 patients died during the observation period. The deceased patients had been treated with mean 4.5 lines (median 4, range 1-18), mean time from last treatment to death was 5.4 weeks (median 0, range 0-224). Luminal B patients (n=79) were younger (mean age 66.4 vs. 70.7 years), had more often 2+ metastatic sites (64.6% vs. 57.8%) and visceral as primary metastatic location (69.6% vs. 60.2%) compared with Luminal A patients (n=83). Generally, Luminal B patients were treated with chemotherapy more frequently than Luminal A patients, and chemotherapy was more often at later treatment lines. Total exposure rate for all chemotherapy were 33.6% among Luminal B patients vs. 24.1% among Luminal A patients (p=0.03), and for all endocrine therapy 49.4% among Luminal B patients vs. 61.9% among Luminal A patients (p=0.02). There was no difference in mortality for Luminal B and A patients when adjusting for age, number of metastatic sites, visceral metastatic location, and treatment (p>0.05).

Conclusion
This observational study of MBC patients in clinical practice shows relatively short OS despite an extensive management with numerous treatment lines and combination therapies. Regardless of differences in treatment patterns for Luminal A and B patients the long-term OS was similar for these patient groups, highlighting the importance of awareness and careful consideration in management of MBC beyond second or third treatment line.
Randomized phase 3 study of anthracycline-containing regimens versus S-1 as first-line treatment for metastatic breast cancer (SELECT BC-CONFIRM)—A combined analysis of two randomized phase 3 studies (SELECT BC-CONFIRM and SELECT BC)—

Youngjin Park¹, Hiromitsu Akabane², Takanori Watanabe³, Masato Takahashi⁴, Yoshiaki Sagara⁵, Reiki Nishimura⁶, Junji Tsurutani⁷, Tsutomu Takashima⁸, Tomomi Fujisawa⁹, Yasuo Hozumi¹⁰, Yukari Uemura¹¹ and Hirofumi Mukai¹². ¹Tohoku Medical and Pharmaceutical University, Faculty of Medicine, Sendai, Japan; ²Hokkaido P. W. F. A. C. Asahikawa-Kosei General Hospital, Asahikawa, Japan; ³National Hospital Organization, Sendai Medical Center, Sendai, Japan; ⁴National Hospital Organization Hokkaido Cancer Center, Sapporo, Japan; ⁵Hakuaikai Medical Corp Sagara Hospital, Kagoshima, Japan; ⁶Kumamoto Shinto General Hospital, Kumamoto, Japan; ⁷Kindai University, Faculty of Medicine, Osakasayama, Japan; ⁸Osaka City University, Graduate School of Medicine, Osaka, Japan; ⁹Gunma Prefectural Cancer Center, Ota, Japan; ¹⁰University of Tsukuba Hospital /Ibaraki Prefectural Central Hospital, Kasama, Japan; ¹¹The University of Tokyo Hospital, Tokyo, Japan and ¹²National Cancer Center Hospital East, Kashiwa, Japan.

Background: Anthracycline-containing regimens and taxane have been standard as the first-line chemotherapy for metastatic breast cancer (MBC). We conducted SELECT BC (randomized phase 3 study of taxane versus S-1 as first-line treatment for MBC) for evaluating the efficacy of S-1 for patients with HER2-negative MBC from 2006 to 2010 in Japan. This study demonstrated non-inferiority of S-1 in overall survival (OS) (median OS was 37.2 months in taxes group and 35.0 months in S-1 group (HR 1.05, 95% CI 0.86–1.27, p=0.015)), and superiority in health-related quality of life (HRQOL) to taxanes. S-1 was also shown as less toxic than taxane (Lancet Oncol 2016; 17: 90-98). S-1 might provide clinical benefit as first-line treatment for patients with HER2-negative MBC. To confirm this suggestion, we have conducted further study (randomized phase 3 study of anthracycline-containing regimens versus S-1 as first-line treatment for HER2-negative MBC: SELECT BC-CONFIRM) from 2011 to present, and a combined analysis of two randomized studies (SELECT-BC CONFIRM and SELECT-BC).

Methods: In SELECT BC-CONFIRM, 230 patients receiving first-line treatment for MBC were randomly assigned to either anthracycline group (n=115) or S-1 group (n=115). Anthracycline group patients received anthracycline-containing regimens (AC, EC, FAC, FEC, q3w) at the discretion of the treating physician. S-1 group patients received S-1 40–60 mg twice daily based on the patient's body surface area for 28 days on, 14-day off. The primary endpoint was OS, and secondary endpoints were progression-free survival (PFS), time to treatment failure (TTF), adverse events, HRQOL, and cost-effectiveness. The results were combined with SELECT-BC, to confirm the hypothesis that S-1 treatment is not inferior to the standard therapy (taxanes / anthracycline) for HER2-negative MBC.

Results: A combined analysis of the two studies showed that HR was 1.06, 95%CI 0.90-1.253, and p=0.0071 between the standard therapy group and S-1 group. The Bayesian posterior probability for which HR would be less than 1.333 was about 99.6%.

Conclusions: A combined analysis of SELECT BC-CONFIRM and SELECT BC clearly demonstrated that OS with S-1 was not inferior to that with the standard therapy in patients receiving first-line treatment for HER2-negative MBC. S-1 could become a standard therapy for this patient population.
Association between exercise, pathological complete response, and treatment tolerability in patients receiving neoadjuvant chemotherapy for operable breast cancer: Results from the CANTO study

Jennifer L Baker1, Antonio Di Meglio2, Mayssam El Mouhebb2, Neil M Iyengar1, Stefan Michiels2, Paul Cottu3, Florence Lerebours1, Charles Coutant6, Anne Lesur6, Oliver Tredan7, Patrick Soulé3, Laurence Vanlemmens9, Christelle Jouanaud10, Christelle Levy11, Sibille Everhard12, Anne-Laure Martin12, Patrick Arveux8, Ines Vaz Luis2 and Lee W Jones1.
1Memorial Sloan Kettering Cancer Center, New York City, NY; 2Institut Gustave Roussy, Villejuif, France; 3Institut Curie, Paris, France; 4Institut Curie Saint Cloud, Saint Cloud, France; 5Centre Georges-François Leclerc, Dijon, France; 6Institut de Cancérologie de Lorraine, Nancy, France; 7Centre Leon Berard, Lyon, France; 8Centre Paul Papin, Angers, France; 9Centre Oscar Lambret, Lille, France; 10Institut de Cancérologie Jean Godinot, Reims, France; 11Centre François Baclesse, Caen, France and 12UNICANCER, Paris, France.

Background: Randomized trials, although not all, suggest exercise therapy improves treatment completion rates / relative dose intensity in patients with early-stage breast cancer receiving adjuvant chemotherapy (CT). In addition, preclinical studies show that exercise therapy adds to the antitumor activity of standard CT in murine models of breast cancer. We evaluated the association between exercise and pathologic complete response (pCR) rate (i.e., ypT0ypN0) in patients receiving neoadjuvant CT for operable breast cancer.

Methods: Using a prospective design, patients with stage I-III breast cancer receiving anthracycline-taxane (± trastuzumab) neoadjuvant CT participating in a multicenter, national cohort study in France (CANTO, NCT01993498) completed questionnaire assessing self-reported exercise behavior (GPAQ 16). Multivariate logistic models were performed to determine the relationship between pre-CT exercise exposure (total MET-h/wk categorized into the proportion of patients meeting WHO exercise guidelines, the equivalent of ≥10 MET-h/wk) and pCR rates, CT± trastuzumab dose reductions, delays, treatment completion or interruptions for the overall cohort and on the basis of clinical subtype.

Results: Between March, 2012 to December, 2014, a total of 989 patients participating in CANTO received neoadjuvant CT and completed GPAQ 16. Here we present interim analyses on 608 patients. Fifty-four percent of patients engaged on of ≥10 MET-h/wk prior to CT administration. In multivariable analysis for the overall cohort, exercise exposure was not associated with higher pCR (p=0.69). The pCR rate was 27.7% for patients reporting <10 MET h/wk compared with 28.0% for those reporting ≥10 MET-h/wk (OR, 1.02; 95% CI, 0.71-1.45). Stratification analyses indicated no differences on the basis of clinical subtype for hormone receptor (HR) positive/HER2 negative (<10 MET h/wk: 15.1% vs. ≥10 MET h/wk: 16.5%; OR, 0.95, 0.41-2.16); HER2 positive (<10 MET h/wk: 38.1% vs. ≥10 MET h/wk: 32.5%; OR, 0.62, 0.28-1.35); or triple-negative disease (<10 MET h/wk: 33.3% vs. ≥10 MET h/wk: 36.7%; OR, 1.04, 0.52-2.10). Rates of CT dose reductions (<10 MET h/wk: 16.1% vs. ≥10 MET h/wk: 18.3%), CT dose delays (<10 MET h/wk: 19.9% vs. ≥10 MET h/wk: 19.8%), CT completion (<10 MET h/wk: 12.03% vs. ≥10 MET h/wk: 11.45%) trastuzumab interruptions (<10 MET h/wk: 9.01% vs. ≥10 MET h/wk: 7.95%) were also not different on the basis of exercise exposure.

Conclusion: On the basis of interim analyses, higher pretreatment exercise exposure is not associated with higher clinical response or treatment tolerability in breast cancer patients receiving uniform conventional neoadjuvant CT. Full results will be presented at the meeting.
Breast cancer recurrence and predictors for recurrence despite pathologic complete response following neoadjuvant chemotherapy

Kristien Borremans¹, Patrick Berteloot¹, Els Van Nieuwenhuysen¹, Siley Han¹, Griet Hoste¹, Hans Wildiers¹, Kevin Punie¹, Ann Smeets¹, Ines Nevelsteen¹, Giuseppe Floris², Chantal Van Ongeval¹, Machteld Keupers¹, Renate Prevos¹, Erik Van Limbergen¹, Johan Menten¹, Caroline Weltens¹, Hilde Janssen¹, Ignace Vergote¹ and Patrick Neven¹. ¹KU Leuven - University of Leuven, Leuven, Belgium and ²KU Leuven - University of Leuven, Laboratory of Translational Cell & Tissue Research and University Hospitals Leuven, Department of Pathology, Leuven, Belgium.

Introduction
Breast cancer patients with a high-risk tumor (for example Triple Negative Breast Cancer) who achieve a pathological complete response (pCR) following neoadjuvant chemotherapy (NACT) have a better outcome compared to patients with residual disease at surgery. This study investigated Breast Cancer Free Survival (BCFS) and predictors for distant relapse despite pCR.

Methods
Monocentric retrospective study of 243 consecutive breast cancer patients who achieved pCR (ypT0/is ypN0/N0(i+)) after treatment with NACT in UZ Leuven between 01/2000 and 08/2017. 58% had stage III breast cancer, 40% Triple Negative Breast Cancer (TNBC) and 47% HER2 pos breast cancer. BCFS was defined as any breast cancer related event (local, contra-lateral, regional, metastatic) that first appeared. Primary endpoints were frequency of BCFS and predictors for metastatic relapse: patient demographics (age, body mass index (BMI)) and tumor characteristics (TNM stage, histological type, hormonal receptor status). Secondary endpoints were breast cancer specific survival (BCSS) and overall survival (OS). Statistical analysis was performed using the Statistical Package for the Social Sciences software (SPSS, version 25). The Kaplan Meier method was used for survival analysis.

Results
Of 1167 breast cancer patients undergoing neoadjuvant treatment, 243 patients (20.8%) achieved pCR and were included. Median follow up was 57 months (range 9-252 months). 22 (9.1%) developed tumor progression; 20 (8.2%) metastatic and 2 (0.8%) contralateral. First metastatic site was the brain in 11/20 patients (55%) and 14/22 (64%) died of breast cancer. Higher clinical tumor stage at diagnosis predicted metastatic relapse (stage I-II 2.9%; stage III 12.1%). Patients with a BMI ≤25 kg/m² had less metastatic relapse than patients with BMI >25kg/m² (3.8% versus 12.0%), better OS (94.6% vs 88.0%) and BCSS (97.7 vs 91.7%). Neither tumor type (TNBC 8.2%; HER2-pos 8.1%; HR-pos/HER2 neg 9.3%) nor younger age < 36yrs (3.3% versus 8.9%) was prognostic for post-pCR relapse. There is a lower OS (mean 174m versus 231m, 95% CI 158-190m, median 208m) and BCSS (mean 191m versus 253m, 95% CI 182-200m) in cN1-3 versus cN0 disease at diagnosis.

Conclusion
Despite NACT-induced pCR, a small proportion (9.1%) will develop a metastatic relapse after a median follow-up of 57 months. We found that a higher stage at diagnosis and a higher BMI were prognostic for worse BCFS while age <36 y and negative hormonal receptor status were not prognostic. cN+ at diagnosis and a BMI >25 predict worse OS and BCSS.
Is absolute lymphocyte count associated with platinum-sensitivity? A phase II single arm study evaluating the efficacy of neoadjuvant carboplatin and docetaxel in triple negative breast cancer

Ina Chen¹, Feng Guo¹, Tracy Summa¹, Jingqin Luo¹, Matthew J Ellis², Cynthia X Ma¹, Katherine N Weilbaecher¹, Michael J Naughton¹, Rama Suresh¹, Lindsay L Peterson¹, Mathew A Cherian¹, Ron Bose¹, Ashley E Frith¹, Leonel F Hernandez-Aya¹, William E Gillanders¹ and Foluso O Ademuyiwa¹. ¹Washington University School of Medicine in St Louis, Saint Louis, MO and ²Baylor College of Medicine, Houston, TX.

Background: Platinum-based chemotherapy is still considered investigational for the treatment of sporadic triple negative breast cancer (TNBC). Since patients with TNBC have a high rate of chemotherapy resistance, it is critical to identify platinum-sensitive individuals prior to initiating therapy. Higher absolute lymphocyte count (ALC) is associated with improved clinical response to anthracycline-based chemotherapy, the current standard of care in TNBC. We report the initial results of a phase II single arm study evaluating the efficacy of neoadjuvant carboplatin and docetaxel in TNBC. We also report results of an exploratory analysis assessing whether ALC can be used to predict pathologic complete response (pCR) after treatment with platinum-based chemotherapy.

Patients and Methods: 78 patients with clinical stage II or III TNBC have been enrolled in this ongoing study evaluating the efficacy of neoadjuvant carboplatin and docetaxel (NCT201404107). Patients received docetaxel 75 mg/m² and carboplatin AUC 6 every three weeks for a total of 6 cycles. Blood samples were collected prior to each cycle, and a posttreatment sample was collected >3 weeks after completing cycle 6. pCR was defined as no residual invasive disease in the breast, with or without ductal carcinoma in situ, and no tumor deposits in sampled lymph nodes. Baseline characteristics of patients were summarized with descriptive statistics. Univariate and multivariate logistic regression analyses were used to identify factors associated with pCR.

Results: Out of the 78 enrolled patients, 60 have completed all 6 treatment cycles and surgery. The preliminary pCR rate is 46.7%. Age, race, clinical stage, and tumor grade determined at time of diagnosis were not significantly different between pCR patients and non-pCR patients. In univariate analyses, patients with higher ALCs at the posttreatment time point were more likely to have pCR than those who had lower ALCs (OR 5.5, 95% CI 1.5-20.7, p=0.011). Additionally, patients who had higher minimum ALCs were also more likely to have pCR (OR 9.1, 95% CI 1.5-54.9, p=0.016). Baseline ALC values were not associated with pCR. The associations of posttreatment and minimum ALCs to pCR remained statistically significant even after controlling for age and clinical stage at time of diagnosis (posttreatment ALC OR 7.6, 95% CI 1.7-34.8, p=0.009; minimum ALC OR 9.0, 95% CI 1.5-55.2, p=0.018).

Conclusion: The pCR rate of our cohort is similar to that of other trials evaluating neoadjuvant platinum-based chemotherapy in TNBC. Baseline ALC did not predict which patients would achieve pCR. However, the associations of posttreatment and minimum ALCs with pCR indicate patients who are able to maintain a robust population of circulating lymphocytes throughout treatment with platinum-based chemotherapy are more likely to respond favorably. The link between patient immunity and platinum-based chemotherapy suggests addition of immunotherapy agents to neoadjuvant chemotherapy may improve patient outcomes.
Impact of serial biopsies in triple-negative breast cancer patients receiving neoadjuvant systemic therapy

Clinton Yam\textsuperscript{1}, Akshara Raghavendra\textsuperscript{1}, Kenneth R Hess\textsuperscript{1}, Beatriz E Adrada\textsuperscript{1}, Rosalind P Candelaria\textsuperscript{1}, Senthil Damodaran\textsuperscript{1}, Michael Z Gilcrease\textsuperscript{1}, Thorunn Helgason\textsuperscript{1}, Gabriel N Hortobagyi\textsuperscript{1}, Lei Huo\textsuperscript{1}, Rachel M Layman\textsuperscript{1}, Bora Lim\textsuperscript{1}, Jennifer K Litton\textsuperscript{1}, Elizabeth A Mittendorf\textsuperscript{2}, Rashmi K Murthy\textsuperscript{1}, Helen Piwnica-Worms\textsuperscript{1}, Gaiane M Rauch\textsuperscript{1}, Lumarie Santiago\textsuperscript{1}, Fraser Symmans\textsuperscript{1}, Alastair M Thompson\textsuperscript{1}, Debasish Tripathy\textsuperscript{1}, Naoto T Ueno\textsuperscript{1}, Vicente Valero\textsuperscript{1}, Carlos H Barcenas\textsuperscript{1}, Stacy L Moulder\textsuperscript{1} and Wei Yang\textsuperscript{1}. \textsuperscript{1}The University of Texas MD Anderson Cancer Center, Houston, TX and \textsuperscript{2}Dana-Farber Cancer Institute, Boston, MA.

\textbf{Background:} Serial biopsies (bx) of triple-negative breast cancer (TNBC) in the curative neoadjuvant setting provides critical information on dynamic changes in the tumor in response to neoadjuvant systemic therapy (NAST) and can help inform the development of novel therapeutic strategies. However, neoplastic seeding following image guided breast bx has previously been reported in TNBC, raising concerns that serial bx may worsen clinical outcomes. Thus, we sought to determine if serial bx were associated with poorer clinical outcomes (using rates of pathologic complete response [pCR]) in TNBC pts receiving NAST.

\textbf{Methods:} We identified 370 TNBC pts who received NAST at MD Anderson Cancer Center from 2011-2017. 200 pts did not have any research bx done (controls) on the index breast carcinoma and 170 pts had at least one research bx done (cases) on the index breast carcinoma as part of the prospective molecular triaging ARTEMIS trial. Baseline characteristics were compared between cases and controls using the Student t-test, Wilcoxon Rank Sum test or Fisher’s exact test as appropriate. Univariable and multivariable logistic regression was used to determine if rates of pCR following NAST were significantly different between cases and controls.

\textbf{Results:} Demographic characteristics demonstrate no significant differences (Table). However, cases were more likely to have received an anthracycline (99\% vs 96\%, \(p=0.02\)) and a targeted agent (22\% vs 0\%, \(p<0.01\)) in the neoadjuvant setting as part of the ARTEMIS trial. A total of 211 bx of the index carcinoma were performed in the 200 controls, of whom, 6\% (11/200) had a second bx of the index carcinoma done solely for diagnostic purposes. In contrast, a total of 407 bx of the index carcinoma were performed in the 170 cases (mean: 2.4 biopsies). Of the 407 bx done in the 170 cases, 58\% (237/407) were done for research purposes. The pCR rate in controls and cases was 48\% (96/200, 95\% confidence interval [CI]: 41-55\%) and 42\% (72/170, 95\% CI: 35-50\%), respectively. The odds of pCR following NAST were not significantly different between controls and cases on both univariable (odds ratio [OR]: 0.80; 95\% CI: 0.53-1.20, \(p=0.28\)) and multivariable logistic regression (adjusted OR: 0.94; 95\% CI: 0.58-1.51; \(p=0.79\)).

\textbf{Conclusion:} This is the first study examining the impact of serial bx on clinical outcomes in TNBC pts in the curative neoadjuvant setting. Our data suggest that research bx in this setting do not compromise rates of pCR.

Phase II trial of neoadjuvant carboplatin and nab-paclitaxel in patients with locally advanced triple negative breast cancer

Yuan Yuan¹, Paul Frankel¹, Min Li¹, Laura Kruper¹, Veronica Jones¹, Tina Treece², James Waisman¹, John Yim¹, Lusine Tumyan¹, Daniel Schmolze¹, Arti Hurria¹, Christina Yeon¹, Joanne Mortimer¹ and George Somlo¹. ¹City of Hope National Medical Center, Duarte, CA; ²Agendia, Irvine, CA and ³Jackson Laboratories, Farmington, CT.

Background: Response to neoadjuvant therapy (NT) predicts progression-free and overall survival in triple negative breast cancer (TNBC). Carboplatin has shown efficacy in patients with TNBC. The current phase II prospective neoadjuvant trial was designed to decrease toxicities and improve efficacy.

Methods: Patients with TNBC received carboplatin (carb) and nab-paclitaxel (nab). Pre-NT biopsies were procured to evaluate for biological predictors of pathological complete response (pCR). Newly diagnosed stage II-III patients with TNBC were treated with 4 cycles of carb (AUC 6, day 1 of 28 day cycle) and weekly nab 100 mg/m² x 16. Targeted accrual goal is 70. RNA extracted from formalin fixed paraffin embedded (FFPE) biopsies pre-NT was tested for MammaPrint/BluePrint and custom Agilent full genome microarrays for gene expression (GE, by Agendia Inc). The raw gMeanSignal was log2 transformed and normalized to the 75th percentile for GE analysis. Association between MammaPrint/BluePrint results and pCR was tested by Fisher exact test. The linear model from R limma package was applied. Ingenuity Pathway Analysis (IPA) was applied to assess functional pathways associated with pCR. Cellular distribution by CIBERSORT analysis was carried out to estimate the abundance of 22 different cell types in each patient sample, and test whether the distribution of cell types is different between pCR and non-responders.

Results: A total of 64 patients were enrolled. Two patients were deemed ineligible (Her2+), and three were too early, resulting in 59 patients evaluable for pathological response. The pCR rate was 47% (RCB0, 28/59). Eight patients had RCB I. RCB0 plus RCBI reached 61%. Sufficient quality RNA and DNA were available from the first 43 of 55 pts with TNBC. 44/59 (75%) required dose modifications (mostly hematologic), 5 patients had grade 3 peripheral neuropathy (PN), 3 had grade 2 PN, and 3 patients had grade 2 LFTs. In the 53 pts with GE assessment, pCR was inversely associated with luminal BluePrint type (p=0.04). With fold change >1.5 and p-value < 0.05, 36 genes were differentially expressed (DE) in TNBC. CIBERSORT analysis suggested that T-cell regulatory cells (T\textsubscript{REGS}) were associated with pCR in TNBC, and 5 cell types (plasma cells, T\textsubscript{REGS}, macrophage, dendritic cells and neutrophils) presented differently between all pCR and non-pCRs with P-value <0.05. TDP analysis to assess correlation with pCR is ongoing.

Conclusions: The combination of carboplatin and nab-paclitaxel given in the neoadjuvant setting reached a promising pCR rate of 47%. The MammaPrint non-luminal BluePrint subtype was predictive of pCR in TNBC. Preliminary analysis suggested that a 36-gene signature for TNBC was associated with pCR. CIBERSORT analysis revealed 5 cell types with different abundance between the pCR and non-responders, suggesting the need to target the tumor microenvironment.
Pathologic complete response rates following neoadjuvant systemic therapy in 794 patients with early breast cancer: The Royal Marsden experience

Nicolò Matteo Luca Battisti¹, Victoria True¹, Narda Chaabouni¹, Neha Chopra¹, Karla Lee¹, Scott Shepherd¹, Tal Shapira-Rotenberg¹, Rashi Joshi¹, Kabir Mohammed¹, Mark Allen¹ and Alistair Ring¹. ¹The Royal Marsden NHS Foundation Trust, Sutton, Surrey, United Kingdom.

Background
The presence and extent of residual invasive cancer after neoadjuvant treatment (NACT) is a strong prognostic factor for risk of recurrence, especially in triple-negative (TN) and human epidermal growth factor receptor 2-positive (HER2+) breast cancer (BC). Recent advances in the standard-of-care NACT improved pathological complete response (pCR) rates in published clinical trials. We evaluated the pCR rates, defined as ypT0-is ypN0, in our real-world BC population and in estrogen receptor-positive [ER+] HER2-, HER2+ and TN subgroups and their association with tumour, patients’ characteristics and disease-free survival (DFS).

Methods
We retrospectively identified early BC patients receiving NACT between January 2013 and December 2017. Demographics, patient and disease characteristics, pathological responses, toxicities, dose delays and reductions were recorded. Simple statistics, Fisher's exact test, chi-squared method and Cox regression were used as appropriate.

Results
794 patients identified had median age of 50 years (range 24-87) and 93.9% (745 patients) ECOG performance status (PS) 0. 3.0% (24) had clinical stage I disease, 68.0% (540) stage II and 29.0% (230) stage III. 71.0% (564) had grade 3 disease and 91.8% (729) ductal histology. 33.7% (257) had ER+/HER2-, 25.8% (205) had TN and 38.0% (301) HER2+ disease. Overall, 6.8% (54) patients received platinum. 36.6% (291) patients had dose reductions and 24.3% (193) dose delays. Along with NACT, 51.6% (147) of the HER2+ patients received Trastuzumab and Pertuzumab and 48.4% (138) Trastuzumab alone.

pCR rate was 33.1% in the overall population and significantly different in ER+/HER2-, HER2+ and TN subgroups (12.84% versus 52.0% versus 28.43% respectively, p<0.001). pCR was influenced by grade (1: 0%; 2: 24.3%; 3: 36.1%, p 0.005) and histology (ductal: 34.2%; lobular: 10.0%; mixed 25.0%; p 0.01). In the HER2+ subgroup, there was a trend for improved pCR rates for patients receiving Pertuzumab and Trastuzumab (57.0%) versus Trastuzumab alone (51.0%). No statistically significant differences were seen based on patients’ characteristics including age and PS or in case of treatment dose reductions and delays. Early discontinuation of NACT was associated with lower pCR rates (20.5% vs 36.29%, p <0.001).

Of interest, pCR rates remained consistent across the period 2013-2017 in the overall population. We observed a trend for improved pCR in the HER2+ (2013: 47.5%; 2014: 44.4%; 2015: 66.7%; 2016: 51.0%; 2017: 51.4%) and TN cohorts (2013: 23.5%; 2014: 25.0%; 2015: 25.0%; 2016: 33.3%; 2017: 34.1%) but not in the ER+/HER2- group.

Median DFS was 83.8 months (95% CI 62.0-NR) in the overall population. Although not reached in the TN cohort, median DFS was different according to disease subgroups (HER2+: 83.78 months; TN: NR; ER+/HER2+: 62.0 months, p <0.0001).

Conclusions
In our analysis pCR rates are consistent with data published in literature and higher in HER2+ and TN disease. The impact of new agents had a relatively low impact on pCR rates in our overall population over the last 5 years, although they produced gradual improvements in the HER2+ and TN subgroups.
Introduction
Neoadjuvant chemotherapy (NAC) in breast cancer is an in vivo marker of chemosensitivity and pathological complete response (pCR) an independent prognostic factor. When there is response, NAC downstages the tumour and may allow for or facilitate a conservative surgery. There are three histological patterns of response to NAC: a concentric pattern in which tumour regression takes place from the periphery to the center, a scatter pattern, where fibrosis is placed between tumoral cells, and a mixed pattern.

Objective
To determine which clinical and histological variables define the type of response to neoadjuvant chemotherapy that facilitates and allows for breast conservation in women with breast cancer.

Material and methods
A retrospective observational study was made including 170 patients with breast cancer who underwent NAC in the Hospital Universitari de Bellvitge between February 2010 and October 2013. Different clinicopathological parameters were recorded: age, menopausal, stage, surrogate molecular subtype, histological pattern of response, and pCR.

Median age was 50 (23-78), Stage I (1.1%) IIA (27.1%) IIB (35%), IIIA (20.9%), IIIB (11.4%), IIIC (4.5%). Molecular surrogated types: Triple negative (30.7%), Luminal B Her 2 negative like (26.2%), Her 2 positive (17.7%), Luminal B Her 2 positive like (16.4%) and Luminal A like tumours (9.0%). NAC included Anthracyclines, Taxanes, and Trastuzumab if Her 2 +++.

Results:
Histological pattern of response: 25.5% of cases achieved a pCR. When residual tumour was observed, 42% of the cases were as scatter pattern, 21.9% as concentric pattern and 8.9% as mixed pattern.

The predictive factors of pCR were in the univariate analysis: absence of multicentricity, negative estrogen receptor, negative progesterone receptor, histological grade 3, Ki 67 > 20%, and her 2 overexpression. In the multivariate analysis, only negative estrogen receptor and her 2 overexpression were predictive factors. The molecular surrogated type Her 2 positive was predictive of pCR.

The predictive factors of the concentric response were in the univariate analysis: tumour size of < 5 cm, absence of nodal involvement, negative estrogen receptor, negative progesterone receptor, presence of tumour necrosis and inflammatory infiltration. In the multivariate analysis, tumour size < 5 cm, absence of lymph node involvement, Ki 67 > 20% and tumour necrosis were statistically significative. The molecular surrogated type predictive of a concentric response was triple negative.

Conservative surgery was more frequent in the concentric pattern group (78.4%) than in the scatter pattern (58.1%) (p=0.032) but the histological pattern of response to NAC is not correlated to survival.

Conclusions
Tumour size < 5 cm, absence of lymph node involvement, Ki 67 > 20% and tumour necrosis were predictive of concentric pattern of response to NAC. Triple negative tumours were related to concentric histological pattern, meanwhile Her 2 overexpressed was predictive of pCR. The conservative treatment was more frequent in the concentric pattern. Histological pattern of response to NAC is not correlated to outcome. Only pCR was related to survival.
A prospective multicenter real-world study on neoadjuvant treatment and clinical outcome in TNBC patients

Elna Kuehnle1, Pavanjot Kaur1, Wulf Siggelkow2, Kristina Luebbe2, Iris Schrader2, Christoph Uleer2, Stefanie Noeding3, Karl-Heinz Noeding4, Thomas Noesselt5, Momme Arfsten6, Christoph Busch5, Nikki Krentel1, Peter Hillemanns1, Thilo Dörk1 and Tjoung-Won Park-Simon1. 1Hannover Medical School, Hanover, Germany; 2DIAKOVERE Henriettenstift, Breast Center, Hanover, Germany; 3Klinikum Hannover Nordstadt, Cooperative Breast Center Klinikum Region Hanover, Hanover, Germany; 4HELIOS Klinikum Hildesheim, Breast Center, Hildesheim, Germany; 5Sana Klinikum Hameln-Pyrmont, Breast Center, Hameln, Germany; 6Kreiskrankenhaus Stadthagen, Breast Center Schaumburg, Stadthagen, Germany and 7PVA Mammographiescreening Niedersachsen Süd, Hildesheim, Germany.

Introduction
Controversy exists with regards to the optimal regimen for neoadjuvant chemotherapy (NAC) of TNBC. Platinum-based regimens seem to be more active in TNBC improving pCR rates significantly. But adding platinum to an anthracycline/taxane chemotherapy regime comes at the expense of greater toxicity. Its impact on survival and long-term-outcomes remains undetermined. Practical guidelines vary across leading international professional societies. In this real-world multicenter study neoadjuvant regimens, pCR rates and survival were evaluated.

Material and methods
This study was conducted from 2012-2017 in six certified breast cancer centers in the region of Hanover, Germany, including rural and urban populations by using a personal questionnaire and data from the medical records. All patients with primary TNBC (ER<1%, PR<1%, Her2/neu 0, 1+ or 2+ FISH/CISH negative) and no evidence of distant disease were eligible.

Results
143/217 patients (66%) received NAC and 74/217 patients (34%) adjuvant chemotherapy. 63/143 (44%) patients achieved pCR. 23/63 (35%) received platinum-based NAC and 40/63 (65%) received chemotherapy without platinum. In 80 patients pCR was not achieved. 12/80 patients received platinum and 68/80 non-platinum-based NAC. pCR was significantly higher among patients with platinum-based chemotherapy (chi-square, p < 0.003). 20/23 patients who achieved pCR received NAC containing anthracycline/taxane/carboplatin, 3/23 patients received a taxane/carboplatin-based regime. Treatment discontinuation was seen in 12/35 (34%) patients receiving platinum-based NAC vs 15/108 (14%) in non-platinum-based NAC. Mean follow up was 17 months (1-70 months). A significant difference in OS (p=0.007) and DFS (p=0.001) was seen for patients with a pCR.

Conclusion
Our trial confirms that platinum based NAC achieves significantly higher rates of pCR in patients with TNBC. pCR was associated with significantly longer DFS and OS. The CALBG protocol (CALBG 40603) was the preferred choice of treatment regimen followed by the GeparSixto protocol. In our study the pCR rate was comparable to that of both trials in which pCR rates of 60% (CALBG 40603) and 53% (GeparSixto) were achieved. However, in our trial 34% of the patients discontinued treatment due to toxicity. Therefore these protocols should be used in carefully selected patients. In a real world setting less toxic chemotherapy regimens achieved a pCR rate of 37%. In terms of toxicity and adherence to chemotherapy, these regimens are reasonable alternative options. In daily care close monitoring of treatment response is essential during NAC. In patients who have a rapid clinical response to platinum-free NAC the benefit of adding platinum is questionable. In contrast, the addition of platinum seems to be appropriate in those patients who show only limited response under NAC.
Predicting pathological complete response (pCR) to neoadjuvant chemotherapy (NACT) based on pre- and post-NACT digital mammography and digital breast tomosynthesis findings

Gaurav Agarwal¹, Chaitra Sonthineni¹, Namita Mohindra¹, Neeraj Jain¹, Zafar Neyaz¹, Vinita Agrawal¹, Narendra Krishnani¹, Sabaretnam Maylivahnan¹, Anjali Mishra¹ and Punita Lal¹. ¹SGPGIMS, Lucknow, Uttar Pradesh, India.

Background: In invasive breast cancer patients being treated with neoadjuvant chemotherapy (NACT), achieving pathological complete response (pCR) is a useful goal of treatment. Monitoring response to NACT and predicting pCR is helpful in planning further therapy and providing robust prognostic information. Digital mammography (DM) and additional digital breast tomosynthesis (DBT) features are important tell-tales of tumor characteristics and behaviour. Following NACT, the mammographic features- both DM and DBT- of responding tumors can vary considerably. In this prospective study, we correlated the DM and DBT features of pre-NACT and post-NACT mammograms to investigate if these can reliably predict pCR to NACT.

Methods: Following approval by institutional ethics committee, starting January 2016, 200 consecutive invasive breast carcinoma patients (mean age 51.2 years, all palpable breast masses) undergoing diagnostic breast imaging had their DM and DBT reviewed by two radiologists independently, who were blinded of the cyto/histology and the original DM and DBT reporting. Of these, 47 patients who were treated with NACT and had pre- and post-NACT DM and DBT were recruited. After a core-biopsy, radio-opaque marker(s) were placed in tumor core/margin. The pre- and post-NACT DM and DBT findings were compared and correlated with the extent of response of the primary breast tumor to NACT. DM and DBT characteristics predictive of (in-breast) pCR of index breast lesion were identified.

Results: Of the 47 patients who underwent NACT, 44 received both anthracycline and taxane, and 3 received only an anthracycline based combination chemotherapy. Twelve patients underwent breast conservative surgery and the remaining underwent mastectomy. pCR was seen in 17 (36.2%) patients based on the surgical specimen histology. On clinical examination, 19 (40.4%) patients had clinical complete response (cCR) of the breast tumor, 11 (64.7%) of whom had pCR as well. Five patients had radiological complete response (rCR, no breast lesion visualised on post-NACT imaging)- 2 patients on DM alone, 2 patients on DBT alone, and one patient on both DM and DBT. Radio-opaque clips had some obscuring effects in 3 of these 5 patients, especially on DBT, in form of reduced visibility of breast lesion on DBT, c.w. corresponding DM images. All 5 patients with rCR had pCR (sensitivity=29.4%, specificity=100%), in contrast to only 11 (57.9%) patients with cCR having pCR. Patients with pCR had benign appearing (forced Bi-RADS 2 and 3) lesions on mammography more commonly on DM (p<0.001) than on DBT (p=0.042) (41.2% vs 23.5%). Post NACT lesion morphology varied significantly between patients with and without pCR on DM (p=0.038) but not on DBT (p=0.182). Pre-NACT forced Bi-RADS score, lesion morphology or margin characteristics on DM and DBT did not vary significantly amongst patients with and without pCR.

Conclusions: Post-NACT DM and DBT features can predict pCR with high specificity but with low sensitivity. Pre-NACT DM and DBT features did not reliably predict response to NACT, and pCR in this study. DM may be better than DBT for assessing response to NACT in the presence of radio-opaque markers/clips.
Axillary lymph node metastasis and HER2-receptor positivity significantly associate with recurrence and worse survival in breast cancer patients who achieved pathological complete response after neoadjuvant chemotherapy

Mariko Asaoka⁵, Kazutaka Narui⁶, Nobuyasu Suganuma⁵, Takashi Chishima⁵, Akimitsu Yamada⁴, Saori Kawai¹, Natsuki Uenaka¹, Eichi Sato¹, Eriko Katsuta⁵, Tsutomu Kawaguchi⁵, Kazuaki Takabe⁵ and Takashi Ishikawa¹. ¹Tokyo Medical University Hospital, Tokyo, Japan; ²Kanagawa Cancer Center, Yokohama, Kanagawa, Japan; ³Yokohama Rosai Hospital, Yokohama, Kanagawa, Japan; ⁴Chigasaki Municipal Hospital, Chigasaki, Kanagawa, Japan; ⁵Roswell Park Comprehensive Cancer Center, Buffalo, NY and ⁶Yokohama City University Medical Center, Yokohama, Kanagawa, Japan.

BACKGROUND
Neoadjuvant chemotherapy (NAC) has become a common practice in breast cancer care since it not only expands the opportunity for breast conservation surgery, but also allows in vivo assessment of individual cancer biology. Patients who achieved pathological complete response (pCR) after NAC are known to have significantly improved outcomes than those who did not. To date, there has been no large study of factors that associate with tumor recurrence after patients had pCR following NAC. To identify such factors, we examined a cohort of 394 patients.

METHODS
Patients diagnosed during 2007-16 with clinical stage I-III breast cancer who achieved pCR following NAC were identified from clinical records at four hospitals in urban Japan. Nearly 70% of patients received standard NAC regimen, which was a combination of anthracycline and taxane, with trastuzumab added as needed. pCR was defined as no pathological evidence of invasive cancer in the breast; residual ductal carcinoma in situ (DCIS) and residual axillary lymph node metastasis were included in this study. The median follow-up time was 63 months (range = 16-161 months). Outcomes were assessed by 5-year disease-free survival (DFS) and 5-year overall survival (OS).

RESULTS
Among the 394 patients with pCR, the breast cancer subtype was as follows: Luminal – 49 (12.4%), Luminal-HER2 – 97 (24.6%), HER2 – 117 (29.7%), and TNBC – 131 (33.2%). During follow up, 28 (7.1%) of the 394 patients had experienced tumor recurrence. In univariate Cox regression analysis, each of HER2-receptor status, pre-NAC tumor size, and pre-NAC axillary lymph node status were associated with recurrence. The hazard ratios, and their 95% confidence intervals (CI) and P values for these significant factors were as follows. HER2-receptor negative vs. positive: 2.5 (CI = 1.0-5.8; P = 0.036); cT1/2 vs. cT3/4: 2.2 (CI = 1.3-6.1; P = 0.008); cN0 vs. cN1-3: 9.5 (2.2-40.7; P = 0.002). However, age (<50 vs. ≥50 y), residual DCIS, post-NAC axillary lymph node status, type of mastectomy (total vs. partial), and adjuvant radiation therapy were not associated with recurrence. Of the 28 patients with recurrence, site of first event was local for 8, and brain and visceral for 10 each. Seven of the 10 patients with brain metastasis were HER2-receptor positive. Eleven of the 28 patients with recurrence had deceased, with a median post-recurrence survival duration of 40 months (range = 2–94 months). Shorter survival was associated with HER2-receptor positivity (P = 0.003).

CONCLUSION
Axillary lymph node metastasis before rather than after NAC, and HER2-receptor positivity are associated with tumor recurrence in patients who achieved pCR in breast cancer. HER2-receptor positive patients had higher risk for brain metastasis and shorter survival. Given the extreme rarity of local recurrence after pCR, we cannot help but speculate that omitting surgical removal of pCR tissue may be permissible when pCR has been diagnosed accurately.
Sentinel lymph node biopsy after neoadjuvant chemo therapy in patients with clinically node negative breast cancer: Can sentinel lymph node biopsy be omitted in selected tumor subtypes?

Irene J Beijert¹, AnneBrecht Francken¹, Aafke H Honkoop¹ and Eva M Noorda¹. ¹Isala, Zwolle, Overijsel, Netherlands.

Background
Selected patients presenting with clinically node negative breast cancer (cN0) stage II-III can be treated with neoadjuvant chemo therapy (NCT) followed by surgery of the breast and sentinel lymph node biopsy (SLNB). Pathological response rates are known to vary by tumor subtype with complete pathological response up to 60% in both ER-, HER2-positive tumors and triple-negative (TN) tumors. However, hormone receptor-positive, HER2-negative tumors exhibits lower response rates to NCT. About 70-80% of the patients with a clinically negative axilla, also have pathologically negative axilla after NCT. Properly selecting those patients with a low probability of sentinel lymph node (SLN) metastasis after NCT might save them an unnecessary SLNB. The aim of our study was to assess the impact of tumor subtypes on final pathologic node (pN) status in patients with clinically node negative (cN0) breast cancer who underwent NCT.

Methods
All cN0 patients diagnosed from 2014-2017 in one large teaching hospital in the Netherlands who were treated with NCT and subsequent surgery including SLNB were selected. This retrospective cohort contained a series of 107 patients with 105 tumors treated for stage II-III breast cancer resp. stage 2 (n=107) and stage 3 (n=2), all cN0. Patient age, tumor size, uni/multifocality at presentation did not differs across subtypes. Histological grading and histological type at presentation did differ across subtypes. Approximated subtype was TN in 21 (19.3 %), HER2-positive in 34 (31.2%), and hormone-receptor-positive, HER2-negative in 54 (49.5%) patients.

Results
In a total of 109 tumors, 88 had a negative post-NCT SLNB (80.7%), 4 had isolated tumor cells (3.7%) 7 had micro metastasis (6.4%), 10 had macro metastasis (9.2%). Rates of pathological nodal negativity were significantly higher in patients with TN (100%) and HER2-positive tumors (97.1%) than in those with hormone-receptor-positive, HER2-negative tumors (63%) (p< 0.001). Furthermore, a total of 41 (37.6%) patients had a complete pathologic response (pCR) of the primary breast tumor of which 40 (97.6%) had pathologically confirmed negative SLN and 1 (2.4%) had isolated tumor cells. A total of 67 patients had no pCR of which 48 (71.6%) had pathologically confirmed negative SLN and 19 (28.4%) were SLN positive (p < 0.001). Rates of pCR were significantly higher in HER2-positive (70.6%) and TN tumors (47.6%) than in those with hormone-receptor-positive, HER2-negative tumors (13.0%) (p< 0.001).

Conclusion
SLNB after NCT might be considered to be omitted in patients presenting with cN0 with TN and HER2+ tumors, as SLN is rarely positive. Furthermore, SLN was rarely found positive in patients who achieved pCR. However, more data are necessary for multivariate logistic regression and definite conclusions.
Neoadjuvant liposomal doxorubicin and carboplatin is effective and tolerable for the treatment of triple negative breast cancer

Nancy Chan1, Gregory M Riedlinger1, Shou-en Lu2, Kien T Pham1, Laurie J Kirstein1, Firas G Eladoumikdachi1, Mridula A George1, Lindsay B Potdevin1, Maria J Kowzun1, Shruti A Desai1, Danielle M Tang1, Coral O Omene1, Serena T Wong1, Lorna Rodriguez-Rust1, Shicha Kumar1, Thomas J Kearney1, Chen Liu1, Shridar Ganesan1, Deborah L Toppmeyer1 and Kim M Hirshfield1. 1Rutgers Cancer Institute of New Jersey, New Brunswick, NJ; 2Rutgers School of Public Health-Biostatistics, Piscataway, NJ; 3Rutgers New Jersey Medical School- Pathology, Newark, NJ and 4Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ.

Background: The use of neoadjuvant platinum with taxane for triple negative breast cancer (TNBC) has gained increased attention for improving rates of pathologic complete response (pCR). Our prior trial combining carboplatin (CAR) with liposomal doxorubicin (DOX) for metastatic TNBC showed good response rates with minimal side effects while allowing for greater platinum dosing compared to a taxane combination. We hypothesized that the doublet of DOX+CAR is effective and tolerable in the neoadjuvant setting for TNBC and that tumor genomics may aid in determining those patients most likely to benefit.

Methods: A phase II single arm trial was conducted for patients (pts) diagnosed with stage II-III TNBC. Patients received 4 cycles of neoadjuvant carboplatin (AUC 5) and liposomal doxorubicin (30mg/m²) administered every 28 days, then underwent definitive breast surgery followed by 12 weeks of adjuvant paclitaxel 80 mg/m² administered weekly. Primary and secondary clinical endpoints were rate of pCR and two year recurrence free survival (RFS) and overall survival (OS), respectively. Cardiac safety of the combination was assessed. Fresh residual tumor samples were obtained at time of surgery for generation of patient derived xenografts (PDX). Tumor genomic profiling was done to determine the mutational spectrum, association of this spectrum in primary tumors with achieving pCR, and identifying alternative treatment strategies for PDX evaluation for patients with resistant disease.

Results: From 2/2015 to 5/2018, 36 pts were enrolled and 32 completed treatment; 4 pts await definitive surgery; 12 (33%) are two years from diagnosis. Median age of the cohort was 53 years. There was high participation by under-represented groups: 23% African American, 20% Asian, 14% Hispanic. Most histologies were invasive ductal but included apocrine, pleomorphic lobular, and metaplastic subtypes. Of the 32 pts who completed surgery, 34% (11) achieved pCR and 64% (23) had clinical response on serial physical exam. At 2 years, there were 2 distant and 1 local recurrence. The most common toxicities during DOX+CAR were grade 1 nausea in 19 pts (53%), grade 3/4 neutropenia occurred in 10 pts (28%); these pts received GCSF support with subsequent cycles; febrile neutropenia occurred in 1 pt (3%) in this group. Grade 3 thrombocytopenia (2 pts), pruritis (1 pt), and mucositis (1 pt) were observed. Only 6 pts (17%) had grade 1 alopecia. There were no delays in treatment due to cardiotoxicity or complications from surgical healing. TP53 (93%), PI3K/PTEN (26.6%), and NOTCH (20%) were the most commonly altered pathways. Structural variants, such as amplifications, rearrangements, and frameshifts were the most frequent alterations detected. Of the 25 pts who had residual disease, PDX was attempted from 14 pts, and 10 (71%) PDX were established, including those for all 3 patients experiencing recurrence.

Conclusion: Neoadjuvant DOX+CAR demonstrated good efficacy and tolerability. Post-chemotherapy PDX is feasible and may help identify targeted approaches for patients with resistant disease. These results warrant further evaluation of this combination for early stage TNBC.
Accuracy of MRI after neoadjuvant therapy for invasive lobular carcinoma of the breast

Kelly E Fahrner-Scott¹, Jasmine M Wong¹, Merisa Piper¹, Cheryl Ewing¹, Michael Alvarado¹, Laura J Esserman¹, Nola Hylton¹ and Rita A Mukhtar¹. ¹University of California, San Francisco, San Francisco, CA.

Background: Invasive lobular carcinoma of the breast (ILC) has higher rates of false negative imaging than invasive ductal carcinoma, and lower rates of neoadjuvant therapy (NAT) use. We evaluated the accuracy of Breast Imaging Reporting And Data System (BIRADS) findings on magnetic resonance imaging (MRI) after either neoadjuvant chemotherapy or endocrine therapy, and determined whether imaging change correlates with disease free survival.

Methods: We queried a database of 674 ILC cases treated at UCSF from 1981-2017 and identified all patients treated with NAT. We reviewed MRI reports and recorded BIRADS descriptors of findings, maximal tumor diameter for mass or non-mass enhancement (NME), and subjective radiologist comments on progression or improvement. We used the t-test, chi-squared test, Pearson's correlation, and Kaplan Meier survival estimates to evaluate the accuracy of MRI after NAT compared to true tumor size on pathology, and the relationship between imaging change and disease free interval in Stata 14.2.

Results: Of 136 patients with ILC treated with NAT, we included 101 women who had a post-treatment breast MRI report available. Of these, 58.4% received neoadjuvant chemotherapy, and 41.6% neoadjuvant endocrine therapy. After NAT, MRI findings were mass only in 43%, both mass/NME in 33%, NME only in 18%, and neither in 5%. Maximal diameter of mass on post-treatment MRI underestimated true size by a mean of 3.3 cm (range -3.6 to 15.3 cm). NME size on post-treatment MRI underestimated true size by a mean of 1.87 cm (range -7.2 to 9.7 cm). Mass size on MRI underestimated true size by ≥1 cm in 61.5% of cases; this size discrepancy was associated with increased positive margins (46.4% versus 20%, p=0.011). NME size on MRI underestimated true size by ≥1 cm in 65.6%. The correlation coefficient between mass size on MRI and true size was 0.34 (p=0.0041), which increased to 0.67 (p<0.0001) when excluding those with associated NME. The correlation coefficient between NME size on MRI and true size was 0.28 (p=0.1239). Subjective progression on post-treatment MRI was associated with increased recurrence rates (80% versus 18.3%, p=0.001). In those with subjective improvement on MRI, there was a trend towards longer disease free interval (89% versus 73% disease free at 4 years, p=0.13).

</table>
Conclusions: Maximal tumor diameter on MRI after NAT in ILC vastly underestimates true tumor size. While these findings suggest using caution when using an MRI for surgical planning in patients with ILC, particularly if there is associated NME, the trend towards improved disease free survival in those with a subjective improvement is intriguing and suggests that MRI changes could become an early predictor of outcomes.
Pathological complete response rates with the addition of carboplatin to standard neoadjuvant chemotherapy in a cohort of real-world patients with triple negative breast cancer

Susana Ramalho¹, Rodrigo de Andrade Natal¹, Cassio Cardoso Filho¹, Mariana Burity Xavier¹, Ana Elisa Ribeiro da Silva¹, Leonardo Roberto Silva¹, Vivian Vasconcelos¹, Tomas Reinert³,⁴, Guilherme Portela Coelho⁵, Geisilene Russano de Paiva Silva² and Cesar Cabello dos Santos¹. ¹Faculty of Medical Sciences, State University of Campinas (UNICAMP), Campinas, São Paulo, Brazil; ²Laboratory of Investigative Pathology, Women's Hospital (CAISM), State University of Campinas (UNICAMP), Campinas, São Paulo, Brazil; ³Laboratory of Investigative Pathology, Women's Hospital (CAISM), State University of Campinas (UNICAMP), Campinas, São Paulo, Brazil; ⁴Laboratory of Investigative Pathology, Women's Hospital (CAISM), State University of Campinas (UNICAMP), Campinas, São Paulo, Brazil; ⁵Grupo Diagnose Patologia e Biologia Molecular, Caxias do Sul, Rio Grande do Sul, Brazil.

Objectives: Addition of carboplatin to standard neoadjuvant chemotherapy (NACT) for triple negative breast cancer (TNBC) remains controversial. There are several randomized trials showing that carboplatin increases the likelihood of achieving pathological complete response (pCR) in TNBC. Patients with TNBC who achieve pCR has been shown to have better disease-free and overall survival. The aim of this study was to assess the impact of adding carboplatin to standard NACT in TNBC in terms of pCR rates and toxicity. Methods: In this cross-sectional study, 252 consecutive patients with primary TNBC who were submitted to neoadjuvant chemotherapy between 2013 and 2018, in a single center, were selected. Patients with biopsy-confirmed TNBC, previously untreated, with clinical stages I-III were included (n=179). Clinical pathological features, pathological response, treatment protocol, and toxicities were analyzed and considered for statistical analysis. Eighty patients treated from 2013 to 2015 received doxorubicin plus cyclophosphamide once every 3 weeks (AC) for four cycles, followed by 12 weeks (wP) or every 3 weeks (P) paclitaxel (AC-T group). Ninety-nine patients, treated from 2015 to 2018 had four cycles of AC followed by wP plus weekly carboplatin (Cb) area under curve (AUC) 1.5-2.0 (AC-TCb group). Pathologic response was determined locally, and pCR was defined as the absence of residual invasive disease with or without ductal carcinoma in situ in the breast and axilla. Results: Data from 179 patients were included in the analysis (AC-T: n=80; AC-TCb: n=99). Patients in AC-TCb group had a median age of 51.7 years vs. 47.4 years in AC-T group, p=0.01. In AC-TCb group 61.6% of patients were postmenopausal vs 43.7% in AC-T group, p=0.03. The distribution of clinical stage in groups AC-TCb and AC-T were as follows: stage I 6.0% vs 0%; stage II 42.4% vs 43.7%; stage III 51.6% vs 56.3%, respectively (p=0.02). In AC-TCb group, 34 patients (35.0%) had pCR in comparison to 20 patients (25.0%) on AC-T group (p=0.22). Pathological stage distribution in groups AC-TCb and AC-T were: stage I 24.7% vs 33.7%; stage II 23.7% vs 26.3%; stage III 16.4% vs 15%, respectively (p=0.42).

More than 85.0% of patients in AC-TCb group received at least 9 weeks of carboplatin and less than 20.0% required dose reduction due to toxicity. **Conclusions:** An improved pathological complete response for TNBC patients submitted to standard NACT plus carboplatin was observed. The results are in accordance with previous studies demonstrating that the addition of carboplatin to NACT improves pCR rate in TNBC with a favorable risk to benefit profile. Therefore carboplatin might be a potential component of NACT and should be considered in this context.
Liposomal-encapsulated doxorubicin (Myocet) as part of primary systemic therapy in HER2-positive operable breast cancer: Efficacy data, cardiotoxicity and long-term follow-up in 81 patients diagnosed from 2005-2016 at a single institution

Silvia Antolin1, Lourdes Calvo1, Javier Prato1, Aurea Molina1, Cristina Reboredo1 and Joaquin Mosquera1. 1 A Coruña University Hospital, A Coruña, Spain.

Objectives
To evaluate the efficacy, cardiotoxicity profile and long-term benefits of liposomal doxorubicin (Myocet) as part of neoadjuvant therapy in HER2-positive operable breast cancer patients.

Methods
The treatment consisted of a sequential regimen of paclitaxel and liposomal doxorubicin (Myocet) plus trastuzumab. Clinical and pathologic response were evaluated and correlated with clinical and biological factors. Cardiotoxicity profile and long-term benefits were analyzed.

Results
Median age was 48 years and 4%, 69%, and 27% were stage I, II, and III, respectively, while 12% had inflammatory breast cancer at diagnosis. Hormone receptor (HR) status was negative in 43% and 70% were grade III.

Patients who achieved pCR had longer DFS and a trend to improve OS.
Four percent of patients showed a decrease in the left ventricular ejection fraction below 50% during treatment. All except one of them recovered after discontinuation of trastuzumab.

**Conclusion:** A sequential regimen of taxanes and liposomal doxorubicin (Myocet) plus trastuzumab was active with high pCR rates and long-term benefit with a very good cardiotoxicity profile.
Nomogram for prediction of axillary and breast pathologic response after neoadjuvant chemotherapy in node positive patients with breast cancer

Hee Jun Choi¹, Seok Won Kim¹, Jai Min Ryu¹, Isaac Kim¹, Seok Jin Nam¹, Jonghan Yu¹, Se Kyung Lee¹ and Jeong Eon Lee¹. ¹Samsung Medical Center, Seoul, Korea.

**Background:** Many patients with cytology prove node-positive breast cancer receive neoadjuvant chemotherapy (NAC). We developed a nomogram to predict probability of breast and axillary pathologic complete response (pCR) in patients with cytologically proven axillary node positive breast cancer with NAC.

**Materials and Methods:** This study is a registered medical record review based on a prospectively collected cohort. We selected 995 patients who were diagnosed with invasive breast cancer and axillary lymph nodes metastasis and treated with NAC followed by curative surgery at Samsung Medical Center between January 2007 and December 2014. Baseline patient and tumor characteristics, chemotherapy regimen, and tumor and nodal responses were analyzed. A nomogram was developed using a binary logistic regression model with a cross validation.

**Results:** Axillary pCR was achieved in 47.3% of the patients who underwent axillary surgery after NAC. Breast pCR was achieved in 24.3% of the patients who underwent breast surgery. Axillary and breast pCR was associated with initial clinical tumor status, negative progesterone receptor status, positive human epidermal growth factor receptor 2 (HER2) status, and nodal responses.

**Conclusion:** Our nomogram might help predict axillary and breast pCR after NAC in patients with initially node-positive breast cancer. Patients with a high probability of achieving pCR might be more minimal surgery trial.
Carboplatin-addition in neoadjuvant treatment of women with triple negative breast cancer (TNBC): Prognostic value in real-world patients

Sara Coelho¹, Miguel Henriques Abreu¹, Carolina Sales¹, Ana Rita Lopes¹, Mário Fontes Sousa¹, Rosário Couto¹, Ines Pousa¹, Ana Ferreira¹, Marta Ferreira¹, Cláudia Vieira¹, Conceição Leal¹, Fernando Castro¹, Susana Sousa¹ and Deolinda Pereira¹.
¹Instituto Portugues de Oncologia do Porto Francisco Gentil, EPE, Oporto, Portugal.

Background
The addition of carboplatin to an anthracycline/taxane-based chemotherapy (CT) in neoadjuvant setting has been suggested to improve pathological complete response (pCR) in TNBC. However, the impact of pCR in prognosis is unknown. We aim to study the value and feasibility of the addition of carboplatin in neoadjuvant setting.

Methods
Demographic and clinical data of TNBC patients treated with neoadjuvant CT in a comprehensive cancer center between 2010-2018 were retrospectively collected. Two cohorts were defined: one treated with Carboplatin/Paclitaxel followed by dose-dense Doxorubicin/Cyclophosphamide (CP-AC) and other with AC followed by Docetaxel (AC-D). Median follow-up time was 3.1 and 6.9 years, respectively. pCR was defined as absence of residual invasive tumor in breast/axilla. Survival analysis using Kaplan-Meier method and Cox proportional-hazards model were applied. Statistical significance was set at p<0.05.

Results
One-hundred and sixty patients were enrolled: 78 CP-AC and 38 AC-D. Groups were balanced regarding patients and tumor characteristics with exception of pre-menopausal status, more frequent in CP-AC(68% vs 47%;p=.04). Age at diagnosis was 47(28-76) years, the majority had ECOG 0(92%) ductal carcinomas(82%), clinical T2/3 stages(76%), grade 3(81%) with lymph node involvement(N+)(57%). 14% had Inflammatory breast cancer (IBC)(CP-AC 14%;AC-D 13%; p=.9).
Neutropenia was the most prevalent adverse event(G3/4: CP-AC 61%;AC-D 16%;p=.02), 12% and 16% of febrile neutropenia(p=.8). G3/4 thrombocytopenia occurred only in CP-AC(6%). Hypersensitivity reactions were more prevalent in CP-AC(19% vs 2.7%;p=.02), majority to paclitaxel, all G1/2. Hospital admission occurred in 12%(CP-AC 13%;AC-D 9%; p=.8).
There were no treatment-related deaths. Treatment schedule was complete in 89%(CP-AC 87%;AC-D 92%;p=.5), with 20% dose reductions(CP-AC 25%;AC-D 11%;p=0.9).
pCR was achieved in 42%(CP-AC 50%;AC-D 28%;p=.03). 1- and 3-year disease-free survival (DFS) was 94%/85% for CP-AC and 72%/58% for AC-D(p=.3). Risk of recurrence was higher in IBC(HR 25.1;CI95% 7.7-81.3;p<.0001), N+ disease(HR 3.6;CI95% 1.2-10.5;p=.02) and non-pCR(HR 10.9;CI95% 2.3-52.3;p=.003). N+ disease was associated with higher recurrence only in AC-D(HR 11.7;CI95% 1.3-104;p=.03).
Cancer-related deaths were 20%(CP-AC 10%;AC-D 40%;p=.001). 1- and 2-year overall survival (OS) was 99%/95% for CP-AC and 70%/61% for AC-D(p=.06). N+ disease was associated with higher risk of death in AC-D(HR 6.3;CI95% 1.1-24.6;p=.04). Risk of death was independently associated with IBC(HR 4.1;CI95% 2.1-18.7; p=.001) but not with N+ disease(HR 2.7;CI95% 0.8-9.5;p=.13) or pCR(HR 4.1;CI95% 0.9-19.7;p=.08) although pCR was statistically significant in univariate analysis (1- and 2-year OS 97% vs 92% and 94% vs 86% for pCR and non-pCR;p=.003).

Conclusions
Carboplatin addition clearly increased pCR with a trend to DFS and OS benefit. This regimen was associated with more, nevertheless manageable, adverse events with most of the patients able to tolerate and complete the full-dose regimen. Though we did not find a subgroup of patients that benefit with carboplatin regimen, we should consider avoiding AC-D at least in N+ disease.
Dietary REstriction as an adjunct to neoadjuvant ChemoTherapy for HER2-negative breast cancer: Final results from the DIRECT trial (BOOG 2013-04)

S de Groot¹, R T Lugtenberg¹, M JP Welters¹, I Ehsan¹, M PG Vreeswijk¹, V THBM Smit², H de Graaf², J B Heijns³, J EA Portielje⁴, A J van de Wouw⁵, A LT Imholz⁶, L W Kessels⁶, S Vrijaldenhoven⁷, A Baars⁸, E Meershoek-Klein Kranenbarg⁹, M Duijm-de Carpentier¹, E van Leeuwen-Stok¹, H Putter¹, V D Longo⁹, J JM van der Hoeven¹, J WR Nortier¹, H Pijl¹ and J R Kroep¹. ¹LUMC, Leiden, Netherlands; ²MCL, Leeuwarden, Netherlands; ³Amphia Hospital, Breda, Netherlands; ⁴Haga Hospital, Den Haag, Netherlands; ⁵Viecuri, Venlo, Netherlands; ⁶Deventer Hospital, Deventer, Netherlands; ⁷MCA, Alkmaar, Netherlands; ⁸ZGV, Ede, Netherlands and ⁹USC, Los Angeles.

Background:
Short term fasting (STF) protects from toxicity, while enhancing the efficacy of chemotherapy in cancer bearing mice and is a promising strategy to enhance the efficacy and tolerability of chemotherapy in humans. A specifically designed low calorie, low amino acid substitution diet (“Fasting Mimicking Diet”, FMD) has similar effects in vivo during chemotherapy as STF. The DIRECT trial evaluates the impact of FMD on toxicity and efficacy of neoadjuvant chemotherapy in women with HER2-negative early breast cancer.

Patients and methods:
Eligible patients had histologically confirmed, HER2-negative, stage II/III early breast cancer, adequate bone marrow, liver and renal function, BMI > 19kg/m² and absence of diabetes mellitus. Women receiving 8 neo-adjuvant AC-T courses (adriamycin/cyclophosphamide - docetaxel) or 6 FEC-T courses (5-fluorouracil, epirubicin and cyclophosphamide - docetaxel); day 1, q 3 weeks, were randomized to receive FMD or regular diet for 3 days prior to and at the day of chemotherapy and 3 days prior to surgery. The FMD group received no dexamethasone during the AC or FEC courses. The primary endpoint of the phase II part was feasibility and grade III/IV toxicity and of the phase III pathological complete response (pCR) rate. Additionally, in a side study increase in DNA damage in lymphocytes before and three hours after chemotherapy was compared between the 2 arms.

Results
From February 2014 to January 2018 131 patients from 11 participating Dutch centers were randomized, whereof 100 received AC-T and 31 received FEC-T. Sixty-six of the patients received FMD. Compliance to the diet was low as 32% fasted at least half of the cycles and 24% of patients fasted during all of cycles. The main reasons of non-compliance were food aversion induced by chemotherapy and the taste of the diet. Intention to treat grade III/IV toxicity was not significantly different between the standard arm (67,2%) and in the FMD arm (79,4%), although the majority of the toxicities in the FMD arm were assessed in patients that did not complete the FMD diet preceding the measurements. The total overall pCR rate was 12,8%, lower than assumed in the sample size calculation and would therefore need minimally a doubling in patient numbers to be able to reach the expected pCR difference between both arms. Due to the poor compliance, slow accrual rate and low overall pCR rate the DIRECT study terminated after completion of the phase II part. Subgroup analysis will be presented at SABCS. In a side study, DNA damage after chemotherapy was significantly less increased in lymphocytes in the FMD group as compared to the control group (p=0.043).

Conclusion
The effect of STF on toxicity and efficacy of chemotherapy was not established due to poor compliance, however STF by FMD reduced a transient increase in chemotherapy induced DNA damage. Close monitoring of patients by nutritionists with expertise in low calorie diets as well as diets with a more variable taste are probably needed to successfully examine the impact on adverse effects and tumor biology.
The molecular characterisation of early and advanced breast cancer in a Middle-Eastern breast cancer cohort treated with neo/adjuvant anthracycline+/-taxane-based chemotherapy

2018 San Antonio Breast Cancer Symposium®

Publication Number: P1-15-21

The molecular characterisation of early and advanced breast cancer in a Middle-Eastern breast cancer cohort treated with neo/adjuvant anthracycline+/-taxane-based chemotherapy

Shaheenah Dawood¹, Darren Korbie², Mike Pheasant², Houriya Kazim², Annett Al Hamadi¹, Charles Lloyd², Rebecca Dent³ and Paul N Mainwaring². ¹Mediclinic City Hospital, Dubai, United Arab Emirates; ²XING Technologies, Pty Ltd Brisbane, Australia and ³National Cancer Center, Singapore, Singapore.

Neoadjuvant therapy for breast cancer enables improved conservative operative approaches for breast cancer with similar survival. In addition, it may be used to define clinical as well as molecular systemic therapy sensitivity, aid molecular subtyping analysis of residual disease as well as incorporating potential mechanisms of resistance. Breast cancer in women in the Middle East is characterized by younger median age, more advanced stage at presentation and a higher proportion of patients with triple-negative disease. Recently, Symmans et al. published the results of neoadjuvant anthracycline+/-taxane-based chemotherapy demonstrating a strong association between residual cancer burden (RCB) and overall survival. In this and other cohorts e.g. TCGA, ICGC molecular data of pts from the Middle-East is under-represented.

Aim:
The aim of this project was to define the above parameters in a cohort of women treated with systemic therapy from June 2016 to October 2017 in a Middle Eastern breast cancer referral centre treated in the neo/adjuvant setting. In the neoadjuvant setting we are examining the association between primary biopsy and pathological response tissue (RCB criteria) integrating molecular pathology using massive parallel sequencing (MPS) analyses.

Methodology:
We designed a custom 1000 gene panel using Illumina IDT capture-based assay design and sequenced tumour samples to greater than 500X coverage. Sequencing analysis and variant calling were performed using Broad GAKT best practice; BWA, Mutect2, Oncotator pipeline.

Results:
We present a cohort of 57 pts with median age of 45(26-66), presenting with clinical stage I 2(4%), stage II 30(53%), stage III 25(44%) breast cancer for neoadjuvant (20) or adjuvant (37) anthracycline +/- taxane-based chemotherapy. Standard immunohistochemical (IHC) analysis revealed ER-pos PR-pos HER2-neg 38(67%) ER-pos PR-neg HER2-neg 2(4%) ER-neg PR-neg HER2-pos 3(5%), ER-pos PR-pos HER2-pos 5(9%), TNBC 9(16%). In the neoadjuvant cohort (20) pts, 7 were clinical stage II and 12 stage 3 at presentation. Anthracycline+/-taxane-based chemotherapy achieved pCR/RCB 0 7(35%), RCB I 3(15%), RBC II 4(20%), RCB III 6(30%). All Her2 positive patients received concurrent taxane-trastuzumab.

Implications:
Predictive molecular expression algorithms for response to systemic chemotherapy in the neoadjuvant setting have been published (Hatzis JAMA 2011; Masuda Clin Ca Res 2013). Molecular characterisation of RCB after neoadjuvant chemotherapy has looked at DNA mutations (Jiang PLOS Med 2016) and RNA expression (Lehmann J PLOS One 2016; Echavarria Clin Ca Res 2018). Integration of both provides insight into mechanisms of sensitivity and relapse using pathway analysis. We present genomic data on 20 of the neoadjuvant samples with sufficient quality DNA analysed using a custom designed 1000 gene panel using Illumina IDT capture-based assay design to greater than 500X coverage. The most commonly aberrant genes TP53, PIK3CA, GATA3, KMT2Dwere observed, with notable differences in PAX3, BRCA2, CHD2, FGFR4. Using integrated comprehensive tumour molecular comparisons pre- and post-treatment in the neoadjuvant patients and circulating tumour DNA analyses of the whole cohort will be presented.
Clinicopathological significance of diversity index for c-MYC copy number variation after primary systemic therapy in breast cancer

Gilhyang Kim¹, Yul Ri Chung¹,², Hyun Jeong Kim¹, Milim Kim¹,², Soomin Ahn¹ and So Yeon Park¹,². ¹Seoul National University Bundang Hospital, Seongnam, Gyeonggi, Republic of Korea and ²Seoul National University College of Medicine, Seoul, Republic of Korea.

Background: Chemotherapy can alter tumor cell populations by exerting selection pressure. This study was performed to evaluate the change in Shannon diversity index for c-MYC copy number variation after primary systemic therapy (PST) and its clinical implications in breast cancer patients treated with PST.

Materials and Methods: One hundred and forty-four breast cancer patients who had residual disease after anthracycline- or anthracycline and taxane-based PST were included in the study. Associations between Shannon index for c-MYC copy number variation in pre- and post-PST breast cancer samples and clinicopathologic features of tumors as well as patient survival were analyzed.

Results: Among the 119 patients with both pre- and post-PST samples available for comparison, 17 (14.3%) underwent change in c-MYC amplification status and 40 (33.6%) in c-MYC copy number gain status with most cases showing positive to negative conversion. In the whole group, Shannon index for c-MYC copy number variation was decreased in post-PST specimens compared to pre-PST specimens. Especially, the chemo-responsive group showed a more significant decrease in Shannon index after PST. However, there was no difference in diversity indices between pre- and post-PST specimens in the chemo-resistant group. c-MYC copy number gain and high Shannon indices for c-MYC copy number variation in both pre- and post-PST specimens were associated with adverse clinicopathologic features of breast cancer. In survival analyses, high Shannon indices for c-MYC copy number variation in post-PST samples as well as pre-PST samples were revealed as an independent prognostic factor for decreased disease-free survival. Upon subgroup analysis according to hormone receptor status, high Shannon indices before and after PST were associated with adverse clinical outcome in hormone receptor-positive group but not in hormone receptor-negative subgroup.

Conclusions: These results suggest that a change in Shannon index for c-MYC copy number variation after PST reflects chemo-responsiveness and that Shannon index after PST can be used as a prognostic factor in breast cancer patients who receive PST.
Higher efficacy of 2-week nab-paclitaxel compared to solvent-based paclitaxel in neoadjuvant chemotherapy of triple negative breast cancers

Jue Wang¹, Fei Xie¹, Ling Zhang¹, Rui Chen¹, Qiannan Zhu¹, Zinan Yin², Sainan You¹, Chaojun Jiang¹ and Xiaoming Zha¹. ¹The First Affiliated Hospital of Nanjing Medical University, Nanjing, China and ²Peking Union Medical College, Beijing, China.

Background: Weekly nab-paclitaxel (nP) has better efficacy and safety for breast cancer patients compared with solvent-based paclitaxel (sP), but the result seems to be compromised when to 3-week nP though more convenient. However, reports about the 2-week nP in early breast cancer (EBC) are few. The current study aims to investigate whether 2-week nP is more effective than 2-week sP when added to an epirubicin/cyclophosphamide containing Neoadjuvant Chemotherapy (NAC) in Chinese EBCs.

Methods: Patients included in current retrospective study must meet at least one of the following criteria: tumor size ≥3cm; positive axillary lymph node; human epidermal growth factor receptor-2 (HER2) overexpression; triple negative breast cancer (TNBC, estrogen receptors (ER), progesterone receptors (PR), and HER2 negative); patients with willingness to receive breastconserving therapy. Based on expressive levels of ER, PR, HER2 and Ki-67, patients were divided into different subgroups. After dose dense EC (E, epirubicin 90 mg/m²; C, cyclophosphamide 600 mg/m²), patients were received either nP (260 mg/m²) q2w or sP (175 mg/m²) q2w, with or without herceptin (first time 8mg/kg and followed by 6mg/kg). The primary endpoint was the pathological complete response (pCR) rates (ypT0N0 and ypT0/isN0) and the second endpoint was the toxicity.

Results: Total 151 patients were recruited from August 2013 to October 2017. Of them, 77 patients received nP and 74 received sP. Baseline characteristics are similar that the mean age was 47.68/51.82 years (nP/sP) and tumor size was 41.23/39.77 mm (nP/sP). After treatment, the pCR rate of TNBC patients was significantly higher in the group receiving nP (6/11, 54.4%) compared to sP (2/16, 12.5%, p=0.0332). No difference of pCR rates was found between nP and sP groups regarding to the threshold (20%) of Ki-67. Only few or no patients in subgroups of Luminal A, Luminal B HER2+ and Ki-67 ≤ 20% experienced pCR. Although the pCR was observed in other subgroups, there was no significant difference between patients with nP and sP.

Table 1. pCR rates.

a, patients received EC-TH, other patients received EC-T.

. The side effects included peripheral neuropathy, allergic reactions, bone marrow suppression, and the incidence of peripheral neuropathy innP was significantly increased.

**Conclusions:** The results suggested that nP (260 mg/m², q2w) was associated with a better efficiency profile compared to sP (175 mg/m², q2w) in NAC for TNBC. Meanwhile, nP also brings more peripheral neuropathy. As a result, nP (260 mg/m², q2w) is also an NAC option for TNBC in China.
Randomized phase II trial to evaluate chemoradiotherapy vs radiotherapy among non-responders breast cancer patients treated with chemotherapy

Maritza Ramos1, Claudia Arce1, Fernando Lara1, Alberto Alvarado1 and Noel Castañeda1. 1Instituto Nacional de Cancerologia, Ciudad de Mexico, Mexico.

Background:
Among patients with locally advanced breast cancer (LABC), preoperative systemic treatment is the standard of care; approximately 80% of the patients treated with neoadjuvant chemotherapy present partial or complete clinical response, however there are patients who progress during this therapy or at the end of it, the tumors remain inoperable, this confers a worse prognosis, with an increase in the rates of metastasis and decrease overall survival. The benefit of concomitant chemoradiotherapy in local control is controversial. The objective of this trial is to analyze the efficacy of local control and survival in patients with locally advanced breast cancer who received systemic treatment plus chemoradiotherapy or radiotherapy alone preoperatively.

Patients and Methods
Prospective, randomized, open label trial; patients with LABC whom after neoadjuvant chemotherapy based con anthracyclines and taxanes have disease progression or inoperable disease. Arm A (standard) received radiotherapy (RT) 50 Gy in 25 fractions or chemoradiotherapy (CRT)(gemcitabine 100 mg/m2 plus cisplatin 30 mg/m2) weekly during radiation. The primary endpoint was local recurrence. Secondary end points included systemic recurrence, overall survival and surgical complications. Statistical analysis was done with SPSS v 20.0, groups comparison was done with X2, survival was analyzed with Kaplan-meier method and comparison among groups with log-rank. Proportional Cox model associate clinical variables with recurrence and death. Local ethics committee approves the trial.

Results:
78 patients were included, median follow-up was 116 months (110-121) at this time, 37 patients had recurrence (local, systemic or both) of which 18 were treated with CRT vs 19 RT alone (51.4 vs 44.2%, p=0.34). Higher rates of local recurrence were in RT alone 63.1% vs 38.9% with chemoradiotherapy with significance difference (p=0.004).

There were no differences in disease free survival (p=0.542) and overall survival was found (p=0.303), 57.1 vs 53.5% respectively. Proportion of surgical complications were similar 71.4% for CRT vs 69.8% for RT (p=0.848). However hematological and gastrointestinal toxicity were more prevalent in patients treated with CRT p<0.005

Conclusion:
Chemoradiotherapy it’s a feasible option to reduce the risk of local recurrence, however without any additional benefit to improve the recurrence-free survival or overall survival. Surgical complications are still the same.
Prognostic factors associated with pathological complete response in early breast cancer patients undergoing neoadjuvant chemotherapy. The importance of Ki-67 and molecular subtype

Bernardo L Rapoport¹, Jacqui Barnard-Tide¹, Teresa Smit¹, Simon Nayler² and Carol-Ann Benn³. ¹The Medical Oncology Centre of Rosebank, Johannesburg, South Africa; ²Drs Gritzman and Thatcher Inc. Pathology Laboratory, Johannesburg, South Africa and ³The Netcare Breast Centre of Excellence, Netcare Milpark Hospital, Johannesburg, South Africa.

Background: Ki-67 immunohistochemical determination is a widely used biomarker of cell proliferation in patients (pts) undergoing endocrine treatment for breast BC. The role of Ki-67 in pts undergoing neoadjuvant chemotherapy (NAC) for early BC remains controversial.

Methods: We analyzed retrospectively data on 137 patients undergoing taxane and/or anthracycline, transtuzumab based NAC. Luminal A was documented in 6 pts, Luminal B in 29 pts, Her-2 positive in 30 pts and triple negative breast cancers (TNBC) in 72 pts. Pathological complete response (pCR) was defined as the complete disappearance of the invasive cancer in the breast and absence of tumor in the axillary lymph nodes examined by axillary clearance.

Results: The pCR rate of the entire cohort was 41.6%. At 2 years 92% of pts who attained a pCR were disease free compared to 80% of pts who did not attain a pCR (log rank test p < 0.0147).

On univariate analysis factors associated with higher pCR included primary tumor size (T1 68% vs. T2 41% vs. T3 or T4 0%, Chi²=20.05, p<0.00017), nodal disease (N0 49% vs. N1 39% vs. N2 8%, p<0.02948), ER receptor status (negative 59% vs. positive 14%, p<0.00000), PR receptor status (negative 53% vs. positive 17%, p<0.00002), molecular subtype (TNBC 53.4%, Her2=50% and Luminal A + B was 8.5%, p<0.00002), Ki67 (>40=55% vs. 15-39=34% vs. <15=0%, p<0.00060) and Stage (I=85% vs. IIA=49% vs. IIB=36% vs. III=5%, p<0.00006). Factors not associated with a higher pCR included age, menopausal status, extranodal spread and lympho-vascular invasion. In a logistic regression model Ki-67 as a continuous variable (p<0.01203) and molecular subtype (p<0.02228) retained its significance; while tumor size, stage of disease, nodal status, ER and PR loss significance.

Conclusion: Ki67 and molecular subtype (Her-2 positive disease and TNBC) are independent prognostic factors of pCR in pts with early BC undergoing NAC.
Efficacy of endocrine- versus chemotherapy-based treatments in hormone receptor-positive (HR+ve), HER2-negative (HER2-ve) postmenopausal metastatic breast cancer (mBC): A network meta-analysis (NMA)

Francesco Schettini¹, Mario Giuliano¹,², Carla Rognoni³, Sabino De Placido¹, Grazia Arpino¹, Manuela Milani⁴, Antonio Giordano⁵, Massimo Cristofanilli⁶, Guy Jerusalem⁷, Thomas Bachelot⁸, Barbara Pistilli⁹, Michelino De Laurentiis¹⁰, Sergio Venturini¹ and Daniele Generali¹¹,¹. University of Naples Federico II, Naples, Italy; ²Baylor College of Medicine, Houston; ³CE.R.G.A.S., SDA Bocconi, Milan, Italy; ⁴ASST Cremona, Cremona, Italy; ⁵Medical University of South Carolina, Charleston; ⁶Northwestern University, Chicago; ⁷CHU Liège, University of Liège, Liège, Belgium; ⁸Centre Léon Bérard, Lyon, France; ⁹Institut Gustave Roussy, Paris, France; ¹⁰Istituto Nazionale Tumori - IRCCS - Fondazione G. Pascale, Naples, Italy and ¹¹University of Trieste, Trieste, Italy.

Background: The international guidelines support upfront use of endocrine therapies (HT), with or without new targeted agents (TA), in HR+ve/HER2-ve mBC. However, routine administration of regimens containing chemotherapy (CT) is still common, even in the absence of visceral crisis. Unfortunately, robust data from head-to-head direct comparisons among CT and HT-based strategies are still not available; therefore, a NMA is now the only valuable methodological approach to compare the efficacy and activity of HT- versus CT-based regimens, and to drive adequate suggestions for a potential therapeutic algorithm in 1st and 2nd line HR+ve/HER2-ve mBC.

Methods: We performed a systematic literature search and selected all available phase II-III RCT published between January 2000 and December 2017, which evaluated CT or HT ± TA as 1st and/or 2nd line treatments for postmenopausal women with HR+ve/HER2-ve mBC. Primary endpoint was progression-free survival (PFS)/time to tumor progression (TTP); secondary endpoint was overall response rate (ORR). A Bayesian NMA was generated to compare posterior median hazard ratios (HR) for PFS and odds ratios (OR) for ORR. The aromatase inhibitor (AI) anastrozole (ana) was chosen as the common comparator for the overall analyses, being the most frequent treatment in the dataset.

Results: A total of 137 eligible trials (48,653 patients) were included in the NMA. Among the regimens approved for clinical use, palbociclib (palbo) + letrozole (let) [HR:0.42, 95% credible intervals (CI):0.27-0.65], ribociclib (ribo) + let (HR:0.43, 95%CI:0.27-0.74), abemaciclib (abe) + ana(let) (HR:0.42, 95%CI:0.25-0.71), palbo + fulvestrant (ful) (HR:0.37, 95%CI:0.25-0.55), abe + ful (HR:0.45, 95%CI:0.30-0.65), everolimus (eve) + exemestane (exe) (HR:0.37, 95%CI:0.25-0.54), and ful alone (HR:0.81, 95%CI:0.66-0.98) were significantly superior to ana in terms of PFS/TTP. Conversely, none of the CT-based regimens (i.e. paclitaxel+bevacizumab, anthracycline-based schemes, capecitabine, eribulin) was significantly superior to ana. Additionally, head-to-head comparisons among the CDK 4/6 inhibitors (CDK4/6i) combined with AI showed no significant difference (palbo + let vs. ribo + let, HR:0.98, 95%CI:0.63-1.54; palbo + let vs. abe + ana(let), HR:1.02, 95%CI:0.63-1.60; ribo + let vs. abe + ana(let), HR:1.03, 95%CI:0.62-1.73). On the other hand, CDK4/6i+AI were significantly superior to many 1st line CT, including taxane- and/or anthracycline-based regimens. Interestingly, no CT±TA regimen was significantly superior to ana or to HT+TA, in terms of ORR.

Conclusions: Our analysis suggests that CT-based regimens are not significantly superior to HT-based therapies as 1st/2nd line treatments for postmenopausal HR+ve/HER2-ve mBC. Instead, HT+TA, including CDK 4/6i and eve, were significantly superior to HT alone and to many 1st/2nd line CT regimens. Moreover, the three CDK4/6i combined with AI did not differ significantly among each other. These data strongly support the combination of a CDK 4/6i along with HT as the preferred first choice of treatment for the 1st and 2nd line in HR+ve/HER2-ve mBC, as indicated in all the international guidelines.
The impact of locoregional treatment on survival in patients with metastatic breast cancer: A national cancer database analysis

Kristine N Kim¹, Daniel Huang², Muhammad M Qureshi², Naomi Y Ko² and Ariel E Hirsch². ¹University of Pennsylvania Perelman School of Medicine, Philadelphia, PA and ²Boston Medical Center, Boston, MA.

Purpose and Objectives: Although systemic therapy is the standard treatment for metastatic breast cancer, the value of locoregional treatment (LRT) to the primary tumor and its impact on survival is controversial. This study evaluates survival outcomes in patients with metastatic breast cancer after receiving LRT (surgery and/or radiation therapy) to the primary tumor.

Materials and Methods: The National Cancer Database (NCDB) identified 16,128 qualifying cases of stage IV breast cancer (M1, 2004-2013) who received systemic therapy with or without local therapy. Treatment modality was divided into surgery, radiation therapy (RT), surgery with RT (Sx+RT), and no LRT. Median survival and three-year actuarial survival rates (OS) were analyzed for each treatment group. On multivariate analyses, adjusted hazard ratios (HR) with 95% confidence interval were computed using Cox regression modeling to adjust for patient characteristics, year of diagnosis, clinical T and N staging, and facility type. Additionally, survival outcomes for each treatment group were analyzed by metastasis groups (bone, visceral, multiple).

Results: A temporal trend of each treatment modality used in years 2004 – 2013 illustrated that the relative use of LRT decreased from 47.2% to 36.2% (p for trend = 0.041). Overall, the median follow-up was 28.3 months and median survival for all patients was 37.2 months. With 9,761 deaths reported, the estimated 3-year survival rate for all patients was 51.3%. The Sx+RT group (n = 2,166) had the highest 3-year survival rate of 69.4%, followed by the surgery group (n = 4,293) with 57.6%, no LRT group (n = 8,955) with 44.3%, and RT group (n = 714) with 41.5% (p < 0.0001). On multivariate analysis, a decreased hazard of death (adjusted HR, 95% CI) was noted in radiation patients compared to no LRT group but without statistical significance (0.91, 0.81-1.0, p = 0.057). Patients receiving surgery (0.68, 0.65-0.71, p < 0.0001) and Sx+RT group (0.46, 0.43-0.49, p < 0.0001) reported statistically significant improved survival compared to the no LRT group.

Additionally, later year of diagnosis, low Charlson-Deyo score, high income, private insurance, white race, age 18 - <50, low T and N stage, ductal histology, positive ER/PR/HER2 status, bone only metastasis, and academic facility type were considered favorable factors for OS. When stratified by metastasis type, patients with bone metastasis had the longest 3-year survival rates (74.4% for Sx+RT, 69.4% for surgery, 53.8% for no LRT, 49.3% for RT, p < 0.0001) whereas patients with multiple metastases had the worst outcomes (56.0% for Sx+RT, 43.5% for surgery, 37.9% for no LRT, 34.4% for RT, p = 0.003).

Conclusion: Patients with metastatic breast cancer have a large range of survival rates. Locoregional treatment, especially surgery followed by RT, in addition to systemic therapy was associated with improved survival in metastatic breast cancer patients. When survival rates for each treatment modality was stratified by metastasis location, the most favorable survival was observed for the surgery with follow-up radiation group, which is consistent with the overall analysis.

Phase II randomized clinical trial (RCT) of metformin (MET) vs placebo (PLAC) in combination with chemotherapy (CXT) in refractory locally advanced (LABC) or metastatic breast cancer (MBC)

Pamela J Goodwin¹², Marguerite Ennis³, David W Cescon⁴, Christine Elser⁴, Rashida Haq⁵, Caroline M Hamm⁶, Ana Elisa Lohmann¹², Isabel Pimentel¹², Martin C Chang⁷, Ryan JO Dowling¹ and Vuk Stambolic⁴.¹

¹Lunenfeld-Tanenbaum Research Institute, Toronto, Canada; ²Mount Sinai Hospital, Toronto, Canada; ³Applied Statistician, Markham, Canada; ⁴Princess Margaret Cancer Centre, University Health Network, Toronto, Canada; ⁵St. Michael's Hospital, Toronto, Canada; ⁶Windsor Regional Cancer Center, Windsor, Canada; ⁷Sinai Health System, Toronto, Canada and ⁸University of Toronto, Toronto, Canada.

Background: MET treatment of diabetes is associated with improved BC outcomes. Hirsch et al (Cancer Res 2009;69:7505-7511) suggested MET may act synergistically with CXT in BC rodent models. We conducted a double-blind Phase II RCT of CXT plus MET vs placebo in LABC/MBC.

Methods: Non-diabetic BC patients (pts) about to commence 1st-4th line CXT (prespecified anthracycline, taxane, vinorelbine, platinum or capecitabine; HER2 Rx permitted) for MBC or refractory LABC (any ER, PgR, HER2) were eligible if (i) age 18-75, (ii) ECOG 0-2, (iii) adequate hepatic, renal, bone marrow, cardiac function and (iv) measurable or evaluable disease. Those with CNS metastases, recent MET use or radiotherapy to target lesions, intake of ≥3 alcoholic drinks/day, history of lactic acidosis or current/planned pregnancy or lactation were ineligible. Randomization was to MET 850 mg po bid (or identical PLAC bid) with a 2 day ramp up of one tablet/day; dose was reduced/drug discontinued in a pre-specified manner for grade 2-4 toxicity. Disease status and toxicity/HRQOL were assessed at baseline and q9 weeks until progression. Primary outcome was progression-free survival (PFS); secondary outcomes included survival (OS), response and toxicity. With 40 subjects and type one error 0.2 (1-sided), a PFS HR of 0.58 could be detected with 80% power. PFS was analyzed using Cox proportional hazards regression.

Results: 40 pts were randomized (22 MET, 18 PLAC). Mean age 55.4 vs 56.9 years; ER/PgR+ in 86.4 vs 83.3%; time from 1st metastases to randomization 297 vs 405 days, in MET vs PLAC respectively. MET pts were more likely to have visceral metastases (95.5% vs 72.2% PLAC) and less likely to be HER2+ (9.1% vs 23.5% PLAC). CXT was 1st line in 68.2% MET and 66.7% PLAC pts. Toxicity - # events: Gr 4: 0 MET vs 1 PLAC, Gr 3: 14 MET vs 14 PLAC; Gr 1 or 2: 193 MET (mainly GI) vs 53 PLAC. Best response: PR 18.2% MET vs 22.2% PLAC, SD 31.8% MET vs 11.1% PLAC, PD 45.4% MET vs 50.0% PLAC, P = 0.41. Mean PFS 164 days MET vs 192 days PLAC; HR (MET vs PLAC) 1.14 (95% CI 0.59-2.2), 1-sided p=0.65. Mean OS 645 MET vs 831 PLAC days; HR (MET vs PLAC) 1.6, 95% CI 0.72-3.54, 1-sided p=0.88.

Conclusion: In these BC pts receiving 1st-4th line CXT, MET (vs PLAC) did not improve response rates, PFS or OS. Gr 1 and 2 toxicity was higher with MET than PLAC. These results do not support use of MET with CXT in refractory LABC/MET BC. MA32, an adjuvant trial of MET vs PLAC in early BC will provide information on MET in the adjuvant setting.

Funded by the Breast Cancer Research Foundation (New York) and Hold'em for Life Charity (Toronto)
Risk of venous thromboembolism with abemaciclib based regimen versus other CDK 4/6 inhibitor containing regimens in patients with hormone receptor-positive HER2-negative metastatic breast cancer

Kyaw Z Thein¹, Somedeb Ball¹, Myo H Zaw², Miguel Quirch¹, Fred Hardwicke¹, Sanjay Awasthi¹, Thein H Oo³ and Catherine Jones¹. ¹Texas Tech University Health Sciences Center, Lubbock, TX; ²Brooklyn Hospital Center, Brooklyn, NY and ³The University of Texas MD Anderson Cancer Center, Houston, TX.

Background: Approximately 70% of patients with metastatic breast cancer (MBC) are hormone receptor (HR) - positive and the cyclin dependent kinases (CDK) along with their D-type cyclin catalysts, have been shown to play a role in mediating the resistance to endocrine therapy. Several CDK-targeted agents have been recently approved by FDA. Nevertheless, the risk of venous thromboembolism (VTE) with the use of different CDK 4/6 inhibitors has never been reported. We undertook a systematic review and meta-analysis of randomized controlled trials (RCT) to determine the risk of VTE with abemaciclib based regimens versus other CDK 4/6 inhibitor containing regimens in patients with HR-positive HER2-negative MBC.

Methods: We systematically conducted a comprehensive literature search using MEDLINE, EMBASE databases and meeting abstracts through February 2018. The randomized controlled trials that mention deep vein thrombosis and pulmonary embolism as adverse effects of CDK 4/6 inhibitor therapy were incorporated in the analysis. The primary meta-analytic approach was a fixed effects model using the Mantel-Haenszel (MH) method. It was used to calculate the estimated pooled risk ratio (RR) and risk difference (RD) with 95% confidence interval (CI).

Results: Five phase 3 studies and one phase 2 study with a total of 3,159 patients with HR-positive HER2-negative MBC were eligible for analysis. The study arms used palbociclib-letrozole, palbociclib-fulvestrant, ribociclib-letrozole, abemaciclib-fulvestrant, and abemaciclib-nonsteroidal aromatase inhibitors (either letrozole or anastrozole) while the control arms utilized placebo in combination with letrozole or anastrozole or fulvestrant. The randomization ratio was 2 to 1 in PALOMA-2, PALOMA-3, MONARCH-2 and MONARCH-3 studies and 1 to 1 in PALOMA-1 and MONALEESA-2 trials. CDK 4/6 inhibitors were utilized as first line treatment in PALOMA-1, PALOMA-2, MONALEESA-2 and MONARCH-3. The I² statistic for heterogeneity was 0, and the heterogeneity X² (Cochran's Q) was 1 (P = 0.707), suggesting homogeneity among RCTs. The VTE incidence was 25 (3.255%) in the abemaciclib group vs 2 (0.520%) in the control group. The pooled relative risk for VTE was 6.222 (95% CI: 1.481 – 26.145, P = 0.013) and the absolute RD was 0.027 (95% CI: 0.013 – 0.042, P < 0.0001). In other CDK 4/6 inhibitor containing regimens, the VTE incidence was reported at 15 (1.243%) vs 2 (0.374%) in the control arm. The pooled RR for VTE was 2.312 (95% CI: 0.852 –6.272, P = 0.100) and the absolute RD was 0.008 (95% CI: - 0.000 – 0.017, P = 0.259).

Conclusion: VTE is a major cause of morbidity and mortality and is particularly common in patients with breast cancer. Our meta-analysis demonstrated that the addition of abemaciclib to endocrine therapy notably contributed to a higher incidence of VTE with a relative risk of 6.22. However, no significant increase in the risk of VTE was noted in other CDK 4/6 inhibitor-based regimen. More randomized trials are required to determine the actual relation and definitive incidence of VTE among different CDK-targeted agents when added to endocrine therapy.
Prognosis and survival in metastatic breast cancer – Ten years in review, a population-based analysis

Nathalie LeVasseur\(^1\), Leathia Fiorino\(^1\), Caroline H Speers\(^2\), Maria Aparicio\(^3\), Caroline Lohrisch\(^1\) and Stephen K Chia\(^1\). \(^1\)BC Cancer, Vancouver, BC, Canada; \(^2\)Breast Cancer Outcomes Unit, BC Cancer, Vancouver, BC, Canada and \(^3\)University of British Columbia, Vancouver, BC, Canada.

**Background:** The rapidly evolving landscape of systemic treatment for metastatic breast cancer (MBC) during the 1990s led to meaningful improvements in the overall survival (OS) of MBC patients\(^1\). Despite ongoing and expanded access to new treatments, it remains unclear if this has translated into further advances in survival. Moreover, the prognosis of MBC patients based on subtype, over time, are also important to differentiate.

**Methods:** The BC Cancer Breast Cancer Outcomes Unit (BCOU) database was utilized to identify patients referred to BC Cancer who were diagnosed with MBC during 3 time cohorts (cohort 1:2003-2005; cohort 2:2007-2009; cohort 3:2011-2013), to reflect changes in MBC treatment over these separate time periods. Baseline clinical and pathological criteria were compiled, in addition to adjuvant treatments received, as well as number of lines of treatment in the metastatic setting. OS was compared across time cohorts for all patients and then between subtypes using Kaplan-Meier survival curves.

**Results:** A total of 3,953 patients met the inclusion criteria, consisting of 2,440 (61.7%) estrogen-receptor positive (ER+) patients\(^\ast\), 778 (19.7%) HER2 positive and 542 (13.7%) triple-negative breast cancer (TNBC) patients. One hundred and ninety-three patients (4.9%) were unable to be subtyped and were therefore excluded from the analysis. A total of 2,205 (90.4%) ER+ patients received at least 1 line of systemic therapy, with 80.0% receiving at least 1 line of hormonal therapy. The median time on hormonal treatment was 8.9 months (range 0.03 - 156.7) for first-line and 6.1 months (range 0.1 – 173.3) for second-line. In the HER2+ group, 665 (85.5%) patients received at least 1 line of treatment, with a median of 2 lines of treatment (range 1-16). Median duration of anti-HER2 treatment was 6.7 months (range 0.03 - 163.8) with a median of 1 line of anti-HER2 directed treatment (range 1-5). For TNBC patients, 357 (65.9%) received at least 1 line of treatment, with a median of 2 (range 1-10). No significant differences in OS were observed between the 3 time cohorts, with a median overall survival (mOS) of 1.63 years, 1.37 years and 1.57 years in cohorts 1-3, respectively (p=0.12).When comparing across subtypes, the ER+ group fared best with a mOS of 1.96 years (95% CI 1.8-2.1), consistent across time cohorts (p=0.72). This was followed by the HER2+ group with a mOS of 1.53 years (95% CI 1.3-1.7), also consistent across time cohorts (p=0.31). The TNBC group fared worst, with a mOS of 0.67 years (95% CI 0.6-0.8) over time (p=0.87).

**Conclusions:** Despite advances in systemic therapy since the early 2000s, no meaningful improvements in overall survival were observed over time, regardless of subtype. It remains to be seen if developments since 2013 will lead to gains in overall survival for MBC patients, at a real life, population-based level.

Improved survival of patients with metastatic breast cancer in routine care is restricted to tumors with positive hormone receptor and/or Her2-expression. Survival analysis of 1,321 patients treated between 1995 and 2017 in oncology group practices.

### Introduction
18,000 women die due to metastatic breast cancer in Germany per year. Median survival is 20–28 months after diagnosis. The question we wanted to answer was whether survival has improved in routine care?

### Methods
Retrospective analysis of all patients with metastatic breast cancer who were treated between 06/1995-12/2017 in 5 community-based oncology group practices in Germany.

### Results
1,321 patients were analyzed with a median age of 62 (23–100). Localizations of metastases were distributed as follows: 49% visceral, 33% bone, 6% CNS, 12% others. 79% were hormone-receptor-positive, 20% Her2-positive, 9% triple-negative. Median overall survival was 37 months (95% Confidence Interval: 34–40), survival probability after 5 years 32.5%. Survival was significantly correlated with localizations of metastases, number of metastasized organs, disease free survival since initial diagnosis, hormone- and Her2-receptor status and age. Patients with hormone-receptor-positive tumors had a median overall survival of 39 months, Her2-positive patients of 45 months and triple-negative patients of 20 months. 86% of hormone-receptor-positive patients received antihormonal therapy. 81% of Her2-positive patients received anti-Her2 therapy. Overall survival according to treatment period 1995-2000, 2001-2005, 2006-2011, 2012-2017 was 34, 35, 37 and 38 months respectively. OS of patients with hormone-positive tumors according to treatment period was 35, 43, 38, and 42 months respectively. OS of patients with Her2-positive tumors according to treatment period was 39, 29, 51, and 54 months respectively. OS of patients with triple-negative tumors according to treatment period was 7, 11, 16, and 25 months respectively.

### Conclusions
Improved survival of patients with metastatic breast cancer in routine care is strongly restricted to hormone receptor- and Her2-positive tumors most likely due to improved targeted therapies directed against the estrogen-receptor and Her2.
Progression-free survival is a surrogate of survival in maintenance therapy for metastatic breast cancer: Randomized trial level analysis

Erwei Song¹, Herui Yao¹,², Yunfang Yu², Qiyun Ou² and Ying Wang¹. ¹Breast Tumor Center, Sun Yat-sen Memorial Hospital, Sun Yat-sen University, Guangzhou, Guangdong, China and ²Sun Yat-sen Memorial Hospital, Sun Yat-sen University, Guangzhou, Guangdong, China.

Background: The validity of progression-free survival (PFS) as a surrogate end point for overall survival (OS) in maintenance therapy trials of metastatic breast cancer (MBC) is uncertain. We aimed to compare treatment effect sizes and the strength of associations between OS and PFS in trials of maintenance therapy for MBC.

Methods: We searched for randomized trials investigating maintenance chemotherapy, endocrine therapy or immunotherapy after first-line chemotherapy in MBC and selected those reporting results for both OS and PFS. Treatment effect size differences between OS and PFS by a ratio of hazard ratios (rHRs) with 95% confidence intervals [CIs] were evaluated using random effects analysis. Surrogacy were analyzed using a weighted linear regression model, correlations were evaluated by squared correlation $R^2$.

Results: We analyzed data from 16 trials and 3,898 patients that received maintenance chemotherapy, endocrine therapy or immunotherapy for MBC. In the all trial-level analysis, treatment effect sizes were 28% greater for PFS than for OS (combined rHR, 0.72; 95% CI, 0.62 to 0.85, $P < 0.001$), and the correlation coefficient $R^2$ between PFS and OS was 18% (95% CI, 12% to 26%). Differences were greater with PFS than OS for trials of maintenance chemotherapy compared with observation (rHR, 0.72; 95% CI, 0.59 to 0.80, $P < 0.001$), and the correlation coefficient $R^2$ between treatment effects on PFS and on OS ranged from 12% (95% CI, 8% to 16%) when all trials were considered to 40% (95%CI, 30% to 54%) after exclusion of one highly influential trial by sensitivity analysis. Differences were also great for trials of maintenance endocrine therapy vs. observation (rHR, 0.54; 95% CI, 0.44 to 0.66), and immunotherapy vs. observation (rHR, 0.85; 95% CI, 0.80 to 0.91).

Conclusion: PFS was greater than OS in the treatment effect sizes, which is a valid surrogate end point for OS to assess treatment effect in MBC maintenance therapy trials.

Response to subsequent therapy after dual immune checkpoint blockade in metastatic breast cancer

Ami N Shah¹, Amulya Yalamanchili¹, Irene Helenowski¹, Sonya Bhole¹, Jill Woodman¹, William J Gradishar¹, Massimo Cristofanilli¹ and Cesar A Santa-Maria². ¹Northwestern University, Robert H. Lurie Comprehensive Cancer Center, Chicago, IL and ²Johns Hopkins University, Sidney Kimmel Comprehensive Cancer Center, Baltimore, MD.

Introduction: While initial studies have found that combining chemotherapy with immune checkpoint blockade (ICB) can augment responses, additional toxicity has been observed. The optimal sequencing of chemotherapy and ICB has not yet been described. Sequential responses to chemotherapy after ICB have been reported in various tumor types; however, data is limited, and this has not been described in breast cancer to date.

Methods: We identified patients (pts) from a small pilot study in HER2-negative metastatic breast cancer (MBC) who received at least 1 cycle of durvalumab (PD-L1 inhibitor) and tremelimumab (CTLA-4 inhibitor). We excluded pts without follow up data or if they did not receive subsequent systemic therapy. Comparison of differences between subgroups was calculated by Fisher's exact test for categorical variables and Wilcoxon rank-sum test for continuous variables. Time to treatment failure (TTF) of subsequent therapy and overall survival (OS) were assessed by the Kaplan-Meier method and differences between breast cancer subtype were compared by log-rank tests.

Results: Twenty-three pts received at least 1 cycle of ICB of whom 14 pts were eligible for this analysis. Nine had estrogen receptor positive (ER+) BC and 5 had triple negative (TN) BC. There were no statistically significant differences between the ER+ and TN subgroups in age, race, ethnicity, ECOG performance status (PS) at end of ICB, or sites of metastatic disease except for more lymph node metastases in the TN cohort (p=0.003). Overall response rates to ICB in this cohort was higher in TN vs ER+ (40% vs 0%, p=0.11). Pts received a median of 4 lines of systemic therapy for MBC prior to ICB. Subsequent therapy after ICB was eribulin in 29%, carboplatin/gemcitabine in 21%, palbociclib + endocrine therapy (ET) in 14%, anthracycline in 14%, ixabepilone +/- capecitabine in 14%, and paclitaxel in 7%. Clinical response was seen in 8 pts (57%), of whom 5 had ER+ BC and 3 had TN BC. The median TTF of subsequent therapy was 3.0 mo (1.9, 5.5), which compared to a median TTF for therapy prior to ICB of 2.5 mo. The median OS was 12.3 mo (2.3-13.3). There were no significant differences between the ER+ and TN cohorts (log-rank test p=0.74 and 0.90 for TTF and OS, respectively. Subsequent therapy was discontinued due to progressive disease in 44%, decline in PS in 19%, liver failure in 6%, treatment related adverse event in 6%, and unknown cause in 13%. Two pts remain on subsequent therapy with palbociclib + ET beyond 6 mo without disease progression. There were no statistically significant differences between TTF >3 mo (n=5) and TTF ≤3 mo (n=9) subgroups. Pts with TTF >3 mo were more likely to have a PS 0-1 (100 vs 78%), liver metastases (80 vs 56%), and ER+ BC (80 vs 56%). Pts with TTF ≤3 mo had more lymphopenia (66% vs 20%) and more lines of prior systemic therapy for MBC (median 6 vs 4).

Conclusions: While median duration of response on subsequent therapy was short, a subset of pts had significant clinical responses. These findings provide rationale for prospective validation as they provide strategies for sequencing ICB with standard therapies.
Low-dose chemotherapy (CT) + bevacizumab (Bev) combined with unchanged endocrine treatment (ET) in patients with recurrent luminal breast cancer progressing during ET – Effect determined by standard imaging and changes in ctDNA and CTC during treatment

Barbro K Linderholm¹, Maria Ekholm², Anna-Karin Wännstig³, Dan Lundstedt¹, Lena Carlsson³, Anna-Karin Tzikas¹, Johanna Svensson¹, Helena Kristiansson⁴, Stefan Filges⁴ and Anders Ståhlberg⁴. ¹Institution of Clinical Sciences, Sahlgrenska University Hospital, Gothenburg, Sweden; ²Ryhov County Hospital, Jönköping, Sweden; ³Sundsvalls Hospital, Sundsvall, Sweden and ⁴Sahlgrenska Cancer Center, Gothenburg University, Gothenburg, Sweden.

**Background:** Several mechanisms are involved in the development of endocrine resistance, such as mutations in the **ESR1**, **PIK3CA**, and **TP53** genes and/or up-regulation of tyrosine kinase receptors such as the endothelial growth factor (VEGF) receptor. Preclinical data have revealed that sensitivity to endocrine therapy may be restored if these pathways are blocked.

**Aims:** To investigate the progression-free survival (PFS), overall response rate (ORR), and the toxicity of the study treatment. To use circulating tumor cells (CTC) and circulating tumor DNA (ct-DNA) at base-line and during treatment for next generation sequencing (NGS) to investigate whether changes in tumor mutations or in levels of CTC/ct-DNA correlate to treatment efficacy.

**Patients and methods:** Thirty-two patients aged 46-77 years with confirmed advanced breast cancer (ABC) progressing during ET were included. Treatment consisted of unchanged ET with the addition of cyclophosphamide 50mg x 1 and capecitabine 500mg x 3 daily + bevacizumab 15mg/kg iv. every third week (q21). Blood samples for analysis of CTC and ctDNA were collected at base-line, after the 1⁰ and 2⁰ course, and at progression. CTC were isolated by use of an immune-magnetic selection (ADNA-test) and sequenced by NGS. ctDNA were analysed by the SiMSen-Seq (Simple Multiplexed PCR-based barcoding of DNA for Sensitive mutation detection using Sequencing) that allows mutant frequencies < 0.1% to be detected.

**Results:** One patient did not start treatment and 2 were not evaluable. Palliative chemotherapy (1-2 lines) had been delivered before inclusion to 28% and > 1 line of palliative ET to 58% of the patients. A total of 72% (n=21) of the patients had visceral disease (of whom 7 had liver metastases), and 28% (n=8) patients bone-only disease. Median PFS was 9.1 months (range 2.1-59.3 months). Best responses were: 1 patient (3%) received complete remission; 7 patients (24%) partial response; 16 patients (55%) SD (of whom 12 had CB, defined as SD > 24 weeks), and 5 (17%) had progressive disease. The ORR (defined as CR, PR, or CB) was 69%. The most common toxicity was hypertension (62%), that resulted in termination in 2 patients, and 1 patient stopped treatment due to thrombocytopenia. Other side-effects were proteinuria grade 1-3 (24%); hand-foot-syndrome grade 1-2 (45%); mucositis grade 1 (14%); nausea grade 1 (14%) and diarrhea grade 1-3 (10%). CTC was isolated in 12 patients (37%). Three out of the 5 patients with PD at 12 weeks had detectable CTCs at base-line. Base-line **ESR1**, **PIK3CA** and **TP53** mutations were found in CTC from 2 patients (17%), 7 patients (58%), and 5 patients (42%), respectively, but did not correlate to response.

**Conclusion:** The treatment was well tolerated with an ORR of 69%, which is considered very good in this setting. CTCs were only isolated in 37% of the patients which is comparable to previously reported results in metastatic luminal breast cancer and thus not a feasible method for monitoring treatment effect. Results on levels of consecutive ctDNA, as well as mutation pattern in relation treatment effect will be presented.
Introduction: The most frequent molecular subtype of metastatic breast cancer (MBC) is the HER2-/HR+ subtype. While there are several treatments available for HER2-/HR+ MBC patients, there is limited knowledge about how patients are treated in a real world setting. In this retrospective study, the aim was to describe the duration of four initial treatment lines, treatment patterns and outcomes in MBC subtypes, with a focus on the HER2-/HR+ subtype.

Methods: The population is a cohort of 370 MBC patients diagnosed during '09-'16 in Uppsala County, Sweden. Data were collected from a regional breast cancer registry which included medical records. The subtypes were HER2-/HR+(59%); HER2+/HR+(12%); HER2+/HR-(7%) and HER2-/HR-(12%) based on immunohistochemistry (IHC) and in situ hybridization (ISH) tests, 11% of records had missing data on subtypes. Kaplan-Meier estimates were used to model duration of treatment line, progression-free survival (PFS) and overall survival (OS). Cox proportional hazard models were used to test the association, expressed in hazard ratios (HR), between the subtypes and PFS and OS.

Results: The median PFS and OS of HER2-/HR+ subtype were 10.6 and 36.7 months, respectively. Compared to the HER2-/HR+ patients, a statistically significant difference was found for HER2-/HR- patients in terms of PFS (HR: 2.1; p-value<0.001) and OS (HR: 3.6; p-value<0.01), indicating a worse prognosis. HER2+/HR+ and HER2+/HR-patients had similar PFS and OS results to HER2-/HR+ patients.

A statistically significant association was found between HR+ expression and OS (HR: 0.5; p-value<0.001) and not between HER2+ expression and OS (HR: 1.0; p-value 0.79 ).

The median duration of treatment decreased with increasing treatment lines; HER2-/HR+ patients' first-line treatment lasted 7.2, second-line 5.5, third-line 4.7 and fourth-line 4.4 months. The proportion of chemotherapy increased with the number of treatment lines: 32%, 38%, 46% and 59% for first to fourth line, respectively.

The ten most used drugs of HER2-/HR+ cohort are summarized in Table 1. In total, endocrine therapy was given during 66% of the total treatment duration.

Conclusion: In this retrospective study of MBC patients, the expression of HR showed an individual positive impact of OS with a
50% reduction in hazards. In our cohort only the prognosis of HER2-/HR- patients were significantly worsened both in terms of PFS and OS compared to HER2-/HR+ subtype. In the analysis of HER2-/HR+ subtype, letrozole was the most durable therapy, used 37% of total treatment time. The most used chemotherapy was capecitabine, used in 11% of the treatment time.
Long term survival benefits of adjuvant zoledronic acid associated with maf status of primary tumor

Robert Coleman¹, Walter Gregory², Joel Jean-Mairet³, Juan Carlos Tercero³, Juan Torres-Martin⁴ and Roger Gomis⁵. ¹University of Sheffield, Sheffield, United Kingdom; ²University of Leeds, Leeds, United Kingdom; ³Inbiomotion SL, Barcelona, Spain; ⁴Syntax for Science SL, Barcelona, Spain and ⁵Institute for Research in Biomedicine and and Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.

Background: Meta-analysis of clinical trials has shown that adjuvant bisphosphonates reduce bone metastases and improve survival in postmenopausal (PM) breast cancer and are now recommended for routine clinical use by international guidelines¹. However, evaluation of menopause is imprecise and the biological rationale for lack of benefit in premenopausal women unclear. To address this, the biomarker, transcription factor MAF on 16q23 was tested retrospectively in the prospective randomized AZURE trial of standard adjuvant therapy +/- zoledronic acid (ZOL). Initial evaluation indicated that women with MAF negative tumors treated with ZOL had a lower rate of disease relapse irrespective of menopausal status.² Here we present the long-term findings of this predictive biomarker on 10 year overall survival.

Materials and methods: The biomarker analysis was completed on TMAs from primary tumors. Quadruplicate cores of breast tumor tissue were arrayed across replicate TMAs. MAF+ was detected using a validated (MAF/D16Z3) FISH test (Inbiomotion SL, Spain). A central laboratory (Targos, Germany) validated the assay for analytic and diagnostic performance, established acceptance criteria, included appropriate quality controls for each assay, and performed the analyses in a blinded fashion. A copy number cut-off ≥2.5 was preset for MAF+ for both prognostic and predictive testing. Interactions between MAF+ and effects of ZOL on Invasive disease free (IDFS), overall (OS) survival and time to bone metastases by menopausal status were evaluated using a Cox proportional hazards model.

Results: 1769 of the 3360 AZURE pts donated primary tumor samples. Median follow-up was 117 (interquartile range 70.4-120) months. 865 pts (49%) had 2 FISH evaluable cores and were included in the analysis. These pts had similar disease and treatment characteristics to the overall study population as well as similar IDFS and OS at 10 years. 184 (21%) had MAF+ tumors and these tumors were more likely to be of higher grade, ER-ve and HER2+. In 680 pts with MAF- tumors, ZOL was associated with improved IDFS (HR=0.75; 95%CI:0.58-0.97, [P=0.02]), reduced relapse in bone (HR=0.65; 95%CI:0.45-0.94, [P=0.022] and, most importantly, better OS (HR=0.69; 95%CI:0.50-0.94, [P=0.019]). In the 185 patients with MAF+ tumors, there was a suggestion of worse outcome (IDFS HR=1.54; 95%CI:0.96-2.47 and OS HR 1.40; 95%CI:0.83-2.33), with a strong interaction between treatment effects and menopausal status. Outcomes in ZOL treated MAF+ pts who were non-PM appeared to be much worse (IDFS HR=2.31; 95%CI:1.18-4.42) and OS HR=2.28; 95%CI:1.07-4.82) due predominantly to an excess of extra-skeletal metastases in ZOL treated patients (HR=4.47; 95%CI:1.66-12.57).

Conclusions: Adjuvant ZOL significantly improved disease outcomes in 79% of patients with MAF negative tumors, irrespective of menopausal status and other clinico-pathologic features. Conversely, more extra-skeletal metastases and breast cancer deaths were seen in women with MAF+ tumors who were not PM at the start of treatment. If validated in ongoing studies, the MAF FISH test could provide a clinically useful biomarker for selection of patients for adjuvant bisphosphonate treatment.

¹EBCTCG, Lancet 2015; ²Coleman RE et al, Lancet Oncol 2017
Outcomes and safety of paclitaxel and granulocyte-colony stimulating factor (GCSF) in breast cancer in pregnancy (BCP) - A multi-institutional retrospective analysis

Pedro Exman¹, Taylor S Freret², Katherine E Economy², Wendy Y Chen¹, Heather Ann Parsons¹, Nancy U Lin¹, Beverly Moy³, Nadine M Tung⁴, Ann H Partridge¹ and Erica L Mayer¹. ¹Dana-Farber Cancer Institute, Boston, MA; ²Brigham and Women’s Hospital, Boston, MA; ³Massachusetts General Hospital, Boston, MA and ⁴Beth Israel Deaconess Medical Center, Boston, MA.

Background

BCP is uncommon; however, the frequency is increasing due to trends in delayed childbearing. Studies have suggested that some systemic therapies, including doxorubicin and cyclophosphamide, can be delivered safely during pregnancy after the first trimester, whereas agents such as trastuzumab and endocrine therapy are contraindicated due to risk to the fetus. Data remain limited on the efficacy and safety of administering taxane chemotherapy or growth factor support during pregnancy. We retrospectively evaluated the safety of systemic therapies, including paclitaxel and GCSF, as well as clinical outcomes, in a multi-institutional cohort of patients (pts) with BCP.

Methods

Pts treated for BCP from 1996-2018 from 3 large academic institutions were included. Demographic, oncologic treatment, and obstetric/neonatal outcomes data were obtained from medical records. Disease-free survival (DFS) and overall survival (OS) were estimated by Kaplan-Meier; Log-rank test were used to compare different groups/outcomes. Associations were calculated by Fisher's exact test.

Results

A total of 114 pts diagnosed with BCP were included. The median age was 35 years (range 25-44) and median gestational age at diagnosis was 18 weeks (range 2-38). BCP was predominantly early stage at diagnosis (stage I 28.0%, stage II 53.5%) and ER+/HER2- negative (48.2%). Sixty-three (55.2%) women received chemotherapy, 13 (11.4%) received paclitaxel and 11 (9.6%) GCSF (daily or depot injections) while pregnant. A total of 78% of pts with HER-2-positive BCP (28/36) received trastuzumab after delivery (11% were treated before 2005 and 5.5% were T1a). With median follow-up of 67.7 months, median DFS (stage I-III) was 212.8 months (CI 95% 108.4-317.1), and median OS (stage I-IV) was not reached. Subgroup analysis suggested a higher DFS for pts diagnosed in the 1st trimester compared to the 3rd trimester among women with stage II-III (HR 0.25 CI 95% 0.09-0.70, p= 0.03). Among women who received paclitaxel, there was no significant increase in adverse obstetrical/neonatal outcomes: preterm delivery (23.1% vs 13.1%, p 0.39), low weight newborn (7.7% vs 9.1 %, p 1.0), congenital malformations (0% vs 6.1%, p 1.0) or acute neonatal adverse outcomes (7.7% vs 4.0%, p 0.51), which include NICU need and Apgar 5<7, compared to pts who did not receive paclitaxel. Among pts who received GCSF during pregnancy, adverse outcomes were numerically but not statistically higher than women who did not receive growth factor: preterm delivery (36.3% vs 11.0%, p 0.051), low weight newborn (27.3% vs 6.9%, p 0.058), congenital malformations (9.1% vs 1.0%, p 0.18) or acute neonatal adverse outcomes (18.2% vs 3.0%, p 0.07).

Conclusion

In this multi-institution cohort of BCP pts, despite a small number of pts, exposure to contemporary therapies including paclitaxel was not associated with unfavorable obstetrical/neonatal outcomes and these results suggest it is safe to administer during pregnancy under the care of a multidisciplinary team. Although not statistically significant, GCSF presented numerical worse outcomes and combining data from several cohorts would be helpful to provide confirmation of these findings.
Statin use, site of recurrence, and survival among post-menopausal women taking bisphosphonates as adjuvant therapy for breast cancer (SWOG S0307)

Darya Kizub¹, Jieling Miao², Alison Stopeck³, Patricia Thompson³, Alexander HG Paterson⁴, Mark Clemons⁵, Elizabeth C Dees⁶, James N Ingle⁷, Carla I Falkson⁸, William Barlow⁹, Gabriel N Hortobagyi⁹ and Julie R Gralow¹⁰. ¹The Everett Clinic, Everett, WA; ²SWOG Statistical Center, Seattle, WA; ³Stony Brook Cancer Center, Stony Brook, NY; ⁴Tom Baker Cancer Center, Calgary, AB, Canada; ⁵Ottawa Hospital Research Institute, Ottawa, ON, Canada; ⁶University of North Carolina, Chapel Hill, NC; ⁷Mayo Clinic, Rochester, MN; ⁸University of Alabama, Birmingham, AL; ⁹University of Texas MD Anderson Cancer Center, Houston, TX and ¹⁰University of Washington, Seattle, WA.

**Purpose:** Statins may mediate suppression of molecular pathways conferring benefit in cancer. Statins have shown anti-tumor effects in preclinical studies and have been associated with decreased recurrence and improved disease-specific survival. While designed to target cholesterol biosynthesis, statins can also have liver, bone and brain effects. We collected data on statin use in the S0307 adjuvant bisphosphonate trial to test the hypothesis that statin use may decrease risk of recurrence to liver, bone and brain as well as second primary (contralateral) breast cancers, and may act synergistically with bisphosphonates to decrease the risk of recurrence to bone.

**Patients and Methods:** In S0307, 6097 patients diagnosed with Stage I-III breast cancer who had undergone surgery and were receiving adjuvant systemic therapy were randomized to receive zoledronic acid, clodronate, or ibandronate for 3 years. No significant difference was found in disease-free survival (DFS) among the 3 groups, including a sub-analysis of patients ≥ age 55. Statin use was infrequent in younger women in S0307, consequently we analyzed statin use in those ≥ age 55. Cox proportional hazard models were used to determine which variables were independently associated with DFS and to estimate hazard ratios (HR) and 95% confidence intervals (CI).

**Results:** Among women aged ≥ 55 years, 684 (27%) reported taking a statin at baseline and 1,848 did not. Both groups were similar in terms of hormone receptor and HER2 status (p = 0.82). Median age in the statin group was 64.3 versus 61.0 years in the no statin group, mean BMI 31.2 v. 29.5, mean tumor size 2.1cm v. 2.3cm, negative lymph nodes 60% v. 54%, Stage I disease 47% v. 36%, and receipt of chemotherapy 62% v. 71% (all p < 0.01). In the statin group, 122 (17.8%) experienced a DFS event compared to 313 (16.9%) in the no statin group (HR 1.18, CI 0.95-1.46). No difference was observed by statin use in overall recurrence (p=0.28), distant recurrence (p=0.64), or recurrences to the bone (p=0.64), liver (p=0.38) or brain (p=0.65) at initial recurrence.

There was no synergy between statin use and specific bisphosphonates.

**Conclusions:** We found no evidence that statins reduce risk of second primary breast cancers or distant metastases among post-menopausal women with early-stage breast cancer. Despite promising preclinical data, they did not appear to act in synergy with a specific bisphosphonate. Though women in the statin group had less advanced disease at study entry, statin use was not associated with improved DFS. Results are limited by lack of information about type of statin used, adherence, or initiation of statin in control group.
Long-term safety follow-up of patients with early stage breast cancer treated with scalp cooling on the Dignitana scalp cooling trial

Hope S Rugo¹, Paula Klein³, Susan A Melin², Sara A Hurvitz², Michelle E Melisko¹, Anne Moore⁵, Ralph B D'Agostino, Jr.², Amy Deluca¹ and Tessa Cigler⁵. ¹University of California San Francisco Comprehensive Cancer Center, San Francisco; ²Wake Forest School of Medicine, Winton Salem; ³Icahn School of Medicine at Mount Sinai, New York; ⁴University of California Los Angeles, Los Angeles and ⁵Weill Cornell Medical College, New York.

Background
Scalp cooling has demonstrated efficacy in preventing hair loss in women with early stage breast cancer receiving neo/adjuvant chemotherapy. Data from 2 prospective trials (Rugo et al, and Nangia et al, JAMA 2017) led to FDA clearance of 2 automated scalp-cooling devices to prevent chemotherapy induced alopecia (CIA). Although scalp metastases from breast cancer are rare, historical concerns about scalp cooling included a theoretical increase in risk of recurrence in scalp due to reduced delivery of chemotherapy to the scalp.

Methods
We conducted a multicenter prospective trial evaluating the efficacy and safety of the DigniCap in women with stage I-II breast cancer receiving neo/adjuvant chemotherapy excluding sequential or combination anthracycline/taxanes with concurrent matched controls. The primary endpoint was unblinded patient self-assessment of 5 photographs using the Dean scale to estimate hair loss 4 weeks following the last dose of chemotherapy, with success defined as a Dean score of 0-2 (≤ 50% hair loss); additional endpoints included quality of life (QOL) and both short and long-term safety.

Results
106 patients using the scalp cooling device and 16 concurrent controls were enrolled. As previously reported, the use of scalp cooling was associated with less alopecia and improvement in several measures of QOL (Rugo et al, JAMA 2017). 91 patients have follow-up (FU) out to 3 years; 73 with estrogen receptor (ER) positive and 18 with ER negative disease. 5 DigniCap patients have developed recurrent breast cancer in breast (n=1), liver (n=1), bone, liver and breast (n=1), bone, liver, lung, and nodes (1), and bone, breast, GI tract and bladder (n=1). Of 12 control patients with available FU, 1 developed metastases to liver. 2 patients have died of metastatic disease, one in the DigniCap arm and one in the control arm. No new safety signals have been detected.

Conclusion
Scalp cooling using the DigniCap system in patients with early stage breast cancer receiving taxane based neo/adjuvant chemotherapy is safe and effective. No scalp metastases have been reported 3 years following completion of study treatment. 4 year FU data will be presented.

The study was funded by The Lazlo Tauber Family Foundation (UCSF), the Anne Moore Breast Cancer Research Fund (Weil Cornell), and the Friedman Family Foundation (Mount Sinai Beth Israel), as well as partially by Dignitana.
The impact of clinical risk assessment versus PAM-50 ROR score on prognosis and therapeutic decision making in patients with hormone-receptor positive early stage breast cancer

Yelena Devyatko¹, Martin Filipits², Richard Greil³, Marija Balic⁴, Zsuzsanna Bago-Horvath⁵, Christian Singer¹, Florian Fitzal¹, Guenther Steger¹, Brad Gray³, Sean Ferree⁶, Christian Fesl⁷, Lidija Soelkner⁷, Gunter von Minckwitz⁸ and Michael Gnant¹.
¹Medical University of Vienna, Vienna, Austria; ²Institute of Cancer Research and Comprehensive Cancer Center, Medical University of Vienna; ³Paracelsus Medical University Salzburg and Salzburg Cancer Research Institute, Salzburg, Austria; ⁴Medical University of Graz, Graz, Austria; ⁵Clinical Institute of Pathology and Comprehensive Cancer Center, Medical University of Vienna, Vienna, Austria; ⁶NanoString Technologies, Seattle, WA; ⁷Austrian Breast and Colorectal Cancer Study Group, Vienna, Austria and ⁸German Breast Group, Neu-Isenburg, Germany.

Background: Therapeutic recommendations for adjuvant treatment of hormone-receptor positive breast cancer patients depend on the individual recurrence risk. A number of genomic assays introduced to achieve this goal, but it's still questioned if they actually offer superior risk assessment compared to traditional risk evaluation by experienced clinicians. This study was designed to compare the prognostic accuracy of PAM-50 to clinical judgment.

Methods: Based on the real data of a large adjuvant trial cohort (ABCSG-8, postmenopausal HR positive breast cancer patients), we created online-questionnaires including demographic, histological, and local-therapy details, with and without results of PAM50 ROR score. Out of 14 international breast cancer experts asked for individual patient's risk evaluation (low, intermediate, high) and therapy recommendations, 9 completed the questionnaire.

Patient data were described by Kaplan-Meier estimates of distant disease free survival (DDFS) stratified by risk group. Cox regression models were compared using the Akaike Information Criterion (AIC).

Results: 10 years DDFS and hazard ratios for distant recurrences stratified by risk-group as estimated giving in Table 1:

Adding genomic information to clinical risk factors leads to escalation of therapeutic recommendations (i.e. additional chemotherapy, extended adjuvant endocrine) in 20% of patients, and de-escalation in 13% of patients.

Conclusions: Clinical judgment accurately identified the patients at high risk of relapse, but was clearly inferior to multi-genomic testing using the PAM-50 ROR score in differentiating low from intermediate risk. Particularly when avoiding unnecessary escalated therapy is the strategic goal, the addition of PAM-50 testing to clinical judgment offers improved accuracy in predicting low vs. intermediate risk of breast cancer recurrence.
Breast cancer in elderly women: Ageism or primum non nocere?

Mahvish Muzaffar¹, Nasreen Vohra¹ and Jan Wong¹. ¹East Carolina University/Brody School of Medicine, Greenville, NC.

Background: The risk of breast cancer increases with advancing age. Routine use of screening mammogram in women after 75yrs and its impact on overall survival is controversial. Studies have also found that elderly breast cancer patients are underrepresented among clinical trials and a tendency for undertreatment may result in inferior outcome.

Method and Material: Female patients with breast cancer who were 75 years or older and diagnosed from 2000-2015 were identified from Surveillance, Epidemiology, and End Results (SEER) 18 database. We excluded patients with unknown stage and race. We performed multivariate and survival analysis using JMP pro 13.

Results: 186,682 women with breast cancer of ≥ 75 yrs. were identified from the SEER. 167,802 patients met the inclusion criteria. Mean age was 81.27 years (CI 95% 81.25-81.30). Most of the patients were white (88%), and had Stage I/II (83%) breast cancer. 78% of patients had estrogen receptor positive cancer, while 66% had grade 1/2 disease. The 5-year overall survival was 74% for Stage I, 60% for Stage II, 38% for stage III and 11% for Stage IV cancer (p<0.0001). The disease specific survival (DSS) for stage I (96%), Stage II (88%), Stage III (64%), and Stage IV (23%). Out of the patients who were deceased at the time of analysis only 24% of deaths were attributed to this cancer. Cox proportional hazards regression model of overall survival [Table:1]

Conclusion: Early breast cancer continues to be the most common presentation for patients ≥75 yrs. of age. Historical prognostic factors of breast cancer like race, hormone receptor status, stage and grade continue to impact cancer outcome among elderly patients. Only 24% of deaths among the deceased were attributed to this breast cancer highlighting the concern for over diagnosis. Nonetheless once diagnoses is established a multidisciplinary comprehensive geriatric assessment should be the cornerstone of the management.
Cancer management and outcome of very young non-pregnant patients with breast cancer diagnosed at 40 years or younger—GBG 29

Introduction
Breast cancer diagnosed in young women who are 40 years (yrs) or younger is a relatively rare disease. However, it represents the most common cause of cancer-related deaths in this age-group. Furthermore, young age at diagnosis is associated with an increased risk of recurrence and worse survival. To date, general concepts concerning oncological cancer management should be driven by clinicopathological tumor characteristics and should adhere to standardized protocols for patients in general, but little is known about the oncological cancer treatment and outcome of this very young women in today’s clinical practice.

Patients and Methods
The breast cancer in pregnancy registry study (BCP/GBG29/BIG 03-02) is a multicenter, international, observational study. BCP was established to investigate the oncological management and outcome of breast cancer in pregnancy. Since 2014 non-pregnant patients who are 40 yrs or younger are eligible if diagnosed with histological confirmed invasive breast cancer, independent of the type of treatment as control cohort. All patients received oncological treatment according to local standards. In this study the following endpoints will be analyzed descriptively for the young non-pregnant women cohort: breast cancer staging at diagnosis, biological characteristics of breast cancer at diagnosis, diagnostic procedures, treatment modalities, toxicity, pathological complete response after neoadjuvant chemotherapy, disease-free survival and overall survival.

Results
From February 2014 until June 2018, 969 non-pregnant patients ≤40 yrs have been registered. The median age at diagnosis was 35 yrs (range 19-40). Overall, 90.1% of patients had a stage T1-2 at diagnosis and 67.1% of patients had negative lymph nodes. 86.7% of tumors were invasive ductal carcinomas and 4.1% lobular carcinomas. Grading (G) 3 was reported in 55.5%. 26.6% of tumors were luminal A-like (ER- and/or PgR-positive, HER2-negative, G1-2), 40.0% luminal B-like (ER- and/or PgR-positive, HER2-negative, G3 or ER- and/or PgR-positive, HER2-positive, any G), 7.7% HER2 positive non-luminal-like, and 25.7% triple negative breast cancers. 3.8% of young non-pregnant patients had metastatic disease at primary diagnosis.

Conclusion
This registry comprises a large cohort of young non-pregnant patients with breast cancer diagnosed at the age of 40 yrs or younger and provides important data about a modern breast cancer treatment as well as oncological outcome in this setting of young women. Further results including oncological management, toxicity, and survival will be presented at the meeting.
Francesco Recchia, Giampiero Candeloro and Silvio Rea. 1,2 Fondazione Carlo Ferri, Monterotondo, Roma, Italy; 2,Università degli Studi Chirurgia Oncologica, L’Aquila, AQ, Italy and 3 Ospedale Civile, Avezzano, AQ, Italy.

**Background:** PBC+10N have a high risk of relapse. Experimental studies suggest that high expression of vascular endothelial growth factor (VEGF) promotes tumor progression through neoangiogenesis and that natural killer (NK) cells mediate lytic activity against cancer cell lines. In a phase I-II study, we have shown that low-dose interleukin-2 (IL-2) and 13-cis retinoic acid (RA) increased NK cells and decreased VEGF, in patients with advanced cancer and a clinical benefit from chemotherapy (Clin Cancer Res 7: 1251, 2001). We assumed that IL-2 and RA, increasing NK and decreasing VEGF, could improve disease-free survival (DFS) and overall survival (OS) in PBC+10N. Primary endpoint was the evaluation of NK cells and VEGF; secondary endpoints were DFS, OS and toxicity. **Methods:** 34 patients with PBC+10N, after high-dose chemotherapy and peripheral blood progenitor cell transplantation were entered into the study. They were given hormonal therapy if needed and subcutaneous IL-2, 1.8 X 10^6 IU and oral RA, 0.5 mg/Kg for 5 days/week, 3 weeks/month, until progression. NK cells, VEGF, response and toxicity were assessed every 4 months. **Results:** After a median follow-up of 120 months (range 69-209), a total of 41 courses of high-dose chemotherapy and 60 courses of immunotherapy were delivered. A statistically significant improvement of NK cells [from a mean of 302 ± 75/mm^3 to a mean of 582 ± 72/mm^3 (p < 0.001)] and a decrease of VEGF [from a mean of 525 ± 68 pg/mm^3 to a mean of 155 ± 13 pg/mm^3, (p < 0.001)], were observed. 18-years DFS and OS were 29% and 32%, respectively. A significant improvement, with respect to NCI SEER data (*), was observed in the 5-year OS rate: 55% vs. 6% No WHO grade 3 or 4 toxicity was observed, while grade 2 cutaneous toxicity and fever occurred in 20% and 13% of patients, respectively. **Conclusions:** Our data show that immunotherapy with IL-2/RA, may determine, with an acceptable toxicity profile, a statistically significant improvement of NK cells, a decrease of VEGF, and better 5-year survival rates with respect to NCI SEER data.
Use of Oncotype DX® testing in nodal positive breast cancer patients: Real-life data from a single center in Munich, Germany

Antonia Kriegmair¹, Nina Szeterlak¹, Simone Schrödi², Oliver Stoetzer³, Martin Pölcher¹ and Michael Braun¹. ¹Breast Center, Red Cross Hospital Munich, Munich, Germany; ²Munich Cancer Registry (MCR) of the Munich Tumor Center (TJM), Bavarian Cancer Registry – Regional Centre Munich of the LGL at the Institute of Medical Information Processing, Biometry and Epidemiology (IBE), LMU Munich, Munich, Germany and ³Hematology and Oncology Outpatient Cancer Care Center, Munich, Germany.

Introduction: Despite a large body of prospective studies showing good prognostic and predictive value of the Oncotype DX® testing in ER+/HER2- early breast cancer patients after breast surgery, the test is currently not reimbursed in Germany by most national health insurance companies. Nevertheless, this multigene assay has been offered to node negative (N-) and increasingly to node positive (N1) patients with 1-3 positive lymph nodes by medical- and gyneco-oncologists for several years. The aim of the present study was to analyze real life data of the test in N1 patients from a German single center with special respect to the intermediate-risk recurrence score (RS) group and event-free survival (EFS).

Patients and Methods: Patients with ER+/HER2- node positive breast cancer after breast surgery, to whom Oncotype DX® testing was consecutively recommended by the interdisciplinary local tumor board from 1/2012 through 12/2016 at the Breast Center of the Red Cross Hospital Munich, Germany, were included in the study. Data was retrospectively retrieved from medical records (e.g. stage and histology), patient interviews as well as from the Munich Cancer Registry (outcome measurements). Patients were stratified according to Oncotype DX® RS distribution (<11 low-risk, 11-25 intermediate risk and >25 high-risk). Proportion of patients choosing adjuvant chemotherapy (CT) within the different RS groups and outcome were analyzed.

Results: Oncotype DX® testing was recommended and performed in 500 (17%) out of 2942 patients with ER+/HER2- tumors. Nodal status was positive in 159 (31.8%) of these patients. Patients with more than 3 positive lymph nodes and with missing data on follow-up were excluded, leaving 121 patients for the main analysis. According to RS distribution, n=19 (15.7%) were low-risk, n=83 (68.6%) intermediate-risk and n=19 (15.7%) high-risk, respectively. Although CT was generally discussed with all N1 patients with RS>10, only 39 patients (38.2%) of the intermediate and high-risk RS-group opted for systemic chemotherapy (24.1% of RS 11-25 and 100% of RS>25). In 13 of the patients (11%) within a median follow-up of 40 months an event occurred (4 loco-regional and 2 contralateral relapses, 5 distant metastases (3 bone, 2 visceral) and 2 deaths of other causes). Of those patients with events, three presented with RS <11, six with RS 11-25 and three with RS >25. In the intermediate group (n=83) EFS was 90% for patients receiving CT followed by endocrine therapy (ET) and 91.9% for patients with ET alone (p= 0.583).

Conclusions: Using real life data from a large single breast center, only around 25% of patients with 1-3 positive lymph nodes from the intermediate RS group decided to undergo CT after Oncotype DX® testing. The outcome of patients receiving ET only in this group was not inferior compared to CT followed by ET.
The impact of age and adjuvant chemotherapy modifications on disease-free and overall survival among African American women with breast cancer

Bethany D Nugent¹, Dianxu Ren¹, Catherine Bender¹ and Margaret Rosenzweig¹. ¹University of Pittsburgh, Pittsburgh, PA.

Background: During chemotherapy for breast cancer, African American women receive less relative dose intensity with more dose reductions and early chemotherapy cessation compared to Caucasian women. Other research has found that older breast cancer patients are most at risk for treatment modifications; however, it is unclear if this remains true for African American patients. Furthermore, the clinical implications of treatment modifications and delays on survival is uncertain, particularly in African American patients.

Purpose: The purpose of this study was to investigate whether age (diagnosis <55 vs. diagnosis ≥55) was a moderator for the association between treatment modifications (dose held, dose delayed, and early cessation) and overall survival (OS) and disease-free survival (DFS) in African American women with breast cancer.

Methods: A retrospective cohort study of early stage African American breast cancer patients treated with adjuvant chemotherapy was employed. Dose held, dose delayed and early cessation were examined as dichotomous variables: any adjustment to the initially prescribed treatment plan was considered a modification. Medical record data extraction was utilized to gather this information. The sample was divided into two groups: those diagnosed <55 years of age and those diagnosed ≥55 years of age. A Cox's proportional hazards regression model was used to examine the interaction between age group and treatment modifications for OS and DFS, while controlling for stage and ER and HER2 status.

Results: In the study of 115 participants, 58 (50.4%) were diagnosed before the age of 55, and 57 (49.6%) were diagnosed age 55 or older. Across the entire sample, 43 (37.4%) patients experienced a treatment modification. There were no significant differences in the proportions of treatment modifications between the two age groups. We found no interaction between age group and treatment modifications for OS. However, there was a significant interaction between age group and held dose for DFS ($p=0.045$). Specifically, those diagnosed at 55 years of age and older, who had doses of chemotherapy held, experienced worse DFS compared to those who did not (hazard ratio (HR)=3.390, 95% CI (1.013,11.34)). In contrast, there was no difference in DFS between those who did and did not have doses held in patients diagnosed below 55 years of age (HR=0.563, 95%CI (0.159, 1.986)).

Conclusions: African American women receiving adjuvant chemotherapy for treatment of early stage breast cancer have high levels of treatment modifications across all age groups. However, held doses of chemotherapy in older African American patients were associated with worse DFS. Further research is needed to elucidate the clinical implications of adjuvant chemotherapy treatment modifications, particularly in African American patients, and the subgroups of patients who are at greatest risk.
Incidence of hypocalcemia in patients with metastatic breast cancer under treatment with denosumab: A non-inferiority phase III trial assessing prevention of symptomatic skeletal events (SSE) with denosumab administered every 4 weeks versus every 12 weeks: SAKK 96/12 (REDUSE)

Background
Monthly Denosumab (DN) has shown superiority over zoledronic acid (ZA) in delaying skeletal related events. Randomized trials have shown that ZA given every 12 weeks (q12w) is non-inferior to ZA given every 4 weeks (q4w). The primary endpoint of the REDUSE-trial is non-inferiority for SSE for DN q12w versus q4w. Here we present early data for hypocalcemia (HC), a secondary endpoint.

Methods
Patients with bone metastasis from breast cancer (BC) not pretreated with DN or Bisphosphonates were randomized 1:1 to receive DN q4w (Arm A) versus q12w (Arm B) after a 3-month induction phase with q4w therapy for both arms. All patients received vitamin D 400 U (VitD) and calcium (Ca) 500 mg daily. Measurement of albumin-corrected serum-Ca was mandatory before each DN injection (HC defined as <2.0 mmol/l like in CTCAE V4.0). This safety interim analysis was performed after 3.5 years of accrual. Patients who received at least 1 dose of DN were considered evaluable.

Results
351 BC-patients are currently included (177 in Arm A, 174 in Arm B). HC was the most common side effect with a rate of 20% in the first 16 weeks (during the induction phase with DN q4w for both Arms) and 19% afterwards (combined for Arms A and B). After week 16 HC-prevalence differed between the two arms: while HC was present in 25% in Arm A (q4w), the rate was only 12% in Arm B (q12w). Grade 3 HC (i.e. corrected Ca 1.5 - 1.74 mmol/l or hospitalisation indicated) was rare (0.3%), no grade 4 HC occurred. After 1 year of treatment, the rate of HC compared to the induction phase had decreased in Arm B but not in Arm A (A: 25%, B: 12%). Since HC improved in more patients in Arm B than in Arm A whereas it worsened in more patients in Arm A than in Arm B, a remarkable difference for HC resulted between the two arms.

*week 16: i.e. the time where the schedules of DN begin to differ between Arm A and Arm B
Arm A: DN q4w for weeks 1 - 12 and likewise thereafter / Arm B: DN q4w for weeks 1 - 12 and q12w thereafter

Conclusions
In our trial up to 20% of all BC patients treated with DN experienced HC in the q4w induction phase despite mandatory supplementation of VitD and Ca. This rate is considerably higher than the numbers reported in the registration trials of DN (where it was 5.5% for BC). After the induction phase, HC is markedly reduced in the q12w arm compared to q4w. This suggests that DN given q12w has a more favorable long-term safety profile in terms of HC compared to DN q4w.
Impact of the metastatic compartment on bone biomarkers and bone outcomes in patients (pts) with breast cancer (BC) and bone metastases (BM) in trial NCT00321464 of denosumab vs. zoledronic acid

Arlindo R Ferreira¹,², Sandra Casimiro², Suhail Ali³, Kim Leitzel³, Allan Lipton³ and Luis Costa¹,². ¹Hospital de Santa Maria, Centro Hospitalar de Lisboa Norte, Lisbon, Portugal; ²Instituto de Medicina Molecular, Faculdade de Medicina, Universidade de Lisboa, Lisbon, Portugal and ³Milton S. Hershey Medical Center, Pennsylvania State University, Hershey, PA.

**Background:** Bone is the most common site of metastatic disease in pts with BC, and BM are frequently associated with skeletal related events (SREs), as e.g., bone pain or fracture. Bone targeted agents (BTAs; denosumab or zoledronic acid) decrease the rate of SREs. Previous exploratory studies in pts with BM showed that the site of metastatic disease (bone-only disease [BO] vs. bone + extraskeletal disease [BES]) might impact both bone remodeling (reflected in the concentration of bone biomarkers) and the risk for SREs. In this large study of pts with BC and BM, we assessed bone biomarkers after the introduction of BTAs, time to first and subsequent on-study SRE/symptomatic SRE (SSE), and bone pain score variation according to metastatic compartment (BO vs. BES).

**Methods:** This is a retrospective analysis of the prospective, multicenter, randomized, registration clinical trial of denosumab vs. zoledronic acid in pts with BC and BM (NCT00321464). Study outcomes were variation of corrected urinary N-terminal telopeptide (uNTX) and bone alkaline phosphatase (bALP) at 3 months, time to first and subsequent SRE and SSE, and brief pain inventory (BPI) scores over time. Chi-squared test and t-test were used to compare biomarkers levels. We used the Kaplan-Meier method to describe time to event outcomes and differences were tested using the Cox proportional hazard model and Andersen–Gill model for multiple failure-time data. BPI scores were compared using mixed linear models.

**Results:** A cohort of 2046 pts was identified, 969 (47.4%) with BO and 1077 (52.6%) with BES, all treated with either denosumab or zoledronic acid. Median follow-up was 20.1 months (interquartile range 15.9-23.8; balanced between arms). Compared to pts with BO, those with BES were more frequently hormone receptor negative (20.9 vs. 15.1%) and HER2-positive (31.0 vs. 23.4%). The number of BM was similar in both groups, but those with BES had less previous SRE (31.7 vs. 42.2%). Pts with BES were more commonly treated with chemotherapy (84.0 vs. 77.5%), but less frequently with radiotherapy (59.7 vs. 65.9%) or surgery (85.0 vs. 88.1%). Absolute levels of uNTX and bALP at baseline and at 3 months, as well as normalization rates, did not differ between groups. However, when compared to those with BO and after controlling for unbalanced clinicopathological and treatment features, pts with BES presented a lower risk of first and subsequent SREs (adjusted-hazard ratio [HR] 0.73, 95% confidence interval [CI] 0.58 – 0.94; p=0.013) and first SSE (adjusted-HR 0.75; 95% CI 0.60 – 0.94; p=0.014). Hazard rates for SRE were higher in the first 6 months of treatment. Despite the small magnitude, pts with BO consistently showed slightly higher BPI scores (+0.2 points; p=0.014). Pts with BES had a shorter OS (HR 1.97, 95% CI 1.66 – 2.33).

**Conclusion:** Despite the consistent reduction in uNTX and bALP in pts with BC and BO or BES disease, pts with BO disease had a higher risk for SREs and higher pain score. Hazard rates for SREs were greater in the first 6 months of treatment. Strategies of treatment de-escalation of BTAs should consider the metastatic compartment and time variation of the hazard for SRE.
Phase I trial to assess the safety, pharmacokinetics and pharmacodynamics of receptor activator of nuclear factor-κB ligand inhibitor (TK006) in patients with bone metastases from breast cancer

Yin Y Mei, Tang J Hai, Li Wei, Huang Xiang, Wu Hao, Zha X Ming and Liu X An. 'The First Affiliated Hospital With Nanjing Medical University, Nanjing, Jiang Su, China.

Background
Within the bone microenvironment, tumor cells secrete factors that stimulate osteoblasts to express and secrete receptor activator of nuclear factor-κB ligand (RANKL), which binds to its receptor RANK on the surface of osteoclasts, thus enhancing the osteoclast-mediated bone resorption and promoting skeletal complications. TK006 is a fully human monoclonal antibody that binds and inhibits RANKL, thus inhibiting osteoclast-mediated bone destruction.

Objective
To investigate the safety, pharmacokinetics and pharmacodynamics of TK006 in patients with bone metastases from breast cancer.

Patients and methods
In this dose-escalating study, patients were sequentially enrolled into 60 mg, 120 mg, 180 mg single-dosing and 120 multiple-dosing cohorts. Before making dose escalation decision, the safety of TK006 during the 14-day period after dosing in the prior cohort must be confirmed. In the three single-dosing cohorts, patients were followed up for 16 weeks after dosing. In the 120 mg multiple-dosing cohort, patients were treated with 120 mg TK006 every 4 weeks for 3 times totally, and followed up for 20 weeks after the first dosing. The primary outcome was safety profile, and the secondary outcomes were pharmacokinetics, pharmacodynamics and immunogenicity. Pharmacodynamics was measured by level of serum bone alkaline phosphatase (BALP) and urine creatinine corrected cross-linked N-telopeptides of type I collagen (uNTX/Cr).

Patients aged 18 to 65 years with breast cancer related bone metastasis were eligible. It was planned to enroll 10 subjects in each cohort for a total sample size of 40 subjects.

Result
As of May 24 2018, the common adverse events (AEs) related to treatment (≥10%) included: hypocalcemia (25.0%), limbs pain (20.0%), gamma-glutamyl transferase increased (17.5%), lactate dehydrogenase increased (12.5%), alpha-hydroxybutyric dehydrogenase increased (12.5%), aspartate aminotransferase increased (12.5%), alanine aminotransferase (10.0%), osphyalgia (10.0%) toothache (10.0%) and hypertriglyceridemia (10%). Most adverse reactions were mild or moderate except one case of grade 3 hypertriglyceridemia and two cases of grade 3 gamma-glutamyl transferase increasement. No esteonecrosis of the jaw or treatment-related SAE was reported.

In the 60 mg single-dosing cohort, a significant reduction in median uNTX/Cr was observed as early as day 1, the nadir of median uNTX/Cr was reach at day 28 and started to return towards the baseline level at day 112 (Table 1).

Ostalgia was measured by visual analogue scale (VAS). In the 60 mg single-dosing cohort, scores were reduced to 2 from 5 and 3 in two patients individually. No increasing in pain was observed in the remaining 8 patients.

**Conclusion**
These results suggested a potential therapeutic role for TK006 in patients with bone metastases from breast cancer.
CTCs and SUV to predict the efficacy of the bone-specific radiopharmaceutical agent radium-223 dichloride combined with hormonal therapy for hormone receptor-positive bone-dominant breast cancer metastasis

Naoto T Ueno¹, Rie K Tahara¹, James M Reuben¹, Hui Gao¹, Babita Saigal¹, Takeo Fujii¹, Anthony Lucci¹, Nuhad K Ibrahim¹, Senthil Damodaran¹, Yu Shen¹, Diane D Liu¹, Gabriel N Hortobagyi¹, Debasish Tripathy¹, Bora Lim¹ and Beth A Chasen¹. ¹The University of Texas MD Anderson Cancer Center, Houston.

Background: Radium-223 dichloride (Ra-223) is a targeted alpha particle-based radiotherapeutic that has a localized cytotoxic effect on bone metastases. We sought to determine whether the circulating tumor cell (CTC) count and the presence of CTCs in epithelial-mesenchymal transition (EMT-CTCs) along with the standardized uptake value (SUV) on positron emission tomography-computed tomography (PET/CT) scans predict the efficacy of combined Ra-223 and hormonal therapy in patients with hormone receptor (HR)-positive bone-dominant metastatic breast cancer.

Patients and Methods: In this single-center phase 2 study (NCT02366130), 36 patients received Ra-223 (55 kBq/kg intravenously) on day 1 and then every 4 weeks for six cycles. Patients also received a standard care endocrine monotherapy. One non-bone metastatic site was allowed. The number of prior endocrine therapies was not limited and one prior chemotherapy was allowed for metastasis. Response was evaluated using the PET Response Criteria in Solid Tumors (PERCIST) with PET/CT at baseline, 6 and 9 months (mo) later. The CTC count (CellSearch) and the presence of EMT-CTCs (AdnaTest) was determined at baseline, 6 and 9 mo later. Progression-free survival (PFS) time was calculated to evaluate efficacy.

Results: Seven patients (20%) had a non-bone metastatic site. The median number of prior therapies for metastasis was 1 (range, 0-4). Six patients (17%) received chemotherapy. The median CTC count at baseline was 4 (range, 0-306). Only four patients (11%) were positive for EMT-CTCs at baseline. The median follow-up time was 14.7 mo (95% confidence interval [CI], 13.2 mo-not reached [NR]). The disease control rate at 9 mo was 46% in 33 patients who reached 9 mo or progressed up to 9 mo. The tumor response rate at 6 mo was 52% (complete/partial response rate; 22/30 %) in 27 patients whose disease was evaluable using PERCIST. The SUV on PET/CT decreased significantly at 6 and 9 mo after baseline (average decreases of 1.5 (p=0.0004) and 2.5 (p=0.0054), respectively). The median PFS duration was 7.4 mo (95% CI, 4.8 mo-NR). The median bone PFS was 16 mo (95% CI, 7.3 mo-NR). Patients with bone-only metastasis (N=28, 80%) had a significantly longer median PFS duration than did patients with non-bone metastases at baseline (N=7, 20%) (13.8 mo versus 4.5 mo; p=0.017). Patients without prior treatment (N=12, 34%) tended to have longer median PFS durations than did those who underwent prior treatment (N=23, 66%) (16.8 mo versus 4.8 mo; p=0.1865). Also, patients with <5 CTCs at baseline (N=19, 54%) tended to have longer median PFS durations than did those with ≥5 CTCs (N=16, 46%) (13.8 mo versus 4.8 mo; p=0.1277). EMT-CTCs status did not predict efficacy.

Conclusions: Bone-only metastatic breast cancer and SUV suppression by Ra-223 are predictive of efficacy. Patients with baseline <5 CTC count tended to have better outcomes than did those with ≥5 CTCs. Combined treatment with Ra-223 and a hormonal agent is especially effective at controlling bone metastasis in patients with HR-positive breast cancer. Bone-only metastatic disease and CTC count should be factored in future clinical trial designs.
Background: Optimal management of bone marrow metastasis (BMM) in advanced breast cancer (ABC) remains unknown. Associated severe cytopenias often urge treatment, but they are also a challenging factor for delivering chemotherapy (CT). Since BMM in ABC is infrequent, available data are scarce.

Aim: Clinical and prognostic characterization of ABC patients with BMM and its management; evaluation of the effectiveness of treating BMM with more myelosuppressive CT regimen (that we hypothesized that could be more active in the BMM) Vs. less myelosuppressive regimen.

Methods: Retrospective cohort study of patients with pathological confirmation of BMM (positive myelogram or osteomedullary biopsy) between Jan’2010 and Dec’2016 in the two major Portuguese cancer centers. Patients with diagnosis of a second carcinoma or active hemato-oncological condition within 5 years before BMM were excluded. We considered the more myelosuppressive regimens those with > 5% risk of febrile neutropenia according to Truong et al 2015(1). Kaplan-Meier and log-rank methodology were used to estimate survival and Cox regression to identify the covariates with independent prognostic value. Statistical level of significance was 5%.

Results: We included 74 patients: 74% with disease stage I-III at presentation, 74% ductal and 12% lobular invasive carcinomas, 58% grade 2 and 27% grade 3, 80% hormone receptor + / HER2-, 4% HER2+ and 12% triple negative (TN). Median time from ABC diagnosis to BMM was 10 months (IQR 2-36), synchronous in 34%. At diagnosis of BMM, median age was 57 years-old (IQR 47-65), 57% were post-menopausal, 97% had bone metastasis, 50% had visceral metastasis, 53% performed ≥ 2 previous palliative systemic treatments and 53% were exposed to bisphosphonates. The most frequent immunohistochemistry change in BMM biopsy was the loss of progesterone receptor expression (37%). Bicytopenia (anemia/thrombocytopenia) was the trigger for BMM investigation in 69% of cases, with grade 3-4 anemia in 16% and grade 3-4 thrombocytopenia in 26%. Median survival after BMM diagnosis was 5 months (95% CI, 3-11); overall survival at 12 and 24 months were 35% (CI 26-48%) and 24% (CI 15-36%), respectively. First treatment after BMM was CT in 58% (median survival, 11 months) and endocrine therapy in 14% (median survival, 3 months). An anti-HER2 regimen was used in 4% and 22% did not receive any treatment after BMM. On multivariate analysis, TN subtype (HR 4.02, CI 1.46-11.01), thrombocytopenia (G0 reference; G1-2: HR 2.47, CI 1.11-5.56; G3-4: HR 4.89, CI 1.85-12.91) and ≥ 2 palliative systemic treatments (HR 2.77, CI 1.46-5.27) were associated with worse prognosis. Within those treated with CT, there was a trend for a deleterious survival effect of more myelosuppressive regimens (HR 2.19, CI 0.94-5.09; 5 months Vs. 14 months, n=31), after controlling for subtype, number of previous regimens and thrombocytopenia.

Conclusion: BMM was not a late event in ABC disease course and had worse prognosis in multi-treated patients, in TN subtype and in the presence of thrombocytopenia. No benefit was shown with the use of more myelosuppressive CT regimens.

First-line treatment for endocrine sensitive bone-only metastatic breast cancer: Is more always better?

Angela Toss, Marta Venturelli, Isabella Sperduti, Chrystel Isca, Eleonora Molinaro, Elena Barbieri, Federico Piacentini, Claudia Omarini, Laura Cortesi, Stefano Cascinu and Luca Moscetti. 1Azienda Ospedaliero - Universitaria Policlinico di Modena, Modena, Italy and 2IRCCS Regina Elena National Cancer Institute, Roma, Italy.

The standard first-line for endocrine sensitive metastatic breast cancer (BC) is represented by endocrine therapy. Several phase III clinical trials searched for more effective endocrine strategies. Nevertheless, the use of combinations for the first-line treatment of bone-only disease (BoD) is widely discussed, due to its indolent course. Our meta-analysis aims to explore the role of new endocrine strategies in BoD.

A systematic review of electronic databases was conducted to identify the phase III clinical trials comparing the standard AI to novel experimental strategies. The hazard ratios (HR) for PFS were pooled in a meta-analysis. The heterogeneity of the data was evaluated by Chi-square Q test and $I^2$ statistic.

8 studies were included in the analyses. 4 trials explored the role of CDK4/6 inhibitors (Monaleesa2 and Monarch3 and Paloma2), 2 trials analyzed Fulvestrant + AI (SWOG and FACT), one trial studied Fulvestrant monotherapy (FALCON), while one trial evaluated the association between Bevacizumab and Letrozole (ALLIANCE). 6 trials reported data regarding the BoD, while 2 trials included the BoD in the non-visceral disease. Overall, the meta-analyses showed a PFS advantage for the experimental arms [HR 0.70 p 0.012], with a significant moderate/high heterogeneity [$I^2$ 66.48% p 0.004]. Only the FALCON and Paloma2 showed a significant improvement in PFS, respectively for Fulvestrant and Palbociclib + Letrozole. Considering only trials reporting data for BoD, the experimental arms significantly improved the PFS [HR 0.66 p 0.005], with a low/moderate non-significant heterogeneity [$I^2$ 44.95% p 0.106].

The novel strategies showed to be able to improve the PFS of BoD. Nonetheless, only Palbociclib + Letrozole provided statistically significant data of advantage in this setting. In clinical trials, BoD is often included in the non-visceral disease subgroup. Future clinical trials should take into account the differences in natural history and better prognosis of BoD, in order to define the best approach to these patients.
A phase 2 study of abemaciclib in patients with leptomeningeal metastases secondary to HR+, HER2- breast cancer

Sara M Tolaney1, Solmaz Sahebjam2,3, Emilie Le Rhun4, Nancy U Lin1, Melissa Markel Bear2, Zhengyu Yang5, Yanyun Chen5 and Carey K Anders6, 1Dana-Farber Cancer Institute, Boston, MA; 2H Lee Moffitt Cancer Center, Tampa, FL; 3University of South Florida, Tampa, FL; 4Centre Hospitalier Regional Universitaire de Lille, Lille, France; 5Eli Lilly and Company, Indianapolis, IN and 6University of North Carolina-Chapel Hill, Chapel Hill, NC.

**Background**
Abemaciclib is a selective CDK4 & 6 inhibitor approved to treat patients (pts) with HR+, HER2- advanced breast cancer (ABC) on a continuous dosing schedule as monotherapy or in combination with endocrine therapy.1-3 Clinical data demonstrate that abemaciclib can penetrate the blood brain barrier resulting in comparable abemaciclib concentrations in brain metastases tissues, cerebrospinal fluid, and plasma.4 We report safety and efficacy results of abemaciclib in pts with leptomeningeal metastases (LM) arising from HR+, HER2- ABC.

**Methods**
Study I3Y-MC-JPBO (NCT02308020) is a multicenter, open-label, Phase 2 trial evaluating the safety and efficacy of abemaciclib in 6 cohorts of pts with brain metastases secondary to HR+ ABC, non-small cell lung cancer, or melanoma. Here we discuss a subgroup of cohort F: pts with HR+, HER2- LM from ABC, documented by positive CSF cytology or by clinical signs and symptoms associated with abnormal MRI features. Pts with concomitant parenchymal brain metastases were allowed, but must have been stable for ≥4 weeks following wholebrain radiotherapy or stereotactic radiosurgery. Abemaciclib was orally administered 200mg twice daily on a 21-day cycle. The key exploratory objectives were to assess the effect of abemaciclib on pts with LM secondary to HR+, HER2- ABC based on safety and tolerability, and radiological assessment from the Response Assessment in Neuro-Oncology leptomeningeal metastases (RANO-LM) criteria.

**Results**
Between December 2015 and July 2016, 17 pts were enrolled in cohort F. This study reports on the 7 pts with HR+, HER2- ABC LM of which 4 pts were diagnosed with concurrent parenchymal brain metastases. Median duration of treatment was 3.9 months (range, 0.9-10.6), with 3 pts remaining on treatment for more than 6 months. Pts discontinued treatment due to progressive disease (PD, n=5) and adverse events (n=2). Median overall survival (OS) was 8.4 months (range, 3.3-14.2). Best investigator-assessed overall response was stable disease (SD) in 5 pts and progressive disease (PD) in 2 pts. Efficacy, as per CNS imaging, revealed SD in 4 pts (no imaging, n=1), 2 of which had stable or improved symptoms per neurological assessment response. Best overall intracranial response of parenchymal metastases was 1 complete response, 1 SD, and 2 PD. All 4 pts with extracranial disease had best overall response of SD. All pts experienced ≥1 TEAE, with the most common grade 3 TEAEs including nausea (28.6%), pain (28.6%), and vomiting (28.6%); 1 pt (14.3%) experienced grade 4 anemia and grade 4 upper gastrointestinal hemorrhage.

**Conclusion**
OS for pts with LM arising from HR+, HER2- ABC is typically 4 months or less despite available therapies5. Here we report the median OS within this subgroup as 8.4 months. Concurrent intracranial and extracranial disease control was observed. Safety and tolerability results are similar to those previously reported with abemaciclib. Further study of abemaciclib in a larger pt cohort is warranted.

Innovation in diagnosis and treatment of brain metastases using multifunctional nanomedicines

Jodi M Saunus¹, Malcolm Lim¹, Simon Puttick²,³, Priyakshi Kalita-de Croft¹, Zachary H Houston⁴, Martina L Jones⁴, Melissa J Latter⁵, Louise C Campbell⁶, Paul Thomas⁵, Rosalind L Jeffree², Stephen E Rose³, Stephen M Mahler²,⁴, Kristofer J Thurecht³, Andrew M Scott⁸ and Sunil R Lakhani¹,⁹. ¹Faculty of Medicine, The University of Queensland, Centre for Clinical Research, Herston, QLD, Australia; ²Australian Institute for Nanotechnology and Bioengineering, Centre for Advanced Imaging and ARC Centre of Excellence in Convergent BioNano Science and Technology, The University of Queensland, St. Lucia, QLD, Australia; ³Australian Institute for Bioengineering and Nanotechnology and ARC Training Centre for Biopharmaceutical Innovation, The University of Queensland, St. Lucia, QLD, Australia; ⁴The Royal Brisbane and Women's Hospital, Herston, QLD, Australia; ⁵Herston Imaging Research Facility (HIRF), The Royal Brisbane and Women's Hospital, Herston, QLD, Australia; ⁶Kenneth G. Jamieson Neurosurgical Unit, The Royal Brisbane and Women's Hospital, Herston, QLD, Australia; ⁷Olivia Newton-John Cancer Research Institute and Austin Health, Heidelberg, VIC, Australia and ⁹Pathology Queensland, The Royal Brisbane and Women's Hospital, Herston, QLD, Australia.

Systemic therapies have limited efficacy against brain metastases, largely because passive delivery of naked compounds via the bloodstream does not achieve sufficiently high or evenly dispersed intratumoural concentrations. Heterogeneous tissue architecture, abnormal perfusion, hypoxic zones and high interstitial fluid pressure are key factors limiting drug delivery, compounded by patchy blood-tumour-barrier permeability. Also, brain metastases are usually detected late, once patients become symptomatic. We are investigating whether engineered biopharmaceuticals might improve diagnostic sensitivity for earlier detection, as well as therapeutic efficacy and side-effect profiles of existing agents through active tumour targeting, delayed clearance and microenvironment-mediated activation. This study is proceeding with parallel preclinical and clinical tracks.

Preclinical aims: (1) Develop and characterise monoclonal antibody (mAb) fragments (scFvs) that target the brain metastasis markers HER2 and HER3; (2) Functionalise polyethylene glycol (PEG)-based nanocarriers with the scFvs, along with imaging agents to facilitate in vivo and ex vivo analysis of tissue distribution; (3) Functionalise HER2/3-targeted carriers with doxorubicin via an acid-labile hydrazone bond for release in hypoxic environments, or the endosome compartment after internalization. Results to date. His-tagged HER2- and HER3-targeted scFvs based on ligand-binding sequences of clinically-approved mAbs were expressed and purified from Expi293 suspension cultures. Binding affinities are an order of magnitude stronger than parent mAbs (K_D 2-8x10^-11 M), determined using surface plasmon resonance analysis. The scFvs are cytostatic and moderately cytotoxic in vitro, with IC50s in order of 0.4-1.0µM. HER2 and HER3 scFvs exhibited dose-dependent, additive growth inhibition when used in combination, and induced internalisation of their receptor ligands within 4 hours in SKBr3 cells. Conclusions. The scFvs are strong carrier-tethering candidates in terms of both extracellular and intracellular payload release. Carrier synthesis is currently underway and preliminary in vivo data will be presented.

Clinical aims: (1) Develop and characterise ⁶⁷Zirconium-labelled HER2-targeted PET tracers based on parent mAb and scFv; (2) Compare uptake and retention of the tracers in breast cancer patients with brain metastases; (3) Computationally relate tumour uptake to the administered dose, perfusion, tumour size and HER2 expression; (4) Determine the uptake range within and between patients, and the minimum size for reliable detection. Results to date. The mAb tracer has been synthesised, characterised and labelling processes scaled for clinical production. It is stable in physiologic conditions, retains HER2-binding activity and has a favourable biodistribution profile in NOD-SCID mice bearing BT474 xenografts. Conclusions. Australian regulatory approvals are in place and recruitment for the mAb imaging trial (“BoNSAI”) has begun. Preliminary data will be presented.
A phase I trial of sorafenib with whole brain radiotherapy (WBRT) in breast cancer patients with brain metastases and a correlative study of FLT-PET brain imaging in patients receiving WBRT with or without sorafenib

Aki Morikawa¹, Komal Jhaveri², Milan Grkovski², Kendrick Tang², John L Humm², Andrei Holodny², Kathryn Beal², Heiko Schoder² and Andrew D Seidman². ¹University of Michigan, Ann Arbor, MI and ²Memorial Sloan Kettering Cancer Center, New York, NY.

**Background:** WBRT is a standard therapy for metastatic breast cancer (MBC) patients (pts) with brain metastases (BM), but disease progression in the brain is common. Sorafenib, a tyrosine kinase inhibitor with anti-VEGF activity, has demonstrated anti-tumor efficacy in MBC and radiosensitizing activity preclinically. [18F] 3'deoxy-3'-fluorothymidine (FLT) is a new PET tracer which correlates with cellular proliferation and may improve response assessment in the brain. **Methods:** A phase I trial of sorafenib with WBRT in MBC pts with BM was conducted using a 3+3 design. Sorafenib was given orally daily at the start of WBRT for a total of 21 days with 3 doses levels: 200mg, 400mg, and 600mg. The primary endpoints were to determine a maximum tolerated dose (MTD) and to evaluate safety and toxicity. The secondary endpoint was central nervous system progression-free survival (CNS-PFS). Macdonald Criteria were used for response assessment with serial MRI brain imaging. Key eligibility criteria include MBC with new or progressive ≥ 1cm BM, ECOG PS 0-2, non-escalating corticosteroid dose, and no other concurrent anti-tumor therapy except trastuzumab. In parallel, we conducted a correlative FLT-PET imaging study (baseline, 7-10 days (FU1), and 10-12 weeks (FU2) after the WBRT) to assess radiographic changes among pts receiving WBRT + sorafenib and in a separate WBRT only cohort. FLT standard uptake value (SUV) and kinetic parameter data were obtained. **Results:** 13 pts were treated in the dose escalation phase and evaluable for dose-limiting toxicity (DLT). The median age was 56 years (range: 43-77). There were 4 HER2 positive (31%) and 3 triple negative (23%) pts. 2 pts had prior stereotactic radiosurgery. DLTs were: Grade (G) 4 increased lipase at 200mg (1 pt) and G3 rash at 400mg (3 pts) level. MTD was determined to be 200mg. 10 pts were evaluable for response (at least 1 follow up brain imaging). The overall response rate was 70%: 4 complete responses (CR) + 3 partial responses. All 13 pts were evaluated for CNS PFS with a median follow up of 29.7 months (min 19.6, max 57.4mo). Median CNS-PFS was 8.2 months (95%CI: 3.4-31.8). Median OS was 15.4 months (95% CI: 3.4-NR). A total of 10 pts with WBRT and sorafenib and 5 pts with WBRT only were enrolled in the FLT-PET study: all 15 pts had baseline FLT PET, 14 with FU1, and 9 with FU2. 55 baseline lesions, 38 at FU1 and 15 at FU2 were observed and analyzed. All lesions with FLT uptake had MRI correlates. Decline in average SUVmax of ≥25% was seen in 9/10 (90%) of WBRT+sorafenib and 2/4(50%) of WBRT only pts at FU1. A complete disappearance of FLT uptake was noted in 1 pt at FU1 and 2 more pts at FU2. **Conclusions:** Concurrent WBRT with sorafenib appears safe at 200mg daily dose with a higher rate of CR compared to historical WBRT data. We are currently enrolling patients in the safety-expansion cohort. This combination should be considered for further efficacy evaluation. Additional analysis of FLT-PET as a complementary imaging modality to MRI is currently ongoing. Clinical trial registry: NCT01724606 and NCT01621906. Support: Bayer, Susan G Komen, ASCO Gianni Bonadonna Breast Cancer Award.
Establishment of a human neural progenitor cell microenvironment model to investigate signalling events in triple negative breast cancer brain metastases in a high-throughput setting

Silke B Chalmers¹, Andrew J Dalley², Priyakshi Kalita-de Croft², Jodi Saunus², John J Bassett¹, Francisco Sadras¹, Sarah J Roberts-Thomson¹ and Gregory R Monteith¹. ¹School of Pharmacy, University of Queensland, Brisbane, Queensland, Australia and ²Centre for Clinical Research, University of Queensland, Brisbane, Queensland, Australia.

Background. Breast cancer brain metastases (BCBM) represents a terminal diagnosis accompanied by neurological decline and diminished quality of life. Average survival is less than a year following detection of neural lesions, due in part to an absence of targeted therapeutics. BCBM affects 12-17% of all breast cancer patients and over 25% of triple negative breast cancer (TNBC) patients. In the search for improved therapies, there is a focus increasingly on the role of the unique microenvironment of the brain in tumour progression. Few studies have investigated the establishment of an in vitro breast cancer brain microenvironment model that could enable the high-throughput identification and modulation of potential targets. In order to address this issue, a novel co-culture model was developed utilising the human neural progenitor cell (NPC) line ReNcell VM and MDA-MB-468 TNBC cells.

Methods. ReNcell VM were differentiated as monolayers or neurospheres for four or ten days and stained for the glial marker glial fibrillary acidic protein (GFAP) and the neuronal marker β3-tubulin. Cultures were imaged via automated epi-fluorescence microscopy (ImageXpress Micro, Molecular Devices) and proportions of cell types were calculated with MetaXpress image analysis software. Differentiation characteristics of neurospheres and monolayers were compared. Functionality of neural cultures was determined using calcium assays with the muscarinic agonist carbachol as a validation tool. MDA-MB-468 cells loaded with a Cell Tracker Green dye were assessed for viability on the neural matrix via bright field and epi-fluorescence microscopy.

Results. ReNcell VM cultured and differentiated for four days as neurospheres displayed a higher expression of β3-tubulin and GFAP than those cultured as monolayers (β3-tubulin 10.4% vs 7.7%, GFAP 53.6% vs 48.8%, respectively). Expression of β3 tubulin was higher after four days of differentiation than after ten days for neurosphere cultures (10.4% vs 4.4%, respectively). Carbachol elicited oscillatory calcium responses from ReNcell VM differentiated as neurospheres or monolayers, indicating functionality of both populations. MDA-MB-468 and ReNcell VM stained after four days of co-culture displayed successful integration of neoplastic cells on the neural matrix.

Conclusions. Human NPCs provide a reproducible model of prominent cell types within the brain milieu and are suited to high-throughput automated epi-fluorescence microscopy applications. Co-culture models of TNBC and differentiated ReNcell VM represent a powerful platform for mechanistic studies and drug screening.
The prognostic value of HER2, YKL-40 and IL-6 in cerebrospinal fluid in trastuzumab naïve breast cancer patients diagnosed with meningeal carcinomatosis

Marianne Ryberg¹, Julia Sidenius Johansen¹, Trine Lønbo Grantzau², Christian Dehlendorff³ and Dorte Lisbeth Nielsen¹.
¹Herlev-Gentofte Hospital, University of Copenhagen, Herlev, Denmark; ²Rigshospitalet, University of Copenhagen, Copenhagen, Denmark and ³Statistics and Pharmacoepidemiology, Danish Cancer Society Research Center, Copenhagen, Denmark.

Background
With the improvements in treatment of patients with metastatic HER2-positive breast cancer (BC) the development of CNS metastases has become a major limitation of life expectancy and quality of life for many patients. Meningeal carcinomatosis represents approximately 10-20% of CNS metastases. The prognosis of meningeal carcinomatosis remains extremely poor. In the present study, we analysed the prognostic value of HER2, YKL-40 and IL-6 in cerebrospinal fluid (CSF) of meningeal carcinomatosis.

Methods
Between June 1985 and August 1992 sixty-nine CSF samples were collected at Herlev Hospital from trastuzumab naïve BC patients suspected of meningeal carcinomatosis. The cohort was composed of BC patients from two previous studies. Meningeal carcinomatosis was confirmed by tumour cells in CSF (or autopsy/scans). The samples were centrifuged, frozen and kept at -80°C. The concentrations of YKL-40, IL-6 and HER2 in CSF were measured by commercial ELISA (Quidel and R&D) or Luminez (HER2 in second study). Overall survival in meningeal carcinomatosis was analysed with Kaplan-Meier curves and log rank tests using the median CSF value of HER2, YKL40 and IL-6 as cut off.

Results
20 patients (29%) had meningeal carcinomatosis (18 patients had tumour cells in CFS, one was diagnosed by autopsy and one by CT scan; 13 of these patients participated in the first study and 7 in the second). 10 patients had concomitant brain metastasis. The median survival was 35 days (4-305 days).

The median [IQR] CSF concentration of YKL-40 was 284 ng/ml (187-597), IL-6 was 15.9 pg/ml (6.5-51.0) and HER2 was 1.5 (0.36-8.70) in the patients with meningeal carcinomatosis. The survival was significantly shorter in patients with high levels of YKL-40 (p=0.03) and IL-6 (p=<0.01). The CSF HER2 level (p=0.51) or presence of brain metastasis (p=0.77) were not associated with survival.

Conclusion
In this cohort high levels of YKL-40 and IL-6 in CSF were associated with short survival in patients with BC and meningeal carcinomatosis. This was not found for HER2 in CSF or concomitant brain metastasis.
Real-world characteristics, treatment patterns, and overall survival in patients with metastatic breast cancer (mBC) and CNS metastases

Alberto Alvarado-Miranda\textsuperscript{1}, Paula Cabrera-Galeana\textsuperscript{1}, Wendy R Muñoz-Montaño\textsuperscript{1}, Fernando Lara-Medina\textsuperscript{1}, Enrique Bargallo-Rocha\textsuperscript{1}, Oscar Arrieta-Rodríguez\textsuperscript{1}, Manuel Perez\textsuperscript{1}, Fany Porras-Reyes\textsuperscript{1}, Alejandro Mohar-Betancourt\textsuperscript{1} and Carlos Gamboa\textsuperscript{1}. \textsuperscript{1}Instituto Nacional de Cancerología, Ciudad de México, Ciudad De Mexico, Mexico.

Background:
CNS metastases are reported in about 10 to 15%. Knowledge about the management of these patients are limited because they are excluded from clinical trials due to its poor prognosis and morbidity. In these study, we aim to describe characteristics, treatment patterns, and overall survival (OS) of patients of mBC with CNS metastases at Instituto Nacional de Cancerología de Mexico (INCan) from January 2007 to December 2015.

Methods:
We include patients with histological diagnosis of mBC and tumoral activity in the CNS (at diagnosis or during follow-up). mBC subtype was defined using HER2 and hormone receptor (HR) status by immunohistochemistry; systemic treatment, and mortality data were used to characterize mBC with CNS involvement.

Results:
During the study period, we found 1272 patients diagnosed with metastatic disease, of whom 408 had CNS disease (novo/recurrence) the median follow up was 52 months. Table 1 describes the percentage of CNS metastases by subtype, clinical characteristics at diagnosis and median OS. Almost all patients (85.6%) were candidate to holocranial radiotherapy; after that, systemic treatment varied according to the subtype of mBC; 69.1% of TN received CT (26% based on platinum); 75.3% of HER2+ received systemic treatment, all included anti-HER2 therapy; luminal subtype, no one were treated with endocrine therapy.

Conclusions:
HER2 positive breast cancer patients have the highest prevalence of CNS metastases, whereas luminal has the lowest. Patients with HER2+ and CNS metastases commonly receive treatment based on anti-HER2 therapy, maybe this target treatment contribute to the better survival achieved than patients with luminal or TN subtype. mBC with CNS metastases continues in the real world to be an unmet medical need.

Prognostic factors of human epidermal growth factor 2 (HER2) positive breast cancer patients with brain metastasis in the context of all available new therapies

Julia C Medeiros de Melo¹, Alexandre ABA da Costa¹, Douglas G de Castro¹, Anderson AD Gomes¹, Andrea PG Guimaraes¹, Solange M Sanches¹, Ana CSL Diniz¹ and Adriana RG Ribeiro¹. ¹AC Camargo Cancer Center, São Paulo, SP, Brazil.

Background:
Patients with advanced human epidermal growth factor 2 (HER2)-positive breast cancer are at the highest risk developing breast cancer brain metastases (BCBM), which are associated with significant morbidity and mortality. The advent of HER2-directed therapy resulted in greatly improved survival outcomes and have been widely used. In this context of a better controlled systemic disease, brain metastases are emerging as a new challenge for the oncologist. The aim of this study was to determine the clinicopathologic factors associated with the prognosis of patients with HER2 positive BCBM, in the scenario of new therapies.

Methods:
A retrospective review of clinical data from patients who have developed HER2 positive BCBM from March 2005 to January 2018 at AC Camargo Cancer Center. Patients characteristics were collected, and overall survival (OS), time to first HER2 positive BCBM and OS after HER2 positive BCBM were estimated by the Kaplan-Meier method. Associations between OS after BCBM and clinical variables were assessed by Cox proportional hazards regression models.

Results
Among 80 patients with HER2-positive BCBM median age was 51 years (range, 24–81 years). Of the patients, 55 patients (69%) had ER-positive/HER2-positive breast cancer, and 25 (31%) had ER-negative/HER2-positive breast cancer. The median brain metastasis-free survival period from primary breast cancer was 33.5 months. The median survival after developing brain metastasis was 28.5 months. Patients with more than 3 brain metastases had significantly shorter overall survival (p=0.01). Nineteen patients (24%) underwent surgical treatment of metastasis in the brain and there was no associated with survival duration (p=0.33). Patients treated with radiotherapy 71 (88%) had significantly better survival (p=0.013), if the patient received stereotactic radiosurgery (53.5%) compared to total brain radiotherapy received (46.5%) was not associated with duration of survival (p=0.24). Treatment with other HER2-targeting agents after BCBM had significantly increased survival (p=0.022), including trastuzumab 53 (67%), pertuzumab 21 (26%), trastuzumab emtansine (TDM1) = 35 (43%) and lapatinib 37 (46%). In multivariate analysis, the presence of more than 3 brain metastases (p=0.005) was the sole independent prognostic factors.

Conclusions:
Our study indicates that HER2-positive patients with more than three brain metastases had a poor prognosis and that regardless of the use of new therapies. The role of new therapies in the management of patients with brain metastases is often not clearly defined. The best treatment strategy is not yet known and the study of prognostic factors may help to choose a better treatment sequence.
Intraoperative ketorolac in high-risk breast cancer patients with and without inflammation. A prospective, randomized, placebo-controlled clinical trial

Martine Berliere¹, Gauthier Bouche², Francois Duhoux³, Pierre Coulie⁴, Jan De Cloedt⁵, Alain Dekleermaker⁶, Jean-Edouard Guillaume⁷, Marc Ledent⁸, Jean-Pascal Machiels⁹, Veronique Mustin⁶, Walter Swinnen⁵, Lionel Vander Essen⁶, Aline Van Maanen⁹, Jean-Christophe Verougstraete⁸, Marc De Kock¹⁰ and Patrice Forget¹¹. ¹Breast Clinic, King Albert II Institute, Cliniques Universitaires Saint-Luc, Université Catholique de Louvain, Brussels, Belgium; ²Anticancer Fund, Brussels, Belgium; ³King Albert II Institute, Cliniques Universitaires Saint-Luc, Université Catholique de Louvain, Brussels, Belgium; ⁴de Duve Institute, Université Catholique de Louvain, Brussels, Belgium; ⁵St-Blasius Hospital, Dendermonde, Belgium; ⁶Clinical Pharmacology Unit, Cliniques Universitaires Saint-Luc, Brussels, Belgium; ⁷Ste-Elisabeth Hospital, Namur, Belgium; ⁸St-Pierre Clinic, Ottignies, Belgium; ⁹King Albert II Institute, Cliniques Universitaires Saint-Luc, Brussels, Belgium; ¹⁰Centre Hospitalier Wallonie Picarde (CHWAPI), Tournai, Belgium and ¹¹Vrije Universiteit Brussel (VUB), Universitair Ziekenhuis Brussel (UZ Brussel), Brussels, Belgium.

Introduction: Perioperative events may affect the risk of breast cancer recurrence after surgery. Ketorolac, a non-steroidal anti-inflammatory drug routinely used to improve pain control postoperatively has been associated with better breast cancer outcome in retrospective studies. However, it is still unknown whether a single dose of pre-incisional ketorolac may be sufficient to prolong recurrence-free survival.

Patients and methods: The KBCt trial (NCT01806259) is a national, multicenter, prospective, double-blind, placebo-controlled, randomized phase III trial in high-risk breast cancer patients. Each patient was assigned to the ketorolac or the placebo group. Patients were given one dose of ketorolac tromethamine (Tarady®, N.V. Roche S.A., Belgium) or a matching placebo 30 minutes before surgery. Eligible patients were ≥18 and ≤75 years old with histologically or cytologically confirmed, invasive ductal or lobular breast carcinoma planned for curative breast cancer surgery, and with at least one of these 3 criteria: a Neutrophil-to-Lymphocyte Ratio ≥4, node-positive disease (cN1-N3) or a triple-negative histology. The primary endpoint of the study was Disease-Free Survival (DFS). Secondary endpoints included safety, pain assessment and overall survival.

Results: Two hundred and three patients were assigned to ketorolac (n=96) or placebo (n=107). Baseline characteristics were similar between arms. Patients had a mean age of 55.7 (SD 14) years. Both intra- and post-operative blood losses were not different between groups and there was no difference in pain at day 1 after surgery. There was no difference between the 2 arms for DFS (p=0.52) nor for OS (p=0.88).

Discussion and conclusion: This study shows that a single administration of 30 mg of ketorolac tromethamine before surgery does not increase disease-free survival in high-risk breast cancer patients. Overall survival is also comparable. No safety concerns were observed in this study.
Incidence of hyperglycemia in non-diabetic patients with early-stage breast cancer treated with chemotherapy

Melissa K Accordino¹, Aijing Lin¹, Jason D Wright¹, Meghna S Trivedi¹, Kevin Kalinsky¹, Katherine D Crew¹ and Dawn L Hershman¹. ¹Columbia University Medical Center, New York, NY.

Background: There are shared risk factors between breast cancer (BC) and diabetes mellitus (DM). BC treatments including chemotherapy given in combination with glucocorticoids can induce hyperglycemia and steroid related DM. Patients with DM are at increased risk of developing chemotherapy related toxicities such as chemotherapy induced peripheral neuropathy (CIPN) compared to those without DM. The incidence of hyperglycemia during chemotherapy in non-diabetic patients with early-stage breast cancer is unknown.

Methods: We performed a retrospective analysis of non-diabetic women with stage I-III breast cancer treated with chemotherapy at Columbia University Medical Center from 9/1/2016-8/31/2017 to evaluate hyperglycemia incidence during chemotherapy and up to six months after chemotherapy completion. Eligible patients were identified in the electronic health record (EHR) by ICD9 and 10 codes (ICD9 174.x and ICD10 C50.x) and a record of chemotherapy administration. Non-diabetic patients were defined by chart review as no recorded history of diabetes and no receipt of a diabetes medication in the EHR. Breast cancer stage was determined by chart review. Glucose values were recorded prior to chemotherapy, during chemotherapy, and for six-months after chemotherapy completion. We defined hyperglycemia as a glucose value of ≥200 mg/dl. Median time to hyperglycemia was also calculated.

Results: We identified 82 eligible patients. The majority of patients received dexamethasone during their chemotherapy course (79 patients, 96.3%). The most frequent chemotherapy regimen was doxorubicin/cyclophosphamide and paclitaxel (32 patients, 39.0%). At baseline, 20 patients (24.4%) had a normal body mass index (BMI), 27 patients (32.9%) were overweight, and 31 patients (37.8%) were obese. Hyperglycemia occurred in 8 patients (9.8%) after initiation of chemotherapy. Among patients with hyperglycemia, the maximum blood glucose was between 200-299 mg/dl in seven patients (87.5%), and between 500-599 in one patient (12.5%). The median time to hyperglycemia was 84 days. Among patients who did not experience hyperglycemia, the maximum blood glucose was between 140-159 mg/dl in six patients (8.1%), between 160-179 mg/dl in eight patients (10.8%), and between 180-199 mg/dl in three patients (4.1%). Three patients were diagnosed with DM following chemotherapy completion. Conclusion: Hyperglycemia occurred in almost 10% of non-diabetic patients who received chemotherapy for early-stage breast cancer. Additionally, over 30% of patients had a blood glucose of 140 mg/dl or higher after chemotherapy initiation. The impact of hyperglycemia on the development of chemotherapy related toxicities in this group is unknown. Future research is needed to identify effective interventions for glucose control during chemotherapy, and to determine if glucose control during treatment can reduce the risk of chemotherapy related toxicities, specifically CIPN.
Nanoformulation of doxorubicin inside H-ferritin nanocages allows a cardio-safe combined therapy with trastuzumab: De-escalating cardiotoxicity in HER2-positive breast cancer

Serena Mazzucchelli¹, Francesco Andreata¹, Arianna Bonizzi¹, Matteo Monieri¹, Michela Bellini², Erika Longhi¹, Roberta Ottria¹, Luca Sorrentino¹, Marta Truffi¹, Davide Prosperi², Pietro Zerbi¹ and Fabio Corsi¹,³

¹University of Milan, Department of Biomedical and Clinical Sciences "L. Sacco", Milan, Italy; ²University of Milan-Bicocca, Milan, Italy and ³ICS Maugeri Spa SB, Breast Unit, Pavia, Italy.

Background: HER2+ breast cancer (BC) accounts for 20-25 % of BCs and it is characterized by high aggressiveness.¹ Despite the anti-HER2 monoclonal antibody Trastuzumab (TZ) has improved BC clinical outcome, it could induce severe cardiac reversible dysfunction:² HER2 signaling is also essential for growth and survival of myocardiocytes.³ Therefore, the concurrent use of TZ with other cardiotoxic drugs as doxorubicin (DOX) is discouraged.³ Both neoadjuvant and adjuvant clinical trials have challenged the notion that TZ should be administered with anthracyclines only sequentially,⁴ despite pre-clinical studies demonstrated the significant enhancement of efficacy by their coadministration.⁵-⁷ Nanomedicine answers to this clinical issue with HFn-DOX: a natural protein-based DOX nanoformulation with native tumor targeting capability that displays a self-triggered nuclear delivery of DOX improving antitumor efficacy and reducing both chemoresistance and cardiotoxicity.⁸

Methods: HER2+ BC bearing mice have been treated 5 times twice a week with placebo, HFn-DOX (1 mg/Kg, i.v.), TZ (5 mg/Kg, i.p.) and with the combination of them. Main end-point were cardiotoxicity and anticancer efficacy. Tumor size was measured by caliper, while antitumor activity and cardiotoxicity were characterized by ICH, immunofluorescence, cytofluorimetry, TEM, mass spectrometry and western blot on resections. Statistical analyses were conducted using two-tailed Student's t-test (P< 0.05)

Results: Although single treatments with HFn-DOX or TZ display a good capability to reduce tumor progression, their combination improves antitumor potential, affecting tumor size and angiogenesis. Since the main TZ activity is the induction of the Antibody-Dependent Cell mediated Cytotoxicity, we have assessed the effect of HFn-DOX on Tumor Infiltrating Lymphocytes (TIL), revealing that both TILs enumeration and TIL activity is unaffected by HFn-DOX. On the other hand, HFn-DOX increases the induction of apoptosis, suggesting that the reduction of the tumor size observed in mice treated with the combination of TZ and HFn-DOX is attributable to the coupling of these activity. Mitochondrial morphology has been checked for cardiotoxicity. A pathological increase in mitochondria area coupled with cristae depletion has been evidenced only in mice treated with TZ alone, confirming the overall safety of the HFn-DOX formulation. Interestingly, mice treated with the TZ and HFn-DOX did not display evidences of cardiac suffering. TZ quantification in tumor and heart revealed that the combination with HFn-DOX couples the increased TZ accumulation and penetration in tumor with TZ reduction in heart, resulting in the lack of cardiotoxicity.

Conclusions: Our results suggest that a combined therapy with HFn-DOX and TZ allows an enhanced anticancer activity and reduced cardiotoxicity, with potential translational implications on the treatment of HER2+ BC patients.

Raman imaging as a tool for the chemical and spatial characterization of breast microcalcifications to improve lesion assessment

Renzo Vanna¹, Carlo Morasso¹, Francesca Piccotti¹, Luca Sorrentino², Laura Villani¹, Emanuele Torti³, Arianna Bonizzi², Francesco Leporati³ and Fabio Corsi¹,². ¹ICS Maugeri S.p.A. SB, Pavia, Italy; ²University of Milan, Milan, Italy and ³University of Pavia, Pavia, Italy.

Background: microcalcifications (MC) are common findings on screening mammography and are among the earliest signs of breast cancer. At the same time, from the use of well-known radiographic risk score systems, which include MC assessment, such as Breast Imaging-Reporting and Data System (BI-RADS), only 20% of screened patients are further associated with malignancy. This leads to repeated biopsies and to unnecessary surgeries with discomfort for patients and increased costs for the healthcare system. Furthermore, the definitive diagnosis by histological and immunohistological evaluations is still laborious and time-consuming.

Raman Spectroscopy (RS) is a photonic approach capable to provide detailed chemical information of analysed samples without complex tissue preparation or staining. RS has a proven ability to distinguish different crystal structures, including those commonly present in MC. In this context some studies based on RS suggested a correlation between MC chemical features and pathology. On the other hand, previous Raman-based studies mainly investigated the overall MC chemical composition (by single-point scans) while an extensive MC characterization by Raman imaging approaches (mapping) for diagnostic purposes is still lacking.

The aim of this study is to assess the usefulness of Raman imaging as a quick and accurate tool for a complete spatial characterization of MC detected on screening mammography and sampled by breast biopsy in order to better distinguish malignant vs. benign lesions.

Method: 30 patients with breast calcifications detected on mammography with radiological classification BI-RAD 3-5 where selected and evaluated by core biopsy. 10 µm formalin-fixed paraffin-embedded (FFPE) histological sections obtained from biopsies were dewaxed with a specifically developed protocol that allows the removal of paraffin in less than 15 minutes. All MC present in each tissue section (usually from 2 to >10 per section) were then characterized by a Raman microscope thus obtaining Raman maps with lateral resolution between 5 and 10 µm. After pre-processing steps the Raman maps were analysed by both clustering and multivariate analysis approaches used to produce false-colour images and to perform automated features identification.

Results: Our results confirm that hydroxyapatite is the prevalent form of calcium phosphate in MC and that MC composition correlates with lesion malignancy. In addition, thanks to the Raman imaging approach used here, we report for the first time that hydroxyapatite is more homogeneously distributed in malignant lesions and that, on the contrary, benign lesions show a heterogeneous distribution of hydroxyapatite, whitlockite and calcium-carbonate, inside the lesion and in the surrounding tissue.

Conclusion: These evidences suggest that the characterization of MC by Raman imaging is a potential tool for the definition of new diagnostic signatures of breast cancer, especially if we consider that these evaluations can be performed by the simple and relative fast scanning of dewaxed slices, without altering the clinical workflow and without the need of staining or antibodies. Further studies with a larger cohort will be done to validate these results.
Association of circulating tumor DNA with clinical outcomes in metastatic breast cancer patients

Antoinette R Tan1, James Symanowski1, Elyssa N Kim1, Madeline Hosking1, Clive D Morris2, Vincent Plagnol2, Carol J Farhangfar1 and Jennifer L Ersek1. 1Levine Cancer Institute, Atrium Health, Charlotte, NC and 2Inivata, Cambridge, United Kingdom.

Background: Circulating tumor DNA (ctDNA) can be used as a non-invasive method to detect and quantify genomic alterations (GA) in blood. We evaluated the relationship between ctDNA features, radiographic disease progression (RDP) and progression-free survival (PFS) in patients (pts) with metastatic breast cancer (MBC).

Methods: A retrospective analysis of 32 female MBC pts with plasma ctDNA tested prior to a radiology scan was performed. Plasma ctDNA tests were run by Inivata using a 36-gene panel for detecting point mutations, short insertions/deletions, and copy number variations. ctDNA features were tabulated for each pt and included number of genomic alterations (numGA), maximum mutant allele frequency (maxMAF), and sum of mutant allele frequency (sumMAF). Univariate and multivariable logistic regression (LR) models were used to explore ctDNA features associated with RDP. Univariate and multivariable Cox proportional hazards models were used to identify ctDNA features that were associated with PFS. All models included ctDNA features as continuous variables.

Results: Frequency of subtypes were 38% HR+HER2-, 28% HR+HER2+, 28% triple-negative, and 6% HR-HER2+. 97% had prior chemotherapy; 92% of HR+HER2-negative pts had prior endocrine therapy. 20 of 32 samples (69%) had GAs. The most common GAs were TP53 (50%), ESR1 (25%), PIK3CA (19%), and GATA3 (9.4%). Median numGA was 1 (0-12); median maxMAF was 1.9 (0-65.5); median sumMAF was 2.2 (0-157.2). Univariate LR analysis identified numGA (p=0.025), maxMAF (p=0.034), and sumMAF (p=0.049) to be significantly associated with RDP; numGA (p=0.056) and maxMAF (p=0.109) were retained in the final multivariable LR model. Univariate Cox regression analysis showed that numGA (HR=1.32, p<0.001), maxMAF (HR=1.02, p=0.045) were retained in the final multivariable Cox model.

Conclusions: Blood ctDNA profiling contributes to the prediction of RDP and PFS in MBC pts. High number of alterations and high allele fraction of these alterations were associated with worse clinical outcomes. These data provide an overview of the ctDNA dynamics in treated MBC pts.
Early relapses in breast cancer can be prevented by a perioperative NSAID, which would be a solution to a 2000 year old problem.

Michael W Retsky, Michael Baum, Jayant S Vaidya, Rick A Rogers, William J Hrushesky, Romano Demicheli and Patrice Forget.

Harvard TH Chan School of Public Health, Boston, MA; University College London (Emeritus), London, United Kingdom; University College London, London, United Kingdom; University of Southern Carolina (Retired), Columbia, SC; University of Milan, Milan, Italy and University Hospital Brussels, Brussels, Belgium.

A bimodal pattern of hazard of relapse among early stage breast cancer patients has been identified in multiple databases from US, Europe and Asia. We have been studying these data to determine if this can lead to new ideas on how to prevent relapse in breast cancer. Using computer simulation and access to a very high quality database from Milan for patients treated with mastectomy only, we proposed that relapses within 3 years of surgery are stimulated somehow by the surgical procedure. During the week post surgery, metastatic development is enhanced 100 fold according to the simulation. Most relapses in breast cancer are in this early category. Retrospective data from a Brussels anesthesiology group suggested a plausible mechanism. Use of ketorolac, a common NSAID analgesic used in surgery was associated with far superior disease-free survival in the first 5 years after surgery. The expected prominent early relapse events in months 9-18 are reduced 5-fold. Transient systemic inflammation accompanying surgery (identified by IL-6 in serum) could facilitate angiogenesis of dormant micrometastases, proliferation of dormant single cells, and seeding of circulating cancer stem cells resulting in early relapse and could have been effectively blocked by the perioperative anti-inflammatory agent. If this observation holds up to further scrutiny, it could mean that the simple use of this safe, inexpensive and effective anti-inflammatory agent at surgery might eliminate early relapses. Similar bimodal patterns have been identified in other cancers suggesting a general effect. Based on the writings of Galen and Celsus, metastatic development after breast tumors were removed was known to them 2000 years ago. This effect has been demonstrated recently in a mouse model by Krall et al Science Translational Medicine and reviewed in NEJM by Komaroff. In a series of experiments in 273 mice, aggressive mouse breast cancer cells were implanted in various locations. Initially, the tumor cells grew but then became dormant. This dormancy occurred only in mice with intact immunity, which suggests that the immune system can contain certain dormant metastases. Surgery of any type (including resection of a primary tumor) led to aggressive growth of metastases in 60% of animals, compared with 10% of control animals that did not undergo surgery. Surgical procedures caused systemic inflammatory responses. Activated monocytes from the marrow traveled to the sites of the dormant metastases and became tumor associated macrophages. These macrophages suppressed the immune system near the tumor, awakening the metastases from their dormancy. Treating the animals with NSAIDs before and immediately following surgery greatly attenuated growth of these metastases.

Since this effect has by now been shown in two Belgian retrospective studies as well as a mouse model we suggest this be tested in one or more clinical trials. We also note that the bleeding potential from using NSAIDs before surgery can apparently be reduced with the use of Tranexamic Acid – currently being tested in a clinical trial for mastectomy.
Whole exome sequencing analysis of the progression from ductal carcinoma in situ to invasive ductal carcinoma

Ju Youn Lee¹, Rui Bi¹, Fresia Pareja¹, Felipe C Geyer¹, David Brown¹, Hannah Y Wen¹, Larry Norton¹, James Hicks², Britta Weigelt¹ and Jorge S Reis-Filho¹. ¹Memorial Sloan Kettering Cancer Center, New York, NY and ²University of Southern California, Los Angeles, CA.

Introduction: Ductal carcinoma in situ (DCIS) is a bona fide non-obligate precursor of invasive carcinoma. Single cell sequencing studies have revealed intra-lesion genetic heterogeneity in DCIS and shown that progression to invasive ductal carcinoma (IDC) may occur through different mechanisms, including the selection of a subpopulation of tumor cells, acquisition of new genetic alterations or multi-clonal invasion. Here, we sought to investigate the genetic heterogeneity of DCIS, and to document further the clonal selection process accompanying progression to IDC.

Materials and methods: Synchronous DCIS (n=16) and IDC (n=15) samples from 14 patients were microdissected separately, and DNA samples of tumor and matched normal tissues were subjected to whole-exome sequencing (WES; n=27) or massively parallel targeted sequencing of all coding regions of ≥410 cancer-related genes (n=4). Somatic genetic alterations and mutational signatures were identified using state-of-the-art bioinformatics algorithms. PyClone was employed to define the clonal architecture of each DCIS and IDC and infer the clonal shifts accompanying progression from DCIS to IDC.

Results: DCIS were found to harbor recurrent somatic mutations affecting PIK3CA (50%), GATA3 (44%), TP53 (38%), CBFB (19%), PTEN (13%), and AKT1 (13%), which are genes known to be significantly mutated in invasive breast cancers. Despite the genomic similarities between matched DCIS and IDCs, NOTCH2 and MYC were found to be amplified solely in the IDC component of two cases, and PPM1D amplification was restricted to the DCIS component of another case. The mutational signature ascribed to aging (i.e. signature 1) was the predominant mutational signature in the DCIS and IDCs analyzed. PyClone analysis revealed that all synchronous DCIS and IDC studied here were clonally related and confirmed the previous observation that DCIS displays intra-lesion genetic heterogeneity. Evidence of clonal selection in the progression from DCIS to IDC was observed in three cases, whereby a minor DCIS subclone likely constituted the substrate for the development of IDC. In one of these cases, from a patient with a BRCA1 germline pathogenic mutation, we observed a shift from the mutational signature associated with defective homologous recombination DNA repair (i.e. signature 3) to the APOBEC-related mutational signatures (i.e. signatures 2 and 13) in the progression from DCIS to IDC.

Conclusion: Intra-lesion genetic heterogeneity is a common feature in DCIS synchronously diagnosed with IDC. Our findings corroborate the notion that DCIS is a direct non-obligate precursor of IDC, and that clonal selection in the progression of DCIS to IDC may be present in a subset of cases, but is unlikely to constitute the most frequent mechanism of progression.
Lipocalin 2 promotes inflammatory breast cancer tumorigenesis and skin invasion

1University of Texas MD Anderson Cancer Center, Houston, TX; 2University of Texas at Brownsville, Brownsville, TX; 3The University of Antwerp, Antwerpen, Belgium; 4Aix-Marseille Univ, Inserm, CNRS, Institut Paoli-Calmettes, CRCM, Marseille, France; 5University of Puerto Rico (UPR) Medical Science Campus and UPR Comprehensive Cancer Center, San Juan, Puerto Rico and 6MD Anderson Morgan Welch Inflammatory Breast Cancer Clinic and Research Program, The University of Texas MD Anderson Cancer Center, Houston, TX.

Background: Inflammatory breast cancer (IBC) is the most lethal form of primary breast cancer and accounts for a significant 10% of breast cancer deaths in the USA owing to its aggressive proliferation and metastasis, and a lack of effective therapeutic options. Unraveling the underlying mechanisms of growth and metastasis of this aggressive disease could lead to effective therapeutic strategies for an improved outcome in IBC patients. We recently generated in vitro and in vivo IBC models for brain metastasis studies [Debeb et al. JNCI, 2016] and observed an upregulation of Lipocalin 2 (LCN2), a small, secreted iron-trafficking protein which plays a significant role in immune and inflammatory responses and the promotion of malignant progression. The purpose of this study was to investigate the function of LCN2 in IBC tumorigenesis and metastasis.

Methods: Stable knockdown (KD) of LCN2 in IBC cell lines was achieved with lentiviral vectors. Proteomic and gene expression profiling were performed using RPPA and Affymetrix Clariom D microarray. For in vivo studies, control and LCN2 KD IBC cells were transplanted into the cleared mammary fat pad of SCID/Beige mice. Tumor-skin involvement was assessed visually during primary tumor growth and tumor excision. LCN2 gene expression levels in clinical samples were analyzed from the IBC Consortium as well as public data sets. LCN2 serum levels in IBC patients were measured using ELISA and were correlated with clinicopathological variables and outcome data.

Results: LCN2 gene expression is higher in IBC versus non-IBC patients (p=0.00036), independently of the molecular subtypes, and higher in more aggressive (TNBC and HER2+) than hormone receptor-positive subtypes (p<0.00001). LCN2 expression in patient tissues is correlated with reduced overall survival (p<0.00001) and metastasis-free survival (p=0.04) in non-IBC; however, LCN2 was not associated with overall survival in IBC patient serum samples. LCN2 expression was also significantly higher in IBC cell lines, in their culture media, and in brain metastasis sublines compared to non-IBC cell lines (p=0.004). In IBC cell lines, LCN2 KD reduced proliferation, colony formation, migration, and cancer stem cell properties. In vivo silencing of LCN2 in SUM149 cells inhibited primary tumor growth (p=0.001) and resulted in a well-differentiated tumor histology. Additionally, SUM149 LCN2 KD significantly reduced skin invasion/recurrence (LCN2 control vs LCN2 KD: 88% vs 25%, p=0.01) suggesting LCN2 is a mediator of tumorigenesis. Analysis of proteomics data showed changes in major signaling pathways including PI3K-Akt signaling and EGF/EGFR signaling pathways. Mechanistically, LCN2 depletion in SUM149 abrogated EGF-induced EGFR phosphorylation and ERK activation.

Conclusions: Our findings suggest that LCN2 may drive IBC tumor progression and skin invasion/recurrence potentially via the EGFR signaling pathway. Future studies will determine the role of LCN2 in metastasis and pinpoint the detailed mechanisms of LCN2-mediated IBC tumorigenesis and recurrence.
Epithelial-mesenchymal transition promotes triple negative breast cancer immune suppression

Michelle M Williams¹, Jessica L Christenson¹, Kathleen O'Neill¹, Thomas J Rogers¹, Lisa I Greene¹, Jill Slansky¹ and Jennifer K Richer¹. ¹University of Colorado Anschutz Medical Campus, Aurora, CO.

Background: Epithelial-Mesenchymal Transition (EMT) is a developmental process co-opted by carcinomas to facilitate metastasis. Triple negative breast cancer (TNBC), which has often undergone at least partial EMT, has a poor prognosis due to frequent and rapid recurrence as metastatic disease when compared to other breast cancer subtypes. To identify drivers of TNBC progression microRNA miR-200c was restored to the human TNBC mesenchymal-like BT549 cell line, which decreased 80% of the pan-EMT mesenchymal signature and restored 60% of the epithelial signature. In addition to decreasing proteins involved in immune-suppression via contact-dependent mechanisms, such as CD274 (PD-L1) and CD273 (PD-L2), Ingenuity Pathway and GSEA analysis revealed reduced expression of genes encoding enzymes, including Tryptophan 2,3-Dioxygenase (TDO2) and Heme Oxygenase-1 (HO-1), that generate immune-suppressive metabolites that function in a non-contact dependent manner. TNBC utilizes these and other immune-suppressive factors made by fetal trophoblasts to suppress the maternal immune system to achieve fetal tolerance during pregnancy, suggesting that TNBC may mimic a physiologically relevant mechanism to promote immune evasion.

Hypothesis: TNBC metabolism is altered as part of an EMT program resulting in generation of immune-suppressive metabolites that promote metastasis by facilitating contact-independent immune evasion.

Methods: Expression and activity of TDO2 and HO-1 were determined by UHPLC-MS for kynurenine (generated by TDO2) and bilirubin (generated by HO-1) in multiple TNBC cell lines. Single cell RNAseq was performed to identify genes co-expressed with these enzymes. To develop an immune competent preclinical model, doxycycline inducible miR-200c (TripZ-200c) was stably introduced into the Met-1 mammary carcinoma cell line derived from the MMTV-PyMT mouse model developed in FVB/NJ mice. Results were confirmed via transient miR-200c expression in 66cl-4 mammary carcinoma cells (from a spontaneous BALB/c tumor).

Results: Restoration of miR-200c decreased TDO2 and HMOX1 (HO-1) by 80% and 40% respectively in Met-1 and 66cl-4 mammary carcinoma cells and reduced secretion of kynurenine and bilirubin. HO-1 was increased in lung metastasis from Met-1 and 66cl-4 cells when compared to cells prior to tail vein injection. ScRNAseq revealed specific gene expression signatures co-expressed with TDO2 and are being analyzed to better detect TDO2 in tumor tissues. In vivo studies are underway to investigate the effects of inhibiting tumor TDO2 and HO-1 on infiltrating lymphocyte composition, the anti-tumor immune response, and tumor progression.

Conclusions: Restoration of miR-200c revealed EMT-associated alterations in tumor metabolism and consequent secretion of immune-suppressive metabolites produced by TDO2 and HO-1. We propose that targeting these contact-independent immune-suppressive factors may complement current contact-dependent therapeutic strategies (checkpoint inhibitors) to boost anti-tumor immune cell function and thereby prevent or decrease TNBC metastasis.
Targeting of casein kinase \( \delta \) inhibits triple negative breast cancer metastasis

Simon Bayle\(^1\), Marie Lafitte\(^2\), Victor Quereda\(^1\), William R Roush\(^1\) and Derek R Duckett\(^1\). \(^1\)The Scripps Research Institute, Jupiter, FL and \(^2\)CRBM University Montpellier CNRS, Montpellier, France.

Metastasis is responsible for most breast cancer mortalities and 30% of the patients with breast cancer will develop metastases. Despite the establishment of efficient targeted therapies for breast cancer, there is no cure for metastatic disease. Our research team have developed a potent, highly selective, small molecule inhibitor of casein kinase-1 delta (CK1\(\delta\)), a serine/threonine kinase. We have demonstrated that our lead molecule (SR-3029) provokes tumor specific cell death and tumor regression in pre-clinical orthotopic xenograft models of triple negative breast cancer (TNBC) including, basal-like patient derived (PDX) breast cancer models. Herein, we demonstrate that targeting CK1\(\delta\) inhibits tumor cell invasion in cell based studies and markedly reduces both the number and size of metastasis lesions spreading from the breast to the lung \textit{in vivo}. We show that invasion impairment is due to the inhibition of key effectors of the epithelial-mesenchymal transition. We have developed Lumifluor patient-derived xenograft models and assessed the effect of our inhibitors at various stages during the process of metastases. We have identified CK1\(\delta\) as an efficacious therapeutic target with dual potential for triggering apoptosis of breast tumor cells and impairing metastatic spread from the primary tumor.
Intravital imaging of the lung reveals the efficiency of the metastatic cascade

Anouchka H Coste¹,²,³, Lucia Boriello²,³, Yarong Wang²,³, Maja Oktay², John S Condeelis¹,²,³,⁴ and David Entenberg²,³,⁴. ¹Albert Einstein College of Medicine and Montefiore Medical Center, Bronx, NY; ²Albert Einstein College of Medicine, Bronx, NY; ³Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY and ⁴Integrated Imaging Program, Albert Einstein College of Medicine, Bronx, NY.

Background: Breast cancer is the leading cause of cancer related-death in women[1] with over 90% of these deaths due to metastasis. In these cases, the lung is the most common anatomical site of metastasis found at autopsy[2]. For the last 100 years, the process of metastasis has been studied through the use of an experimental metastasis (EM) assay [3] consisting of tail vein injection of tumor cells into tumor-free mice, followed by histopathological analysis of the lung weeks later to gain insight into tumor cell arrival, survival, and the growth of metastases. These studies have concluded that metastasis is an inefficient process[4]. Using a new technology developed at Albert Einstein College of Medicine, called the Window for High Resolution Imaging of the Lung (WHRIL)[5], we have directly compared EM to the more clinically relevant process of tumor cells spontaneously metastasizing (SM) from a primary tumor in situ to the lung and have found significant differences in metastatic efficiency between EM and SM.

Methods: Real-time images of tumor cell dissemination were captured using the WHRIL (Figure 1) in both EM and SM models. Metastatic potential was analyzed, and compared between the models, the percentage of tumor cells surviving in the lung over time, their endothelial crossing-time, their frequency of interaction with macrophages, the fraction of cells which are dormant, and the percent of cells that developed into metastases.

Results: Tumor cells which spontaneously metastasize from primary tumors show a ten-fold higher rate of survival in the lung and three times greater efficiency in forming metastases compared to those directly injected into the lung vasculature. Most of SM tumor cells are dormant indicating that the residual disease phenotype is programmed by the primary tumor either directly in the primary site or indirectly at the secondary site.

Conclusion: These results indicate that experimental metastasis does not accurately reflect the true clinical process and that spontaneous dissemination from a primary tumor has significant influence on the survival and growth of disseminated cells. This suggests that the tumor microenvironment of the primary tumor educates disseminating tumor cells for survival, dormancy and growth at the primary site, and/or prepares the pre-metastatic niche, in the secondary site. Understanding where and how disseminated tumor cells are educated is critical to preventing their survival and growth at secondary sites. This discovery will open the door to new strategies for the treatment of metastatic tumors to prevent metastatic progression and death.
M2-like tumor-associated macrophages require Tartrate-resistant acid phosphatase as overall function to promote breast cancer metastasis

Ming-Shen Dai¹, Hao-Chan Lo¹, Li-Chia Chen¹, Anthony Janckilla¹ and Shun-Fu Tseng¹. ¹Hematology/Oncology, Tri-Service General Hospital, Taipei, Taiwan.

Tartrate-resistant acid phosphatase (TRAP) is a member of the purple acid phosphatase family and is also known as type 5 acid phosphatase. It is mainly expressed in cells of the monocyte lineage, including osteoclasts, macrophages, and dendritic cells (DCs). There are two isoforms of TRAP enzyme: TRAP-5a and TRAP5b, and TRAP-5b is produced by post-translational modification of TRAP-5a. TRAP-5b is the major isoform of TRAP secreted by osteoclasts and it has been shown that TRAP-5b activity correlates with the number of osteoclasts and serum activity in rat and human studies. In contrast, macrophages and DCs are thought to secrete TRAP-5a as the major subtype, whereas TRAP-5a is a non-specific marker of macrophage activation. The recent studies show that higher-grade proliferative tumors with much necrosis were associated with abundant macrophage expressing TRAP. Here we generate TRAP-/- knockout mice to study the function of TRAP in tumorigenesis. In vitro experiments have found that the expression of TRAP in macrophages is essential for the full promoting tumor function of M2-like tumor-associated macrophages (TAM) including tumor growth and metastasis. Marrow-derived macrophages (BMDM) extracted from the TRAP-/- mice lost promote tumor migration activity. The 4T1 tumor (murine breast cancer cell line) conditioned medium was used to induce TAM formation found M2-like TAM formation in wild type BMDM was promoted higher than that of TRAP-/- BMDM. In contrast, the TRAP-/- is much higher M1-like TAM formation than the wild type. Xenograft tumor formation assays were used to monitor tumor formation by combining 4T1 and different M2 polarized macrophages into BALB/c mice. M2-polarized macrophages with trap-defective BMDM showed reduced promoted neoplastic activity compared to wild type. In MMTV-PyMT transgenic mice, spontaneous tumor formation in knockout trap-/- significantly repressed tumor formation compared to TRAP+/+ wild type mice. Finally, we hypothesized that TRAP is essential for the full function of M2-like tumor-associated macrophages and promotes tumor metastasis.
The potential role of CTNND1 (catenin (cadherin-associated protein), Delta 1) in breast cancer bone metastasis

Chang Gong1,2, Andrew Andrew1, Yi Feng1, Sioned Owen1, Gehao Liang2, Eleri Davies3, Erwei Song2 and Wenguo Jiang1. 1Cardiff China Medical Research Collaborative, Cardiff University School of Medicine, Cardiff University, Cardiff, United Kingdom; 2Guangdong Provincial Key Laboratory of Malignant Tumor Epigenetics and Gene Regulation and Breast Tumor Center, Sun Yat-Sen Memorial Hospital, Sun Yat-Sen University, Guangzhou City, China and 3Cardiff Breast Centre, University Hospital Llandough, Cardiff and Vale University Health Board, Cardiff, United Kingdom.

Background:
The bone is a frequently visited site by breast cancer cells. Most women who die of metastatic breast cancer would already have bone metastases, whether they are micro- or macro-metastases. Metastatic bone metastasis from breast cancer is mostly osteolytic, with reasons unclear and little in vitro and in vivo studies exploring the osteolytic nature of bone metastasis. In the present study, we investigated the potential role of CTNND1, Catenin (Cadherin-Associated Protein) Delta 1, in the context of bone metastasis of breast cancer.

Materials and Methods:
In order to identify potential genes involved in bone metastasis, we established a novel in vitro model named Bone Matrix Extract (BME) which was extracted from human femur and used to mimic the bone environment. Full profile of gene expression in response to BME was conducted using Ampliseq technology. Potential genes associated with bone metastasis was examined in a clinical breast cohort containing both cancer and normal tissues (n = 103), collected immediately following surgery. Gene transcript levels were quantified using QPCR and analysed against patient's pathological information and clinical outcome. We generated a series of cell models by knocking down and over-expressing one of the most relevant genes, CTNND1, using siRNA, sh-RNA, ribozyme transgenes and insertion of full coding sequence containing plasmids. Function assays including Matrigel based-adhesion, cancer cell-osteobalstic cell contact, proliferation, transwell invasion and migration were used to investigate the changes of biological features after interfering with CTNND1 expression in relation to BME / co-culture models.

Results:
CTNND1 was down regulated in all breast epithelial cells following BME treatment at both mRNA and protein level. From the clinical cohort, we found that compared with benign tissue, breast cancer tissues had significantly decreased CTNND1 transcript expression. Reduced CTNND1 was associated with advanced TNM stage and poor distant metastasis, local recurrence and bone metastasis. We went on to knockdown CTNND1 by siRNA, ribozyme as well as lenti-shCTNND1 transfection in MCF-10A and MDA-231 cells and overexpressed CTNND1 in MCF-7 cells. In vitro study demonstrated that knockdown of CTNND1 expression led to decreased capacity of Matrigel-adhesion, migration and invasion but increased cancer cell-osteobalstic cell adhesion. No effects were observed on cell proliferation after altering CTNND1 expression, in the presence or absence of BME.

Conclusions:
In this initial study on CTNND1 in breast cancer, our current data suggests that lower transcript expression of CTNND1 associates with a poorer patient prognosis. CTNND1 reduction may play a role in the progression of breast cancer bone metastasis.
ESR1 mutations drive breast cancer metastasis by context-dependent alterations in adhesive and migratory properties

Zheqi Li\(^1\), Amir Bahreini\(^1,2\), Kevin M Levine\(^1,2\), Peilu Wang\(^3\), Nilgun Tasdemir\(^1,2\), Maritza A Montanez\(^1\), Prithu Sundd\(^1\), Callen T Wallace\(^1\), Simon C Watkins\(^1\), David Chu\(^4\), Ben H Park\(^4\), Weizhou Hou\(^1\), Meghan S Mooring\(^1\), Li Zhu\(^1\), George C Tseng\(^1\), Jason S Carroll\(^5\), Jennifer M Atkinson\(^1,2\), Adrian V Lee\(^1,2\) and Steffi Oesterreich\(^1,2\).\(^1\)University of Pittsburgh, Pittsburgh, PA; \(^2\)UPMC Hillman Cancer Center, Pittsburgh, PA; \(^3\)Tsinghua University, Pittsburgh, PA; \(^4\)Johns Hopkins University, Baltimore, MD and \(^5\)Cancer Research UK Cambridge Institute, Cambridge, United Kingdom.

Background: Estrogen receptor alpha (ER\(_\alpha/ESR1\)) is mutated in 30-40\% of endocrine resistant ER\(_+\) breast cancer. These mutations, primarily located in the ligand binding domain, are associated with worse outcome in patients, and preclinical studies have shown that they cause ligand independent growth. An open question is whether these mutations contribute to actual metastatic process, or merely endocrine resistance.

Methods: Using Y537S and D538G genome-edited MCF7 and T47D cells, 3D growth was assessed in ultralow attachment plates. Cell-cell adhesion was determined using calcein-labelled adhesion assay and quantitative microfluidic fluorescence microscope (qMFM). Collagen-based adhesion and spheroid invasion assays were used to test adhesive and invasive properties. Wound scratching, spheroid collective migration and Boyden chamber transwell assays were applied to monitor cell migratory phenotypes. Mutated ER cistromes were profiled using ChIP-sequencing. ESR1 mutations in clinical samples were characterized using ddPCR.

Results: Visual inspection of cells grown in suspension culture revealed more compressed multicellular spheroids in ESR1 mutant cells, indicative of increased cell-cell interactions. This observation was confirmed in both static and microfluidic conditions. This effect was more pronounced in MCF7 than T47D cells, correlating with increased expression of desmosome and gap junction genes. Pharmacological blockade of gap junctions decreased cell-cell adhesion. Decreased attachment and increased invasion to collagen were discerned in all mutant cell types. Further functional analysis identified alterations in the TIMP3-MMP axis causing these phenotypes. The cell-cell adhesion phenotypes were restricted to MCF7-Y537S/D538G and T47D-Y537S, whereas T47D-D538G cells showed significantly increased migration. A GSEA screen identified Wnt signaling as uniquely induced in this context, and combination treatment using the Wnt inhibitor LGK974 and Fulvestrant led to synergistic inhibition of migration. ChIP-seq identified mutation-specific cistromes with an overall increased ligand-independent ER binding. However, it did not reveal binding sites in any candidate metastases genes, suggesting secondary epigenetic mechanisms. The motif analysis revealed the enrichment of FOXA1 motifs in mutated ER cistromes except T47D-D538G cells. However, knockdown of FOXA1 induced significantly higher inhibition of T47D-D538G migration than Fulvestrant treatment alone, indicating a FOXA1-dominated mechanism. Collectively, these data show that ESR1 mutant cells gain metastatic properties, in addition to endocrine resistance. To prove this using clinical samples, we measured ESR1 mutations in a well-defined cohort of endocrine resistant local or distant recurrences. Significant enrichment of ESR1 mutations in distant (9/55) vs local (0/27) recurrences confirms critical role of mutant ER\(_\alpha\) in metastases.

Conclusion: Further analysis of context dependent changes in cell-cell adhesion and migration of ESR1 mutant cells might guide the design and development of drugs targeting ER\(_\alpha\)-mutant tumors, such as inhibitors of gap junction, FOXA1, MMP, and Wnt signaling pathways.

A peptide with the conserved amino acid residue of integrin α6 inhibits metastasis through disruption of complex formation in breast cancer cells

Junji Itou¹, Sunao Tanaka¹, Noriko Senda¹, Atsuo Iida¹, Atsuko Sehara-Fujisawa¹, Fumiaki Sato¹ and Masakazu Toi¹. ¹Kyoto University, Kyoto, Japan.

Metastasis inhibition may improve survival of breast cancer patients. Our previous study revealed that a transcription factor SALL4 promotes cell migration for metastasis through up-regulation of integrin α6β1 in metastatic basal-like breast cancer cells. In these cells, integrin α6β1 modulates Rho GTPase activity, which enhances focal adhesion dynamics for cell migration. We therefore focused on integrin α6 as a therapeutic target for metastasis. We investigated the expression level of integrin α6 in breast cancer cell lines and a tissue microarray of breast cancer patients. In both experiments, we observed higher integrin α6 expression in basal-like breast cancer cells than in luminal ones. We performed shRNA-mediated integrin α6 knockdown in basal-like breast cancer cells and conducted Boyden chamber assays. In the results, reduced cell migration was observed in integrin α6 knocked-down cells. Reciprocally, we introduced integrin α6 overexpression in low-migratory luminal breast cancer cell lines and observed increased cell migration. These results indicate that integrin α6 promotes cell migration in breast cancer cells.

To identify the functional residue of integrin α6, we analyzed its amino acid sequence by in silico analyses. First, we extracted integrin α6 specific residues in integrin α family in the human genome. Then, we compared integrin α6 sequences among vertebrates. In the result, we obtained an integrin α6-specific and vertebrate-conserved sequence, Asp-358, as a candidate for the functional residue.

To inhibit integrin α6 function, we designed an 8-amino acid peptide with the sequence around Asp-358. Basal-like breast cancer cells treated with the peptide showed reduced cell migration in a dose-dependent manner. The peptide did not reduce cell migration in integrin α6 knocked-down cells, suggesting that the peptide inhibits integrin α6 function. To determine whether the peptide inhibits metastasis, we performed zebrafish metastasis assays, and observed reduced metastasis rate in the peptide-treated group. These results indicate that the peptide inhibits metastasis through reduction in cell migration. To understand the effect of the peptide, we performed chemical cross-liking assay in a basal-like breast cancer cell line. Protein samples from the cells treated with a cross-linker showed bands of integrin α6 complexes, and the intensities of these bands were reduced in the peptide-treated group. Moreover, we immunostained cells with an antibody for focal adhesion marker, phospho-paxillin, because integrins regulates focal adhesion formation for cell migration. In the results, the peptide reduced the number of focal adhesions. These observations indicate that the peptide inhibits integrin α6 function. In the future, our findings may contribute to development of a metastasis inhibition therapy.
Detection of circulating cancer stem cells: A novel approach as a predictive marker for breast cancer metastases. This may be especially useful in patients with undetectable circulating epithelial tumor cells

Monika Pizon¹, Dorothea Schott¹, Ulrich Pachmann¹ and Katharina Pachmann¹. ¹Transfusion Center Bayreuth, Bayreuth, Germany.

**Background:** Breast cancer is one of the most common types of cancer in women worldwide. It has been demonstrated that even localized tumors without clinically apparent metastases give rise to circulating epithelial tumor cells (CETCs). Recent studies have provided strong support for the circulating cancer stem cell (cCSC) hypothesis, which suggests that a more aggressive subpopulation of circulating tumor cells are the source of metastatic spread from the primary tumor. Measuring CETCs in blood of patients has emerged as a non-invasive diagnostic procedure for screening patients who may be at high risk for developing metastatic cancers. However, accurate detection of CETCs may provide erroneous results, since CETCs undergoing EMT during metastasis are down-regulated for the expression of epithelial cell markers.

**Methods:** 26 breast cancer patients were included into the study. The determination of CETCs and cCSC was performed using maintrac® method and tumorsphere forming assay, respectively. Cell viability, surface marker expression and ALDH 1 activity of the cells in the spheres were evaluated by fluorescence scanning microscope.

**Results:** Sphere formation was observed in 80% of patients. We found that the number of tumorspheres depended on stage of disease. The number of tumorspheres increased significantly with tumor progression, especially with the presence of metastases. Tumorsphere formation was observed in all metastatic patients (median of 30 tumorspheres/100µl of blood), although only 27% of them had detectable CETCs. Analysis of surface marker expression profile showed that the cells in the spheres had typical phenotype of cancer stem cells. Sphere formation was not observed in healthy subjects (n=20).

**Conclusion:** There is a high correlation between the numbers of tumorspheres cultured from peripheral blood with clinical stage of disease. This may be an indicator of tumor aggressiveness, especially presence of metastases and may provide clinically useful prognostic information.
The splicing factor PHD finger protein 5A inhibits apoptosis to promote breast cancer progression

Yi-Zi Zheng1,2, Meng-Zhu Xue3, Hong-Jie Shen4, Xiao-Guang Li1, Ding Ma1,2, Yue Gong1,2, Xin Hu1,2 and Zhi-Ming Shao1,2. 1Key Laboratory of Breast Cancer in Shanghai, Fudan University Shanghai Cancer Center, Shanghai, China; 2Shanghai Medical College, Fudan University, Shanghai, China; 3Key Laboratory of Systems Biology, Shanghai Advanced Research Institute, Chinese Academy of Sciences, Shanghai, China and 4Epigenetics Laboratory, Institutes of Biomedical Sciences and School of Basic Medicine, Shanghai Medical College of Fudan University, Shanghai, China.

Background: All the widely accepted hallmarks of cancer are known to be affected by aberrant splicing (AS), and splicing dysregulation itself is considered a valuable therapeutic target. Understanding the AS that promote cancer progression is crucial for the development of effective strategies for treating breast cancer.

Methods: An in vivo CRISPR screen targeting RNA-binding proteins (RBPs) was performed to reveal the key splicing modulator (PHD finger protein 5A, PHF5A) of breast tumor progression. Immunohistochemistry method and survival analysis were performed using a tissue microarray (TMA) containing 450 breast carcinoma. Proliferation, transwell migration and in vivo tumor formation assays were utilized to assess the biological role of PHF5A. RNA sequencing and RT-PCR assay were used to identify PHF5A-regulated AS events in breast cancer cells. Biological functions and molecular pathways of the affected genes were investigated through a gene ontology (GO) analysis. Flow cytometry and Western blot analysis were used for apoptotic assessments. The correlation between PHF5A expression and AS events was further analysed using mRNA-Seq data of 40 paired breast cancer and adjacent normal breast tissues. And the correlation between the levels of PHF5A and cleaved caspase-3 were evaluated in the TMA.

Results: According to RNA sequencing analysis of MCF10 cell series (MCF10A, MCF10AT, MCF10DCIS and MCF10CA1a), 159 RBPs were found to be up-regulated in cancer cells compared with non-cancer cells. And the CRISPR screen targeting these 159 RBPs systematically identified highest-ranking genes including PHF5A. In TMA cohort, high PHF5A expression was correlated with poor disease-free survival. PHF5A is frequently up-regulated in breast cancer and is essential for cancer cell proliferation, migration and tumor formation. Knockdown of PHF5A induces genome-wide AS events. The RT-PCR assay of MCF10CA1a cells showed that splicing changes of nine arbitrarily selected target genes were all modulated by PHF5A. GO analysis showed that PHF5A-regulated AS events were involved in apoptotic and anti-apoptotic pathways, among which FAS-activated serine/threonine kinase (FASTK) AS showed significant PSI (percent spliced in) difference. PHF5A knockdown appeared to switch full-length FASTK (FASTK-L) to an intron 5-retained variant (herein termed FASTK short, FASTK-S) in MCF10CA1a cells. The knockdown of PHF5A resulted in cleavage of caspase-3 and poly-ADP-ribose polymerase and conversion of the FASTK-L (61 kDa) and FASTK-S (42 kDa) proteins. Intriguingly, cells transduced with exogenous FASTK-S showed the most significant apoptotic effect, whereas the FASTK-L group presented a decreased apoptotic effect. The PHF5A ratios of paired non-tumor to tumor tissue were negatively correlated with the FASTK PSI differences between non-tumor and tumor tissues. A strong negative correlation was found between the PHF5A and cleaved caspase-3 levels in TMA.

Conclusions: PHF5A depletion sensitizes cancer cells to apoptotic signaling partially through AS-mediated FASTK isoform conversion. This apoptotic suppressor plays a key role in breast cancer progression and acts as a prognostic indicator, and should be critically considered for optimization of the current therapeutic strategy.
Adipocytes and cancer cell interactions promote leptin receptor expression and drive β-catenin-mediated progression in triple negative breast cancer

Zhe Feng¹, Zhonghua Tao¹ and Xichun Hu¹. 'Fudan University Shanghai Cancer Center, Shanghai, China.

Background Triple negative breast cancer (TNBC) patients suffer from poor prognosis due to short-term recurrence and/or metastasis. Obesity is reported to predict poor prognosis of TNBC. However, the mechanisms connecting obesity to progression of TNBC remain unclarified.

Methods We co-cultured TNBC model cells with adipocytes differentiated from human adipose-derived mesenchymal stem cells (hMSC-ad) and TNBC patients derived primary adipocytes to examine migration, invasion and metastasis abilities using Transwell assays and tail vein injection xenograft mouse model, respectively. Expression levels of leptin receptor (LEPR), epithelial-mesenchymal transition (EMT) markers and β-catenin signaling pathway related molecules in the control and co-cultured TNBC model were analyzed by real time quantitative polymerase chain reaction (RT-qPCR) and western blot assays. Downregulation of LEPR by LEPR specific short hairpin RNA (shRNA) and upregulation of the downstream pathway with continuous activated β-catenin were applied to access their roles in adipocytes and cancer cell interactions. Degree of adipocytes infiltration in tumor tissue was evaluated by histopathology. LEPR mRNA expression level in breast cancer and corresponding patients' information was retrieved from The Cancer Genome Atlas (TCGA) database.

Results Here we first reported that both hMSC-ad- and patients-derived adipocytes promoted migration and invasion of TNBC model cells in vitro and lung metastasis in vivo. Adipocytes were then confirmed to induce upregulation of LEPR in each TNBC model cell compared to the control groups (p<0.0001), resulting in higher expression of EMT markers and molecules related to β-catenin signaling pathway. Afterwards, LEPR knockdown led to decreased migration, invasion and metastasis capacities, as well as reduced expression of EMT markers and molecules related to β-catenin signaling pathway, while activation of β-catenin could restore robust EMT and metastatic abilities of TNBC model cells. Last, clinical specimen analyses showed that infiltration of adipocytes to tumor tissue was significantly associated with shorter DFS of TNBC patients (p<0.05) and upregulated LEPR in breast cancer tissue indicated poor prognosis (median OS of 7.43 vs 10.81 years of the LEPR-low group, p < 0.05).

Conclusions To our knowledge, adipocytes are first shown to promote progression of TNBC via previously uncharacterized LEPR-β-catenin signaling pathway.
Inflammatory breast cancer cells are characterized by attenuated SMAD dependent TGFβ signaling leading to impaired cell motility responses

Charlotte Rypens1,2, Christophe Van Berckelaer1,2, Charlotte Billet2, Jan Hauspy2, Francois Bertucci3, Vermeulen Peter1,2, Luc Dirix1 and Steven Van Laere1,2. 1University of Antwerp, Wilrijk, Belgium; 2GZA Hospitals Sint-Augustinus, Wilrijk, Belgium and 3Institut Paoli-Calmettes, Marseille, France.

Introduction. Inflammatory breast cancer (IBC) is an aggressive form of locally advanced breast cancer with elevated metastatic potential, characterized by the frequent presence of tumor emboli in dermal and parenchymal lymph vessels. In the past, evidence was provided that TGFβ signaling is part of the molecular biology of this disease. In this study, this relation was further examined.

Materials and methods. TGFβ1 induced cell motility (i.e. XCELLigence, wound healing assays), gene expression (RNA-sequencing) and peptide phosphorylation (i.e. PAMGene technology) patterns were investigated in a panel of 3 IBC and 3 subtype-matched nIBC cell lines. In addition, a series of tissue samples from 75 and 135 patients with and without IBC was investigated for nuclear expression of total SMAD2, SMAD3 and SMAD4 using immunohistochemistry. Finally, SMAD protein expression data were related to gene expression data from patients with available Affymetrix HGU133plus2 profiles.

Results. The cell motility inducing capacity of TGFβ1 was strongly abrogated in all IBC cells independent of their molecular subtype (P=0.003). Genes differentially expressed between IBC and nIBC cells post 4 hours of TGFβ1 revealed attenuated expression of SMAD3 transcriptional regulators with concomitant overexpression of MYC target genes in IBC. Assessment of SMAD expression in patient samples demonstrated a near absence of nuclear SMAD3 expression in the primary tumors from patients with IBC (P<0.001) and a further reduction of SMAD3 staining intensity was observed in tumor emboli (P=0.019). Integrated analysis of gene and protein expression data revealed that a substantial fraction of the IBC signature genes correlated with SMAD3 and these genes (i.e. 21/24; P<0.001) carry evidence in favor of attenuated SMAD3 signaling in IBC.

Discussion. It is demonstrated that IBC cells are characterized by attenuated SMAD3 protein expression and transcriptional activity that obliterates the cell motility inducing capacity of TGFβ1. Recent studies revealed that SMAD3 is essential for TGFβ1 induced cell motility through induction of epithelial to mesenchymal transition (EMT). In the absence of SMAD3 expression, a partial EMT is induced leading to collectively invading cancer cells that are gifted with a high metastatic potential and favor lymphatic dissemination, thereby providing an intriguing explanatory model of the biology of tumor emboli in IBC.
CRISPR-Cas9 screen identifies TMEM106A as a suppressor of breast cancer metastasis

Liu Yang¹, San-Jian Yu¹ and Zhi-Ming Shao¹. ¹Fudan University Shanghai Cancer Center, Shanghai, China.

目的: 乳腺癌是女性中最常见的恶性肿瘤之一。大多数癌症相关的死亡是由于转移引起的。许多生物学变化在这一复杂过程中发生,包括上皮-间质转换 (EMT), 免疫逃逸, 穿血管迁移 (TEM)。然而, 转移性疾病的生物学机制尚未完全理解, 需要更多工作来统一对乳腺癌转移背后的理解。

方法: 我们使用 CRISPR-Cas9 基因组规模 CRISPR 突变体 (GeCKO) 库进行功能筛选, 以识别乳腺癌转移相关的基因。我们通过转孔试验确认了一组基因的功能, 以证实体外筛选的有效性。此外, 我们进行了体内外试验来探索 TMEM106A 在抑制乳腺癌转移中的机制。

结果: CRISPR-Cas9 库筛选识别出具有抑制乳腺癌转移潜能的基因。进一步验证 COPS2、SSBP2、TDG、DYRK4、GSG1、TMEM106A 和 PRR5L 表明, 这些基因的敲低促进了细胞迁移和侵袭能力。在 MDA-MB-231 和 MDA-MB-468 细胞中, TMEM106A 的敲低促进了体外迁移、侵袭、愈合和体内促转移能力。此外, E-cadherin 下调和 N-cadherin 上调与 TMEM106A 的抑制作用相关。相应地, 当在 MDA-MB-231 和 MDA-MB-468 细胞中过表达 TMEM106A 时, 促转移效应被逆转。我们发现 TMEM106A 和 WDR77 之间的相互作用通过 Co-IP 和 MS 分析。TMEM106A 敲低促进了 WDR77 的表达, 这主要发生在细胞质中。为了验证 TMEM106A 和 WDR77 之间的关联, 我们干扰了 WDR77 在 MDA-MB-231 sg-TMEM106A 中的表达, 并证明了 TMEM106A 敲低的促转移效应被逆转。

讨论: CRISPR-Cas9 库筛选是识别与乳腺癌转移相关的基因的有效策略。正向选择提供了具有抑制细胞迁移和侵袭潜能的基因集合。TMEM106A 可能通过影响 WDR77 位点的转移来抑制乳腺癌转移。
Epigenetic and transcriptomic profiling of mammary gland development and tumor models disclose regulators of cell state plasticity

Christopher P Dravis¹, Chi-Yeh Chung¹ and Geoffrey M Wahl¹. ¹Salk Institute for Biological Studies, La Jolla, CA.

Cell state reprogramming during tumor progression contributes to the intra-tumoral cellular heterogeneity that complicates accurate diagnosis, compromises therapeutic effectiveness, and fuels metastatic dissemination. As cancer is a caricature of normal development, we used chromatin accessibility assays and transcriptional profiling to analyze epigenetic changes that occur during mammary development as an agnostic approach to identify candidate cell state regulators that could also be involved in cancer cell state interconversions. We show that fetal and adult basal cells share epigenetic features consistent with multi-lineage differentiation potential. We find that DNA-binding motifs for SOX family transcription factors are uniquely enriched in chromatin regions that are accessible in stem/progenitor cells and inaccessible in differentiated cells. In both mouse tumor models and human tumor samples, levels of Sox10 expression are heterogeneous and correlate with stem/progenitor identity, de-differentiation, and invasive characteristics. Strikingly, we demonstrate that SOX10 binds to genes that regulate neural crest cell identity, and that SOX10-positive tumor cells uniquely exhibit neural crest cell features.
Sphingosine-1-phosphate affects tumor-associated macrophages in breast cancer patients

Junko Tsuchida1, Masayuki Nagahashi1, Kazuki Moro1, Mayuko Ikarashi1, Yu Koyama1, Jun Sakata1, Takashi Kobayashi1, Hitoshi Kameyama1, Qianya Qi3, Li Yan3, Kazuaki Takabe2,4 and Toshifumi Wakai1. 1Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan; 2Breast Surgery, Roswell Park Cancer Institute, Buffalo, NY; 3Roswell Park Cancer Institute, Buffalo, NY and 4University at Buffalo Jacobs School of Medicine and Biomedical Sciences, the State University of New York, Buffalo, NY.

Background: Tumor-associated macrophages (TAMs) are considered to be one of the key players in the tumor microenvironment, which regulates cancer invasion and metastases. TAMs can be divided into two phenotypes with opposite functions. While M1 macrophages are known to exert anti-tumor activity by promoting pro-inflammatory effects and immune responses such as interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α), M2 macrophages influence an anti-inflammatory response, wound healing, and pro-tumorigenic properties. A bioactive lipid mediator, sphingosine-1-phosphate (S1P) has emerged as a key regulatory molecule in cancer progression. We previously demonstrated that S1P generated by sphingosine kinase 1 (SPHK1), is a crucial mediator of breast cancer-induced angiogenesis and lymphangiogenesis, and promotes its metastasis. In particular, we found that SPHK1 is highly expressed in HER2 negative breast cancer, and the patients who developed lymph node metastasis demonstrated significantly higher levels of S1P (J Surg Res 2016). Although we have previously reported the role of S1P in recruitment of TAMs in vivo (Cancer Res 2018), its relevance in patients is yet to be uncovered. Here, we test our hypothesis that S1P signaling affects TAMs in human patients with breast cancer.

Materials and Methods: The expression level of each enzyme-encoding gene involved in S1P production was evaluated by retrieving RNA sequencing and gene expression quantification data using the Genomics Data Commons (GDC) data portal of the The Cancer Genome Atlas cohort. Gene expression levels were derived using normalization methods provided in the DESeq2 package. We compared the difference in expression levels of tumor associated macrophage related genes, including CD68, CD163, IL-6, andTNF-α between SPHK1-high breast tissue, and SPHK1-low breast tissue in the group of HER2 negative or positive patients. Unpaired t-tests were performed to compare expression differences between SPHK1-high and SPHK1-low breast tissue. All tests were two-sided and P values < 0.05 were considered statistically significant.

Results: CD68, pan-macrophage marker, is significantly increased in SPHK1-high breast cancer tissues both in HER2 negative and positive breast cancer patients (p<0.001, <0.01). CD163 which is a scavenger receptor that is regarded as highly specific for M2 macrophages is significantly increased in SPHK1-high breast cancer tissues in HER2 negative breast cancer patients, but not in HER2 positive breast cancer patients (p<0.001, 0.2). IL-6, which characterize M1 phenotype is significantly increased in SPHK1-high breast cancer tissues both in HER2 negative and positive breast cancer patients (p<0.001, <0.001). TNF-α, which also characterizes M1 phenotype, is significantly increased in SPHK1-high breast cancer tissues in HER2 negative breast cancer patients, but not in HER2 positive breast cancer patients (p<0.001, 0.05).

Conclusion: Our results suggest that S1P affects TAMs in breast cancer patients, which implicate the important roles of S1P in the complicated immune system related to tumor progression. Our results also indicate that S1P have a large role in HER2 negative breast cancer patients. Further investigations are needed to understand the underlying mechanisms.
LAP2alpha, a novel tumor marker candidate is related to metastasis of breast cancer

Yue Hu¹, Jili Qiu¹, Meiqi Zhou¹, Xiaofen Li² and Yanqin Huang². ¹The Second Affiliated Hospital of Zhejiang University, School of Medicine, Hangzhou, Zhejiang, China and ²Cancer Institute, the Second Affiliated Hospital of Zhejiang University, School of Medicine, Hangzhou, Zhejiang, China.

Background: To date, there is no suitable serum marker for diagnosis and prognosis of breast cancer. In our early research, a new tumor marker candidate of breast cancer whose molecular weight was 5.6 kDa was screened from serum using mass spectrometry technology. It was decoded to be a fragment of isoform alpha of lamina-associated polypeptide 2 (LAP2α). The survival analysis revealed that LAP2α was over-expressed in breast cancer patients and indicated poor prognosis.

Materials and Methods: Immunohistochemistry (IHC) was utilized to evaluate LAP2α expression in paired primary breast tumor, metastasis of axillary lymph node and ipsilateral normal breast tissue of 29 breast cancer patients. An inhibition plasmid vector of LAP2α-small hairpin RNA (LAP2α-shRNA) was constructed and transfected into MCF-7 cells. The abilities of cell proliferation and metastasis were assessed both in vitro and in vivo. The association of LAP2α with epithelial-to-mesenchymal transition (EMT) was determined by western blot.

Results: LAP2α expression of paired tissue descended in order of metastasis of axillary lymph node (21/29, 72.4%), primary breast tumor (11/29, 37.9%) and ipsilateral normal breast tissue (4/29, 13.8%) (P<0.05 in comparisons between each two groups). CCK-8 experiments on transfected and control cells showed that inhibition of LAP2α could not influence cell proliferation. Transwell and matrigel-transwell assays indicated that inhibition of LAP2α could significantly reduce cell migration and invasion abilities. In vivo experiments utilizing subcutaneous xenograft model and tail vein-injection mouse model revealed that the down-regulation of LAP2α might suppress tumorigenesis and metastasis of breast cancer. Western blot suggested that down regulation of LAP2α increased the E-cadherin expression level but repressed N-cadherin and vimentin expression levels.

Conclusions: A novel tumor marker candidate, LAP2α is related to metastasis of breast cancer both in clinical samples and tissue culture experiments. Inhibition of LAP2α could suppress aggressiveness and metastasis of breast cancer probably via EMT suppression.

Re-activation of mutant p53 with APR-246 suppresses stem-cell like properties and lung metastasis of triple-negative breast cancer cells

Salman M Hyder¹, Matthew T Cook² and Yayun Liang¹. ¹University of Missouri, Columbia, MO and ²Washburn University, Topeka, KS.

Triple-negative breast cancers (TNBC) lack ER, PR and Her2neu, proteins that are commonly targeted in breast cancer therapies. As a consequence, women who suffer from TNBC have poor prognosis and few treatment options and are usually administered toxic, non-specific chemotherapeutic agents. New therapeutic strategies are therefore urgently needed. TNBCs generally express mutant forms of tumor suppressor p53 protein (mtp53). Wild-type p53 (wtp53) induces apoptosis, restricts cell-cycle progression, and prevents metastasis, which is the major cause of death in patients afflicted with TNBC. Conversely, mtp53 lacks these properties and therefore cannot prevent the unfettered spread of metastatic TNBC. APR-246 is a recently developed small-molecule drug that reactivates mtp53 by covalently modifying the DNA-binding core domain thereby restoring wild-type conformation and function. Restoration of wtp53 renews its ability to promote apoptosis of tumor cells; however, the capacity of APR-246 to control metastasis is not known. With this in mind we conducted studies to determine whether APR-246 suppresses metastasis of TNBC to lungs. Using a well-developed lung metastasis model (MDA-MB-435 TNBC cells), we showed that low concentrations (1-5 mM) APR-246 suppress both ALDH activity and mammosphere formation \textit{in vitro}. Thus APR-246 suppressed characteristics associated with stem-like cells and metastasis. For \textit{in vivo} studies, female nude mice (n = 10-11/group) were injected with MDA-MB-435 cells. After 5 days APR-246 administration commenced with 100 mg/kg APR-246 every other day (11 treatments), followed by twice a week for a further 8 treatments. Compared with mice receiving no treatment, those given APR-246 exhibited a reduction in the number of metastatic colonies/lung from 24 ± 4 to 4 ± 1; P < 0.05. Our data suggests that APR-246 suppresses the formation of metastatic colonies in lungs by possibly inducing apoptosis and reducing cell cycle progression of cells lodged in the lungs, thereby preventing their expansion. No animals exhibited weight loss, indicating that APR-246 did not cause drug-induced toxicity during treatment. Using a different TNBC cell line, MDA-MB-231 we showed that APR-246 suppressed cellular migration. APR-246 also suppressed lung metastasis of MDA-MB-231 (4175) LM2, an aggressive subpopulation of clinically relevant cells (kindly provided by Dr. J. Massagué; Minn et al. Nature. 2005, 436:518-24) derived from MDA-MB-231 cells, that metastasizes to lungs efficiently. Overall these data suggest that APR-246 inhibits the growth of metastatic TNBC colonies in lungs. Its ability to also suppress the initial process of metastasis, including invasion and survival in the circulation, remains to be tested. These studies demonstrate that the use of APR-246 deserves further investigation as a treatment option for women suffering from metastatic TNBC.

Supported by a peer-reviewed COR award from the College of Veterinary Medicine, University of Missouri.
KLF4 improve prognosis of triple negative breast cancer by suppression of epithelial mesenchymal transition

Takuya Nagata¹, Shinichi Sekine¹, Mie Arai¹ and Tsutomu Fujii¹. ¹University of Toyama, Toyama, Japan.

Background
Triple negative breast cancer (TNBC) is highly malignant and prone to metastasis and relapse, and therefore has poorer prognosis than other sub-types. The mechanism of higher malignancy of TNBC has not been sufficiently elucidated. KLF4 is reported to be a transcription factor that is associated with both tumor suppression and oncogenesis. We have reported that breast cancer patients with strong expression of KLF4 had better prognosis, especially in TNBC patients. And here we report that KLF4 negatively regulates the metastasis and growth of TNBC.

Methods
We assessed the expression levels of KLF4 in 84 patients with TNBC by immunohistochemical staining and studied the patterns of metastasis/recurrence clinicopathologically. The overall survival (OS) rate and the disease free survival (DFS) rate after surgery was calculated by Kaplan-Maier method. In addition, circulating tumor cells (CTCs) in the peripheral blood of TNBC patients were identified and compared with primary lesions in terms of KLF4 expression. Moreover, the expression of KLF4 was inhibited by transfecting cultured TNBC cells (MDA-MB231) with the small interfering RNA (siRNA) of KLF4 to analyze the effects of KLF4 on cell proliferation and epithelial-mesenchymal transition (EMT)-like changes. For the proliferation assay, measurements were made by MTT assays. Cell migration and invasion assays of KLF4 suppressed TNBC cells were also examined. Total RNA was extracted from these cells, cDNA was synthesized, and used for the quantitative polymerase chain reaction (qPCR) analysis.

Results
In the 84 TNBC patients, higher KLF4 expression was associated with significantly better OS and DFS. An analysis of KLF4 expression in CTCs of the TNBC patients showed that KLF4 expression was lower in CTCs than in primary cancer lesions. TNBC cells (MDA-MB231) that were transfected the KLF4 siRNA exhibited a greater ability to growth than controls. These cells also underwent EMT-like changes with reduced expression of epithelial factors such as E-cadherin. Treating these TNBC cells with eribulin resulted a reduction of the expression of stem cell/EMT markers.

Conclusion
TNBC patients with reduced KLF4 expression had poor outcomes. The results of our experiments suggest the expression of KLF4 is one of the important factors that inhibit the EMT and growth of TNBC.
The role of DCC in inhibiting tumor progression in breast cancer

Wanying Xing¹, Qiang Li¹, Rangjuan Cao¹, Guang Sun¹ and Chengwei Jiang¹. ¹China-Japan Union Hospital of Jilin University, Changchun, Jilin, China.

Background
Although benefiting from early diagnosis technology the prognosis of breast cancer has been improved significantly, metastasis and recurrence are now still the leading causes for cancer-related death in breast cancer worldwide. Genes, which have been proved to promote breast cancer metastasis proliferation, include ERBB2 (alias HER2, NEU), CTNNB1, KRAS, PI3KCA (alias PI3K), EGFR, MYC, TWIST1, SNAI1 (alias SNAIL), SNAI2, MET, and ID1. Thus, by studying and interfering the pathway transduced by these factors, we might find a method to intervene the tumor from progressing. DCC (deleted colorectal carcinoma) has been implied in many studies that it could play an important role in tumorgenesis. The aim of this study was to evaluate the expression level of DCC in both breast cancer tissues and cell lines. Then we discussed the clinical significance of DCC in predicting prognosis of breast cancer and the mechanism of DCC in modulating migration, invasiveness and metastasis.

Materials and Methods
By real-time PCR and Western Blot test, we compared the expression level of DCC in MCF-10A, MCF-7, BT-549 and MDA-MB-231 cells, and by using immunohistochemistry staining and real-time PCR we compared the expression of DCC in breast cancer tissues with its matched non-cancerous tissues. Then we associated the expression of DCC mRNA with clinicopathological parameters, such as tumor size, number lymph node, vascular invasion status, breast cancer subtype, TNM stage, and biomarker (ER, PR, HER-2, and Ki67). After that, we up-regulated DCC expression with pcDNA3.1-eGFP-DCC in MDA-MB-231 cells and used Boyden Chamber assay to study migration and invasive changes. Finally, we detected the mRNA level of a series of Matrix metalloproteinase (MMP) family members related to cell migration and invasiveness by real-time PCR.

Results
A total of 58 cases of primary breast cancers were collected by the Department of Breast Surgery of China-Japan Union Hospital of Jilin University in Jilin province of China from July 2013 to September 2014. None of these patients received preoperative chemo-, radiation-, or endocrine therapy. The mean age of these cases was 49.3 years. We observed that the expression level of DCC mRNA was lower in breast cancers while compared with that in matched non-cancerous tissue(P<0.05). And the level of DCC was even lower in breast cancers tissues and cells with more potential to metastasis (P<0.05). By Boyden chamber assay we observed that migration and invasion were decreased in MDA-MB-231 cells after DCC expression being up-regulated (P<0.05). The expression level of migration and invasion related genes MMP-1 and MMP-9 decreased obviously (P<0.05), while MMP-2, MMP-3, MMP-7 was not affected obviously. TIMP1 was up regulated obviously, while TIMP2 was not affected obviously (P<0.05).

Conclusion
The level of DCC expression went down in high metastasis potential breast cancers in both cell lines and pathological tissues. Up-regulating expression of DCC would inhibit migration and invasion of breast cancer cells by modulating expression of MMP-1 and MMP-9 and TIMP1.
Sulindac and triple negative breast cancer progression

Yaguang Xi, Bin Yi and Adam Riker. 'LSU Health Sciences Center, New Orleans, LA.

In 2018, a total of 266,120 new cases and 40,920 deaths from breast cancer in the United States were estimated by the American Cancer Society. Breast cancer is the most common malignancy and the second leading cause of death among American women. In this study, we will focus on triple negative breast cancer (TNBC), which is viewed by oncologists as a problematic and unpredictable sub-category of breast cancer because of higher rates of recurrence and poorer prognosis. TNBC accounts for up to 20% of all breast cancers and is highly prevalent in minority and young women. On average, 70% of women with metastatic TNBC die within 5 years, regardless of chemotherapy or other treatments. As such, there is an urgent medical need to develop more effective drugs to manage this deadly disease that already raised a health disparity concern, especially in the State of Louisiana. Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used drugs for the treatment of pain, fever, and inflammation. Epidemiological studies have reported that the long term use of NSAIDs can prevent the occurrence multiple types of cancers, including breast cancer. However, their long term use for chemoprevention is not recommended because of toxicities associated with cyclooxygenase (COX) inhibition and the suppression of physiologically important prostaglandins. Our results show that the NSAID, sulindac sulfide (SS) and its non-COX inhibitory derivatives, can significantly inhibit the growth of the major subtypes of TNBC cells (basal-like, mesenchymal, and luminal). In addition, the compounds significantly inhibit tumor cell invasion. The animal experiments using Patient Derived Xenograft models supported the in vivo efficacy of these drugs. While studying the mechanism, we found that four oncogenic miRNAs, miR-10b, miR-17, miR-21, and miR-9 can be downregulated by SS and derivatives, and they were reported to promote tumor metastasis exclusively. Therefore, we conclude that those oncogenic miRNAs are involved in anti-metastatic activities of SS and its new non-COX inhibitory derivatives in TNBC.
The role of neogenin in inhibiting migration, invasion and metastasis of breast cancer

Wanying Xing, Qiang Li, Rangjuan Cao, Guang Sun and Chengwei Jiang. "China-Japan Union Hospital of Jilin University, Changchun, Jilin, China.

Background
Metastasis and recurrence are the main leading causes of cancer-related death in breast cancer worldwide, and migration of malignant cell is the basis of invasion and metastasis. Therefore, modulating the factors which have function in the pathway of migration, invasion and metastasis will help to control progression procedure. Neogenin is a multifunctional transmembrane glycoprotein, which could modulate cell migration while binding to its ligands and deliver signals into cells. Our previous study had proved that the expression level of Neogenin was lower in breast cancer tissues while compared with their matched adjacent non-cancerous tissues, and the expression of Neogenin was correlated to the pathological grade of breast cancer. So in this study, we evaluated the role of Neogenin in migration, invasion and metastasis in breast cancer.

Materials and Methods
MCF-10A, MCF-7, BT-549 and MDA-MB-231 cell lines were obtained from China Cell Line Bank. A total of 78 specimens were collected from females, aged 26–70 years, who underwent modified radical mastectomy at the China-Japan Union Hospital of Jilin University between June 2015 and February 2016. None of these patients received preoperative therapy. This study was approved by The Ethics Committee of Jilin University and all patients provided informed consent. Tissue specimens were collected during the surgery, snap-frozen in liquid nitrogen, and stored at −80°C. We compared the expression of Neogenin in 78 cases of breast cancer tissues with different lymph node metastasis status and with different expression of E-cadherin by using immunohistochemistry staining and western blot. We compared the expression level of Neogenin in MCF-10A, MCF-7, BT-549 and MDA-MB-231 cells by real-time PCR and western blot. Neogenin mRNA was transfected into MDA-MB-231 cells by using pcDNA3.1-eGFP-Neogenin, and after up-regulating Neogenin expression we detected migration and invasiveness changes of MDA-MB-231 cells by scratch wound model and Boyden chamber assay.

Results
The level of Neogenin was lower in breast cancer tissue with lymph node metastasis (P<0.05) or with E-cadherin expression positive (P<0.05). There was still a negatively correlation trend among three groups with different numbers of metastasis lymph node (P=0.07). Comparing with MCF-7, BT-549 and MDA-MB-231 cells the expression level of Neogenin was significantly higher in MCF-10A cells (P<0.05). The expression of Neogenin in MCF-7, BT-549 and MDA-MB-231 cells showed negatively correlated to the invasive potentiality of cells. By scratch wound model and Boyden chamber assay we observed that migration and invasion were inhibited in MDA-MB-231 cells after Neogenin expression up-regulated.

Conclusion
In this study we observed that the level of Neogenin expression went down in high metastasis potential breast cancers in both cell lines and pathological tissues. Neogenin plays an important role in migration, invasiveness and metastasis breast cancer. Up-regulating expression of Neogenin would inhibit migration and invasion potentiality of breast cancer cells.
Inhibition of creatine kinase metabolism represses invasion and sensitizes estrogen-receptor negative breast cancer cells to standard chemotherapies

Hilaire P Barch, Raisa Krutilina, Danielle L Brooks, Deanna Parke and Tiffany N Seagroves. 'The University of Tennessee Health Science Center, Memphis, TN.

Dysregulated tumor cell metabolism is a hallmark of cancer progression and therapeutic resistance. In a screen for Hypoxia-Inducible Factor (HIF)-dependent genes regulating metabolism, we identified creatine kinase, brain isoform (CKB) as down-regulated in HIF-1 knockout mammary tumor cells. CKB is a member of a family of cytosolic and mitochondrial creatine kinases (CKs) that reversibly catalyze the transfer of a high-energy phosphoryl group from ATP to creatine, generating local stores of phosphocreatine in the forward reaction, and re-generating ATP in the reverse reaction. Creatine kinases are up-regulated in a variety of solid tumors, including breast cancers. CK activity is inhibited by cyclocreatine (cCr), a creatine kinase substrate that represses the CK-dependent generation of ATP from phosphocreatine >170-fold. Knockdown of CKB in tumor cells derived from the polyoma middle T (PyMT) transgenic model of metastatic breast cancer did not impair cell proliferation or wound healing, but potently suppressed invasion in vitro, suggesting utility for treating stage IV disease. When female FVB/Nj mice were injected with wild type PyMT cells in a tail vein assay and then treated with cCr, lung metastasis was repressed to the same extent as CKB gene knockdown. These data were validated using a variety of human estrogen receptor (ER)-negative breast cancer cell lines. CKB loss- and gain-of-function models were created and effects on cell proliferation, survival, wound healing and ATP production were compared to cCr treatment. Overall, whereas deletion of CKB had no effect on cell proliferation or survival in either adherent or suspension conditions, either deletion of CKB or cCr therapy potently reduced intracellular ATP levels, which was associated with reduced invasive potential. In contrast, over-expression of CKB enhanced chemotaxis to EGF and invasion towards serum. Whereas cCr monotherapy is generally cytostatic, combination with either doxorubicin or paclitaxel is synergistic to kill tumor cells. Together, these data suggest that inhibition of CK activity may be effective in treating stage IV breast cancer patients with established metastatic disease. We are currently exploring the cell signaling and cell survival pathways that are altered by CKB gene deletion or cCr treatment to understand how the creatine kinase arm of metabolism promotes tumor progression, metastasis and response to conventional chemotherapies.
The receptor tyrosine kinase EphA2 promotes glutamine metabolism in tumors by activating the transcriptional coactivators YAP and TAZ

Deanna N Edwards¹, Verra M Ngwa², Shan Wang¹, Eileen Shiuan², Dana M Brantley-Sieders¹, Laura C Kim², Albert B Reynolds² and Jin Chen¹,². ¹Vanderbilt University Medical Center, Nashville, TN and ²Vanderbilt University, Nashville, TN.

Malignant tumors reprogram cellular metabolism to support cancer cell proliferation and survival. Although most cancers depend on a high rate of aerobic glycolysis, many cancer cells also display addiction to glutamine. Glutamine transporters and glutaminase activity are critical for glutamine metabolism in tumor cells, and upstream regulatory signaling pathways may represent a novel mechanism for targeted therapies in glutamine-addicted breast tumors such as Her2-overexpressing and triple-negative breast cancers (TNBC). We have found that the receptor tyrosine kinase EphA2 activated the transcriptional coactivators YAP and TAZ (YAP/TAZ), likely in a ligand-independent manner, to promote glutamine metabolism in cells and mouse models of breast cancer. Overexpression of EphA2 induced the nuclear accumulation of YAP and TAZ and increased the expression of YAP/TAZ target genes. Inhibition of the GTPase Rho or the kinase ROCK abolished EphA2-dependent YAP/TAZ nuclear localization. Silencing YAP or TAZ reduced the amount of intracellular glutamate through decreased expression of SLC1A5 and GLS, respectively, genes that encode proteins that promote glutamine uptake and metabolism. The regulatory DNA elements of both SLC1A5 and GLS contain the consensus sequence of the TEAD family of transcription factors that are closely associated with YAP/TAZ and were bound by TEAD4 in an EphA2-dependent manner. In patient breast cancer tissues, EphA2 expression positively correlated with that of YAP and TAZ, as well as that of GLS and SLC1A5. Although high expression of EphA2 predicted enhanced metastatic potential and poor patient survival, it also rendered breast cancer cells more sensitive to glutaminase inhibition. The findings define a previously unknown mechanism of EphA2-mediated glutaminolysis through YAP/TAZ activation in breast cancer and identify potential therapeutic targets in patients.
FASN inhibition as a potential treatment for therapy of endocrine resistant breast cancer

Aleksandra Gruslova¹, Gangadhara R Sareddy², Ratna K Vadlamudi², Suryavathi Viswanadhapalli² and Andrew Brenner¹. ¹Mays Cancer Center at UT Health San Antonio MD Anderson, San Antonio, TX and ²University of Texas Health at San Antonio, San Antonio, TX.

INTRODUCTION: Fatty acid synthase (FASN) is a key enzyme in tumor cell biology controlling endogenous lipid biosynthesis. It is overexpressed in a biologically aggressive subset of tumors, including breast carcinoma. We previously reported prolonged stabilization of disease with TVB-2640 in patients with advanced metastatic breast cancer, including some endocrine resistant ER+ tumors. Using in vitro and in vivo models, we assessed the role of FASN inhibition by TVB-3166 (preclinical version of TVB-2640) for treatment of endocrine resistant breast cancer. METHODS: Breast tumor cells were incubated with TVB-3166 (200nM), imaged and analyzed by automated Live-Cell analysis system (IncuCyte). For tumor growth inhibition, cells (2X10⁶) were subcutaneously injected into SCID mice implanted with estrogen pellets. Once tumors were measurable, mice were divided into treatment groups: tamoxifen (4mg/kg), TVB-3166 (60mg/kg) and the combination. Patient tumor explants were incubated for 72h on gelatin sponges in culture medium in the absence or presence of 200nM TVB-3166. Tissue were fixed in 10% formalin and processed into paraffin blocks. Sections were stained with H&E, ERα and Ki67. RESULTS: The effectiveness of FASN inhibition on the growth of tumor cells has been confirmed in a number of breast cancer cell lines such as MCF7, ZR75, MDA-MB-231 and others. TVB-3166 leads to a marked inhibition of growth in tamoxifen resistant (TamR) cells, which 15% greater than in the parent line. IHC and Western blot showed FASN inhibition leads to significantly reduction of ERα levels. Immunofluorescent confocal microscopy showed inhibition of FASN by TVB-3166 alters subcellular localization of ERα. TVB-3166 was able to significantly inhibit tamoxifen resistant breast tumor growth in mice (p<0.05). Additionally, TVB-3166 treatment of primary tumor explants decreased their proliferation (Ki67) compared to untreated controls (21% vs 38%, p<0.01). CONCLUSION: Our preclinical data provide evidence that FASN inhibition by TVB-3166 presents a promising therapeutic strategy for treating of endocrine resistant breast cancer. RNA sequencing of tumor explants is being performed to evaluate FASN inhibition impact on canonical and non-canonical ERα signaling pathways.
CD73 expression regulated by estrogen signaling associates with poor prognosis in estrogen receptor (ER)-positive breast cancer

Eriko Katsuta\textsuperscript{1}, Vivek Anand\textsuperscript{1}, Li Yan\textsuperscript{1}, Subhamoy Dasgupta\textsuperscript{1} and Kazuaki Takabe\textsuperscript{1}. \textsuperscript{1}Roswell Park Comprehensive Cancer Center, Buffalo, NY.

Introduction: CD73, a cell surface enzyme, catalyzes the generation of adenosine from ATP and ADP in the tumor microenvironment along with CD39. Accumulated extracellular adenosine functions as immune-suppressor, and also binds to adenosine receptors which promotes angiogenesis and cell proliferation that results in accelerate cancer progression. However, the clinical significance and molecular function of CD73 expression in breast cancer remains unclear.

Methods: Utilizing publicly available breast cancer cohorts of The Cancer Genome Atlas (TCGA) and Gene Expression Omnibus (GEO), clinical significance as well as underlying mechanisms were investigated. Molecular experiments were carried out in MCF7 cells, ER-positive breast cancer cell line, to investigate the role of estrogen signaling on CD73/CD39 expression.

Results: In treatment naïve TCGA cohort, CD73 expression level was significantly lower in ER-positive breast cancers compared to ER-negative tumors. Higher CD73 expression was associated with worse overall survival in whole cohort (p=0.021) and ER-positive tumors (p=0.003), but not in ER-negative tumors. Gene Set Enrichment Analysis revealed that estrogen response gene sets (Early; NES=-1.57, p=0.043, Late; NES=-1.61, p=0.021) were significantly enriched in CD73 low expressing ER-positive tumors, suggesting estrogen signaling may repress CD73 expression. To test this hypothesis, we analyzed the expression of CD73 and CD39 in MCF7 cells treated with estrogen, tamoxifen or both. Our data revealed that estrogen treatment suppressed CD73 and CD39 expression, whereas tamoxifen treatment enhanced expression of the genes. These findings suggest that CD73 and CD39 gene expression is suppressed by estrogen signaling, whereas binding of ER antagonists such as tamoxifen can remove the repressive effect on gene expression. On the other hand, epithelial-mesenchymal transition (EMT) (Normalized Enrichment Score; NES=2.41, p<0.001) and angiogenesis (NES=2.33, p<0.001) gene sets were significantly enriched in CD73 high expressing ER-positive tumors. CIBERSORT, which is an algorithm to estimate infiltrating immune cells by gene expression, demonstrated that CD73 high expressing ER-positive tumors have less infiltrating CD8-positive T cells, memory B cells and plasma cells, implying that CD73 high expressing tumors have immune suppressive environment, which is in agreement with the notion that CD73 high tumors are immunosuppressive. Finally, we found that CD73 expression was significantly elevated post-chemotherapy compared to tumors prior to the treatment (p=0.007), and CD73 high expression patients showed worse relapse-free survival in neoadjuvant chemotherapy patients cohort (p=0.003).

Conclusion: Molecular studies revealed that CD73 expression is regulated by estrogen signaling. Increased expression of CD73 significantly correlates with worse outcomes in ER-positive breast cancer patients. This may be due to upregulated pro-metastatic gene signatures such as EMT and angiogenesis as well as less infiltration of anti-cancer immune cells by adenosine generated by CD73 in the tumor microenvironment. Our data reveals an intriguing mechanism which may be responsible for recurrence and metastasis of ER-positive breast cancer.
Targeting PFKFB3 enzyme induces cell death via reactive oxygen species-mediated toxicity in endocrine therapy-resistant breast cancers

Surojeet Sengupta¹, Catherine M Sevigny¹, Brandon C Jones¹, Lu Jin¹, Paula R Pohlmann¹ and Robert Calrke¹. ¹Georgetown University, Washington, DC.

Reprogrammed glucose metabolism is one of the key hallmarks of cancer. High-energy demand in cancer cells leads to increased glycolysis to maintain anabolic processes that are often driven by altered enzyme levels. 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase 3 (PFKFB3) is an enzyme that converts fructose-6-phosphate (F6P) to fructose-2,6-bisphosphate (F2,6BP). F2,6BP is an allosteric activator of phosphofructokinase-1 (PFK1), a critical rate-limiting control within glycolysis. PFKFB3 expression and activity are upregulated in many cancers including breast cancer, facilitating the increased glycolytic activity associated with neoplasia. In ER+ breast cancer cells, PFKFB3 is further upregulated by estrogen, but whether this affects responsiveness to endocrine therapies is largely unknown.

Expression of PFKFB3 mRNA and protein was measured in estrogen-responsive MCF7 cells and in endocrine therapy-resistant LCC9 and MCF7:5C cells (estrogen-independent; 4-hydroxytamoxifen (4OHT) and fulvestrant (Fulv) crossresistant). Both MCF7:5C and LCC9 cells expressed higher levels of PFKFB3 compared to MCF7 cells. Cells with higher PFKFB3 levels also showed increased basal glucose uptake and lactate secretion, consistent with the enhanced aerobic glycolysis often referred to as the “Warburg Effect.”

To evaluate the potential translational relevance of these observations, the association of PFKFB3 mRNA expression with clinical outcomes in ER+, node-negative breast cancer patients treated with an endocrine therapy was studied in two publicly available data bases. High expression of PFKFB3 was strongly associated with adverse recurrence-free survival (hazard ratio = 4.12 and p= 5.5x10⁻⁵).

Next, the effect of pharmacological inhibition of PFKFB3 was investigated on the growth of endocrine-resistant breast cancer cells using PFK158, an inhibitor of PFKFB3 that is currently being evaluated in clinical trials. PFK158 treatment suppressed the basal glucose uptake in LCC9 and MCF7:5C cells. PFK158 treatment alone was effective in inducing apoptotic cell death in both cell models. However, combining a lower, sub-optimal concentration of PFK158 with either 4OHT or Fulv significantly enhanced cell death in endocrine-resistant LCC9 and MCF7:5C cells. Notably, the cytotoxic effects of PFK158 alone or in combination with 4OHT or Fulv were markedly diminished by blocking reactive oxygen species (ROS) using either of the ROS scavengers N-acetyl cysteine (NAC) or Tempol.Overall, this study reveals that (1) PFKFB3 expression drives high glycolytic activity in endocrine-therapy resistant breast cancer cells; (2) PFKFB3 mRNA expression in ER+ LN- breast cancer is a prognostic factor; and (3) targeting PFKFB3 in combination with endocrine-based therapy induces enhanced cell death mediated by high ROS levels. Based on this intriguing data, combination of the PFKFB3 inhibitor PFK158 with an antiestrogen should therefore be regarded as a potential therapeutic intervention for patients with endocrine therapy-resistant breast cancer.
Deregulated lipid metabolism fuels the genesis of estrogen receptor negative breast cancer

Shivangi Yadav¹, MiRan Choi¹, David VanDerway², Greta Bauer², Vadim Backman², Seema A Khan¹ and Susan E Clare¹.
¹Northwestern University, Chicago, IL and ²Northwestern University, Evanston, IL.

Background:
There are no targeted pharmacologic interventions currently available for the prevention of hormone receptor negative breast cancer. Primary prevention with endocrine agents decreases the risk of ER positive disease with no effect against ER negative (ER-) disease. Thus, there is a compelling need to identify women at high risk for ER-negative breast cancer and to uncover the molecular mechanisms involved in its genesis. Our recent observation that a set of lipid metabolism (LiMe) genes are over-expressed in the contralateral unaffected breasts of women with unilateral ER- breast cancer suggests the novel hypothesis that specific lipid metabolism pathways in the breast produce a physiological milieu favoring the development of ER- breast cancer. We are now testing the specific hypothesis that lipids are the source of the acetyl-coA that is utilized to acetylate histones, an epigenetic modification that reprograms transcription.

Methods:
We developed an in-vitro model that relies on octanoic acid, a medium chain fatty acid that freely diffuses though the plasma and mitochondrial membranes. MCF-10A cells were plated and allowed to adhere overnight and then exposed to an increasing dose of sodium octanoate for 24 hours in complete media. Acetylation of Lysine 9 of Histone 3 (H3K9) was analyzed by Western blot and RNA was extracted for qPCR and RNA-seq. Chromatin packing density at the nanoscale was quantified by partial wave spectroscopic (PWS) microscopy. Mammary organoids were prepared from breast tissue by collagenase digestion and similarly treated.

Results:
We found a striking, dose-dependent increase of H3K9 acetylation in octanoate treated MCF-10A cells. The acetylation is specific to the lipids as no acetylation was observed in cells treated with the same concentration of the alcohol 1,4-Cyclohexanediethanol. RNA-Seq revealed the differential expression of LiMe genes together with a significant upregulation of Hedgehog and Notch signaling pathways. Individual genes from various pathways were further verified by qPCR which revealed, for example, a four-fold increase in SHH expression and 25-fold increase in DLL4. The expression of two of the previously identified LiMe genes, HMGCS2 and ACSL3, was increased four-fold in the octanoate treated MCF10A cells. We repeated the octanoate treatment in organoids and found similar effects. PWS in live cells showed a dose-dependent increase in chromatin packing scaling (D) in cells exposed to octanoate, suggesting that accessibility of chromatin to transcription factors is increased upon fatty acid treatment.

Conclusion:
A lipid rich microenvironment affects metabolism in ER- MCF10A cells and stimulates pro-neoplastic signaling via histone modifications. This supports our hypothesis that perturbed lipid metabolism plays an important role in the development of ER-breast cancer. Further mechanistic studies will determine if the genes differentially expressed in cell culture are also differentially expressed in antecedent benign breast biopsies from women eventually diagnosed with ER+ and ER- cancer.
Iron-sulfur clusters are cell-essential protein cofactors in at least 48 human enzymes supporting diverse cellular functions, including genomic integrity and oxidative phosphorylation, and acting as molecular sensors for oxygen and iron levels. We recently described that breast cancer cells are particularly dependent upon robust iron-sulfur cluster biosynthesis for the survival of elevated oxygen conditions, including seeding lung metastases (1). Moreover, we found that even partially blocking cluster synthesis activated an iron-starvation response, rendering breast cancer cells susceptible to oxidative stress and death by ferroptosis (1). However, the precise mechanisms underlying these phenotypes remain to be fully elucidated. Here, we find that basal-like breast cancer cells are particularly susceptible to suppression of iron-sulfur cluster biosynthesis. By systematically evaluating proteins containing iron-sulfur clusters, we discovered that this susceptibility lies in the intrinsic vulnerability of basal-like breast cancer cells to genomic instability. These results have enabled us to define specific molecular targets in basal-like breast cancer which induce DNA damage, replication fork instability, and apoptosis, with striking subtype specificity. Our findings have broad implications for the underlying differences in genomic integrity in basal-like and luminal breast cancer subsets, and will inform future novel strategies to target genomic integrity in basal-like breast cancer.

This work was supported by a Susan G. Komen Career Catalyst Award and the NCI (R01 CA214948).
Slit2 induced anti-tumor activity may be mediated through metabolism driven immunomodulation

Kirti Kaul¹, Dinesh K Ahirwar², Martin Benej², Nicholas Denko² and Ramesh Ganju¹,² ¹Comprehensive Cancer Center, The Ohio State University, Columbus and ²The Ohio State University, Columbus.

Metabolism of immune cells plays an important role in regulating tumor growth by modulating the anti-tumor M1 phenotype or pro-tumor M2 phenotype in macrophages. However, the role of bone marrow derived macrophages (BMDM) and their metabolic profile in promoting tumor growth is unknown. Slit2 is an anti-tumor molecule that is suppressed in breast cancer; however, the mechanism by which Slit2 mediates its function is not fully elucidated. We hypothesize that Slit2 mediated metabolic reprogramming of BMDMs favors anti-tumor M1 phenotype in these macrophages, which in turn reduces tumor growth. Here we assessed cellular metabolism in BMDMs from the MMTV-PyMT mouse, a model showing spontaneous tumor development. Shortly, age matched female mice with palpable tumors and control mice without tumors were treated with recombinant Slit2 (Slit2) or PBS intraperitoneally every third for 2 weeks (n=4 mice per group). Tumor volume was measured in each mouse before and at the end of treatment. Next, mice were euthanized and bone marrow was flushed from both the tibia and femor for culturing in vitro in the presence of macrophage chemotactic factor rich conditioned media. Rate of glycolysis was described based on extracellular acidification rate (ECAR) as measured by the Seahorse Bioanalyzer® under glycostress conditions. Lactate dehydrogenase (LDH) activity, which is linked with breast cancer progression and pro-tumor macrophage phenotype in experimental models, was also assayed using a commercially available kit. Finally, to elucidate potential pathways involved in Slit2 induced metabolic change, we assessed the expression of several proteins and factors involved in cellular metabolism.

Firstly, we observed that PyMT mice treated with Slit2 showed lower tumor volume compared to mice treated with PBS confirming Slit2 anti-tumor activity. Hematoxylin & Eosin staining of tumor sections from these mice also showed better tissue structure, with a higher cytoplasm to nuclear ratio in Slit2 treated PyMT mice compared to PBS treated mice. Furthermore, BMDMs from PyMT mice show lower aerobic glycolysis with higher lactate dehydrogenase activity (LDH) compared to control mice. Moreover, treatment with Slit2 appeared to lower LDH activity and trended to increase glycolysis in the BMDMs isolated from Slit2 treated PyMT compared to PBS treated PyMT.

Expression analyses using quantitative PCR showed a 2-4 fold decrease in PGC-1α and CPT-2 in Slit2 treated BMDMs, indicating a reduction in fatty acid oxidation in these cells. This coupled with a 3 fold increase in IL-6 expression, and 2-3 fold decrease in arginase and IL-10 expression in tumor tissue suggest a potential shift from pro-tumor M2 to anti-tumor M1 phenotype. In spite of these preliminary trends, changes in metabolism and associated signals may be clearer in isolated, enriched populations of macrophages alone. Nevertheless, our findings suggest that Slit2 reduces tumor growth by affecting immune cell metabolism. Furthermore, these studies provide novel evidence of the potential immunomodulatory effects of Slit2 on macrophages. This may lead to development of Slit2 as a novel non-invasive therapeutic strategy against highly aggressive and metastatic cancers associated with high mortality and low quality of life.
Obesity is associated with breast cancer, especially postmenopausal obesity is a risk factor for breast cancer. Various studies have shown that obesity is correlated with microbiome. In particular, Firmicutes and Bacteroidetes occupy a significant portion of the intestinal microbiome at phylum-level. As the relation between obesity and intestinal microbiome, breast cancer may be associated with the microbiome and obesity as well. This study analyzed the microbiome of breast cancer patients and normal controls. We also investigated the relationship among breast cancer, body mass index, and eating habits.

The intestinal symbiotic bacteria secretes bacterial extracellular vesicles to the blood and lymphatic fluid, and communicate with distant organs through these vesicles which are including metabolites and bacterial materials. Therefore, we analyzed the microbiome of breast cancer patients and normal controls through blood samples. The 287 blood samples in female (95 breast cancer patients and 192 normal controls) from September 2014 to August 2015 were collected and analyzed by NGS using a universal bacterial primer of 16S rDNA. A t-test was performed to find out the discrepancy between cancer and control groups.

We examined the Firmicutes/Bacteroidetes (F/B) ratio of normal controls and breast cancer patients, and the result showed that the F/B ratio in normal group was 2.6 times higher than breast cancer group. In the normal group, Firmicutes were five-fold higher than Bacteroidetes at the phylum level. Among them, Staphylococcus and Bacillus at the genus level were especially higher.

Bacteroidetes in breast cancer patients were elevated at the phylum level, particularly Bacteroides and Parabacteroides were elevated at the genus level. In breast cancer patients, the F/B ratio was 1.3 fold higher in the group with high BMI (BMI>30) compared to normal BMI (BMI 20-24). The F/B ratio of breast cancer patients who are meat lovers was increased (F/B ratio: 2.3), followed by vegetative diet (F/B ratio: 2.0) and omnivorous patients (F/B ratio: 1.8). Menopause did not affect the F/B ratio. However, Verrucomicrobia phylum was lower in breast cancer patients with premenopausal status. The most distinct genus in Verrucomicrobia phylum was Akkermansia, which was the highest in the normal group.

Breast cancer patients have lower Firmicutes and higher Bacteroidetes than normal controls. Notably, the proportion of Bacteroides and Parabacteroides belonging to Bacteroidetes was high and may be related to the incidence of breast cancer. Conversely, Staphylococcus and Bacillus belonging to Firmicutes phylum may have protective effects in breast cancer. The higher BMI was related to the higher F/B ratio. This result is consistent with the higher F/B ratio in the meat lover groups with breast cancer. Menstruation did not affect the F/B ratio but influences the Akkermansia genus. That is, changes in intestinal bacteria which are affected by the postmenopausal status and hormonal level may have affected the prognosis of breast cancer.

In the future, the research on microbiome of breast cancer patients is expected to provide microbiome-based supplements that help to treat and prevent breast cancer.
Progesterone receptor membrane component-1 interacts with proteins of the cholesterol synthesis pathway resulting in altered cholesterol metabolism in breast cancer cells: Potential mechanism contributing to breast cancer progression

Marina Ludescher¹, Nadia Stamm¹, Dieter Niederacher¹, Eugen Ruckhäberle¹, Tanja Fehm¹ and Hans Neubauer¹. ¹University Hospital and Medical Faculty of the Heinrich-Heine University, Duesseldorf, Germany.

Background: Progesterone Receptor Membrane Component-1 (PGRMC1) is upregulated in breast tumors and elevated expression of PGRMC1 is associated with increased tumor growth, indicating that PGRMC1 plays a role in carcinogenesis of breast cancer. However, the mechanism by which PGRMC1 contributes to breast cancer progression is not understood yet. Here we describe a potential mechanism by which PGRMC1 contributes to progression of breast cancer via deregulation of cholesterol synthesis and metabolization.

Methods: PGRMC1 interaction partners were identified by co-immunoprecipitation followed by mass spectrometry and validated using proximity ligation assay (PLA) in various breast cancer cell lines. To study how elevated PGRMC1 expression contributes to cholesterol balance, we generated PGRMC1 overexpressing breast cancer cells and determined levels of cholesterol-, lathosterol- and the cholesterol metabolite 27-hydroxycholesterol. Since 27-hydroxycholesterol is presumed to have estrogenic action, stimulating the growth of ER-positive breast cancer cells and limiting the effectiveness of aromatase inhibitors, we further investigated the activity of ERα in PGRMC1 overexpressing cell lines.

Results: Interaction of PGRMC1 with proteins involved in cholesterol synthesis, including Acyl-CoA desaturase (SCD), Squalene synthase (FDFT1) and Lanosterol 14-alpha demethylase (CYP51A1), was detected by mass spectrometry and verified by PLA. Elevated levels of cholesterol and its metabolites were detected in PGRMC1 overexpressing cells, suggesting a contribution of PGRMC1 to cholesterol synthesis and metabolization. Further, increased activity of ERα was found in PGRMC1 overexpressing cells, indicating activation of the receptor by cholesterol metabolites.

Conclusion: Cholesterol metabolism is involved in cancer cell proliferation as well as resistance to anti-cancer therapy. Our results indicate that elevated cholesterol metabolism induced by interaction of PGRMC1 with enzymes of the cholesterol biosynthesis pathway might contribute to malignant transformation and promote breast cancer progression. PGRMC1 might therefore present an interesting target for anti-cancer therapy.
Combinational treatment of biguanides and fatty acid β-oxidation inhibitor in triple-negative breast cancers

Jun Hyoung Park¹, Kwang Hwa Jung¹, Sajna Vithayathil¹, Dongya Jia² and Benny A Kaipparettu¹,². ¹Baylor College of Medicine, Houston, TX; ²Center for Theoretical Biological Physics, Rice University, Houston, TX and ³Dan L. Duncan Comprehensive Cancer Center, Baylor College of Medicine, Houston, TX.

Among breast cancers (BCs), the driver pathways and therapeutic targets are still poorly understood for triple negative (TN) BCs. Advances in cancer metabolism research over the last decade have enhanced our understanding on metabolic reprogramming in cancer therapy. We have previously shown that metabolic reprogramming to fatty acid β-oxidation (FAO) is a major energy pathway in metastatic TNBC. Moreover, we reported that FAO regulates c-Src, one of the frequently upregulated oncopathways in TNBC via autophosphorylation of Src at Y419. Since FAO inhibitors alone cannot effectively control the tumor progression in TNBC, suitable combination therapies with other metabolic targets are necessary. Recently increasing evidences show that anti-diabetic biguanides have attractive anticancer effect in various cancer types including BC. However, its significance as an anticancer drug is not well established due to parallel metabolic pathways that support tumor growth. Phenformin, a biguanide derivative similar to metformin, has a greater potency than metformin. Like metformin, phenformin also inhibits mitochondrial electron transport chain (ETC) through complex I inhibition. In addition, biguanides lead to the activation of AMPK, which plays a key role in insulin signaling and energy sensing. Importantly, AMPK is an upstream regulator of FAO pathway because it can phosphorylate ACC to activate FAO. Considering the dependency of TNBC to FAO, we evaluated the therapeutic significance of the combination of biguanides(ETC inhibitors) and FAO inhibitors in TNBC progression and metastasis. We hypothesize that blocking both ‘arms’ of the pathway can provide more pronounced and durable responses in TNBCs. Our different in vitro and in vivo studies using TNBC cell line and PDX models suggest that the combination of both inhibitors can provide better therapeutic significance in metastatic TNBCs. This is a rationale and cost-effective metabolic approach to manage the currently non-targetable metastatic TNBCs. Further investigation into the clinical effectiveness of this combination may provide better treatment opportunities for TNBC patients.
Gain-of-function of mutant P53 elevates glucose uptake via membrane translocation of GLUT1 in breast cancer

Sung Gwe Ahn¹, Soong June Bae¹, Chang Ik Yoon¹, Chihwan Cha¹, So Eun Park¹ and Joon Jeong¹. ¹Gangnam Severance Hospital, Seoul, Korea.

Background
High rate of glycolysis exhibited by cancer cells plays a crucial role in carcinogenesis and tumor progression. Previous study showed that gain-of-function (GOF) by mutant P53 drives the Warburg effect via GLUT1 membrane translocation in malignancies. Also, in the patients with a preoperative 18F-fluorodeoxy glucose positron emission tomography (FDG-PET), which enables to estimate glucose uptake by tumor as standardize uptake value (SUV), we identified high SUV as a poor prognostic marker. In this study, we wondered whether P53 mutation promotes GLUT1 membrane translocation and increases glucose uptake in MCF10A cells and patients with breast cancer.

Methods
Transcriptomic profiling was carried out using gene expression data from 66 breast cancer patients who underwent preoperative FDG-PET to identify a molecular signature associated with SUV. Gene network analyses revealed dysregulation of P53 pathway. We generated both MCF10A cell lines with P53-knock down and P53-mutant which include sequence variants (R175H, R273H, and R248W). Glucose uptake assay and confocal imaging studies with 2NBGD were performed. Confocal imaging system was used to detect GLUT1 membrane expression. In case-matched patients according to P53 mutation (n=114), we compared SUV. Mutational analysis of exons 5-9 of the P53 gene was carried out using Sanger sequencing.

Results
Glucose uptake assay showed that the level of glucose uptake was increased in P53 mutant MCF10A cell lines with a 1.5-1.8 fold change compare with wild-type MCF10A. The increase of glucose uptake by mutant-P53 was reproducible with the experiments with 2NBGD. By contrast, stable knock down of P53 did not induce an elevation of glucose uptake in MCF10A cells. The confocal imaging studies captured translocation to membrane of GLUT1 in mutant P53-MCF10A. However, in wild-type MCF10A, GLUT1 was diffusely expressed in cytoplasm. In tumors from patients, membraneous expression of GLUT1 was significantly higher in tumors with p53 mutation than in tumors with intact p53 (P=0.022). Further, the mean SUV of p53-mutational group was significantly higher than that of wild-type p53-group (7.49 vs. 5.44, P=0.013). In multivariate analysis for recurrence-free survival, p53 mutational status carried prognostic significance (hazard ratio 3.73, 95% CI 1.15-12.07) independent of tumor size, nodal status, and estrogen receptor status.

Conclusion
We showed that GOF by P53 mutation promotes GLUT1 translocation to membrane, which consequently induces glucose influx in MCF10A cells, elucidating that P53 mutation contributes to the increase of SUV in patients with breast cancer.
Computational metabolism modeling predicts risk of relapse in breast cancer patients

Pilar Zamora\textsuperscript{1}, Lucia Trilla-Fuertes\textsuperscript{2}, Angelo Gámez-Pozo\textsuperscript{2,3}, Guillermo Prado-Vázquez\textsuperscript{2}, Andrea Zapater-Moros\textsuperscript{2,3}, María Ferrer-Gómez\textsuperscript{2}, Mariana Díaz- Almirón\textsuperscript{4}, Rocío López Vacas\textsuperscript{3}, Enrique Espinosa\textsuperscript{1} and Juan Angel Fresno Vara\textsuperscript{2,3}. \textsuperscript{1}Servicio de Oncologia Médica. Hospital Universitario La Paz, Madrid, Spain; \textsuperscript{2}Biomedica Molecular Medicine SL, Madrid, Spain; \textsuperscript{3}Molecular Oncology & Pathology Lab, Institute of Medical and Molecular Genetics-INGEMM, La Paz University Hospital-IdiPAZ, Madrid, Spain and \textsuperscript{4}La Paz University Hospital-IdiPAZ, Madrid, Spain.

Introduction
Breast cancer is one of the most prevalent cancers in the world. In previous works we observed differences in glucose metabolism between breast cancer subtypes, suggesting that metabolism plays an important role in this disease. Flux Balance Analysis (FBA) is widely used to study metabolic networks, allowing predicting growth rates or the rate of production of a given metabolite.

Material and methods
Proteomics data from 96 breast cancer tumors were obtained applying a high-throughput proteomics approach to routinely archive formalin-fixed, paraffin-embedded tumor tissue. Proteomics tumor data were analyzed using the human metabolic reconstruction Recon2 and FBA. The tumor growth rate for each tumor was calculated. In order to analyze fluxes from the different metabolic pathways, flux activities were calculated as the sum of the fluxes of each reaction in each pathway defined in the Recon2. Then, flux activities were used to build prognostic models.

Results and discussion
Using the results obtained from FBA in the proteomics dataset, flux activities were calculated for each pathway. Employing these flux activities, a prognostic signature was built. Flux activities of vitamin A, tetrahydrobiopterin metabolism and beta-alanine metabolism pathways split our population into a low and a high risk group (p=0.044).

Conclusion
Vitamine A, beta-alanine and tetrahydrobiopterin metabolism flux activities could be used to predict relapse risk. Flux activities is a method proposed in a previous work to study response against drugs that now also demonstrated its utility in summarizing FBA data and is associated with prognosis.
c-Src (Src) is a proto-oncogene involved in signaling that culminates in the control of multiple biological functions. Src is also one of the most frequently upregulated pathways in triple negative breast cancer (TNBC). Dysregulation of Src has been detected in TNBC and is strongly associated with tumor metastasis and poor prognosis. However, even after promising preclinical studies, Src inhibitors did not show major clinical advantage in unselected TNBC populations. We have previously published that metastatic TNBC has high energy-dependency to mitochondrial fatty acid beta-oxidation (FAO) and FAO activates Src by inducing autophosphorylation at Y419. However, our recent analysis suggests that as observed with the Src inhibitors, TNBC tumors treated with FAO inhibitors also develop drug-resistance and continue tumor growth. Evaluation of their drug resistance mechanism revealed that while short-term inhibition of FAO or Src induces autophagic and apoptotic cell deaths, long-term inhibition results in autophagy-mediated drug resistance and survival. Further analyses suggest that FAO and Src inhibitors activate mitogen-activated protein (MAP) kinase kinase (MEK)/extracellular signal-regulated kinase (ERK) pathway via the induction of cellular reactive oxygen species (ROS) in TNBC. Activated MEK/ERK then induces survival pathways for drug resistance and tumor survival. Validation of in vitro findings using in vivo TNBC models confirmed that combination of FAO/Src inhibitors with MEK/ERK inhibitors can provide significant benefit to overcome the therapeutic resistance of TNBC. These findings open-up new therapeutic opportunities to manage TNBC patients with currently non-targetable metastatic tumors.
All-trans retinoic acid perturbs the lipidomic profiles of luminal breast cancer cells characterized by sensitivity to the anti-proliferative activity of the retinoid

Mineko Terao¹, Valentina Celestini¹, Mami Kurosaki¹, Arianna Vallerga¹, Marco Bolis¹, Maddalena Fratelli¹, Gabriela Paroni¹, Alessandra Di Veroli², Gabriele Cruciani², Laura Goracci² and Enrico Garattini¹. ¹Istituto di Ricerche Farmacologiche Mario Negri, Milano, Italy and ²University of Perugia, Perugia, Italy.

**Background:** All-trans retinoic acid (ATRA) is the active metabolite of vitamin A and a promising agent in the prevention and treatment of breast cancer. We recently demonstrated that approximately 70% of estrogen-receptor-positive (ER⁺) breast cancer cell lines and primary tumors are sensitive to the anti-proliferative effects of ATRA (1,2). In contrast, only 10-20% of the HER2-positive and triple-negative counterparts respond to the retinoid. The significance of lipids in the growth, progression and drug sensitivity of specific types of solid tumors, including breast cancer, is largely overlooked. In particular, the role, if any, of specific lipids in the anti-tumor action of ATRA in breast cancer has never been studied.

**Aims and Approach:** The principal aim of the present work was to evaluate the specific perturbations induced by ATRA on the homeostasis of lipids in breast cancer cells characterized by sensitivity to the anti-proliferative action of the retinoid. To this purpose, we took a high-throughput approach and defined the lipidomic profiles of 16 breast cancer cell lines in basal conditions and following challenge with ATRA (1 µM) for 48 hours. The panel consisted of eight cell lines characterized by a luminal phenotype and eight cell lines with a basal phenotype. Four ATRA-sensitive cell lines (SKBR3, HCC1500, CAMA1 and MDAMB361) and 4 ATRA-resistant counterparts (HCC202, MDAMB175VII, ZR75.1 and HCC1419) were included in the luminal group. Similarly, the basal group contained 4 ATRA-sensitive (HCC1599, MB157, MDAMB157 and Hs578T) and 4 ATRA-resistant (MDAMB231, CAL851, HCC1187 and MDAMB436) cell types.

**Results:** Using Lipostar, a unique and recently developed software for high-throughput LC-MS lipidomics analysis (3), we identified lipid species whose levels were modified by ATRA in each cell line. This resulted in the generation of a lipid fingerprint consisting of 530 elements. We observed that ATRA reduced the amounts of cardiolipins in luminal and ATRA-sensitive breast cancer cell lines specifically. Similar effects were not observed in luminal and ATRA-resistant cells. ATRA-dependent reduction in the amounts of cardiolipins was never observed in basal cells, regardless of their sensitivity to the retinoid. Given the role played by cardiolipins in the homeostasis of the mitochondria, we evaluated the action of ATRA on the functional activity of these organelles in the luminal and ATRA-sensitive or ATRA-resistant cell lines. In SKBR3 and the other sensitive cell lines, we observed that ATRA modulated mitochondria-dependent oxygen consumption and ATP production. These effects were accompanied by an increase in mitochondrial membrane fluidity, which is consistent with the effects exerted by ATRA on the cellular content of cardiolipins. ATRA-dependent action on cardiolipins and mitochondrial homeostasis precedes maximal growth inhibition. The results provide new insights on the mechanisms underlying the anti-tumor action of ATRA.

Cancer/testis antigen-Plac1 promotes invasion and metastasis of breast cancer through Furin/NICD/PTEN signaling pathway

Yongfei Li¹, Jiahui Chu¹, Jun Li¹, Jinhai Tang¹ and Yongmei Yin¹. ¹The First Affiliated Hospital of Nanjing Medical University, Nanjing, Jiangsu, China.

Plac1 is a cancer-testis antigen that plays a critical role in promoting cancer initiation and progression. However, the clinical significance and mechanism of Plac1 in cancer progression remains elusive. Here we report that Plac1 is an important oncogenic and prognostic factor which physically interacts with Furin to drive breast cancer invasion and metastasis. We have shown that Plac1 expression positively correlates with clinical stage, lymph node metastasis, HR status and overall patient survival. Overexpression of Plac1 promoted invasion and metastasis of breast cancer cells in vitro and in vivo. Co-immunoprecipitation and immunofluorescence cell staining assays revealed that interaction of Plac1 and Furin degraded Notch1 and generated Notch1 intracellular domain (NICD) that could inhibit PTEN activity. These findings are consistent with the results of microarray study in MDA-MB-231 cells overexpressing Plac1. A rescue study showed that inhibition of Furin and overexpression of PTEN in Plac1 overexpression cells blocked Plac1-induced tumor cell progression. Taken together, our findings suggest that functional interaction between Plac1 and Furin enhances breast cancer invasion and metastasis and the Furin/NICD/PTEN axis may act as an important therapeutic target for breast cancer treatment.
Metabolism-driven cancer identification with GLUT5-specific molecular probes

Avik Ghosh¹, Srinivas Kannan¹, Vagarshak V Begoyan¹, Lukasz J Weselinski¹, Smitha Rao¹ and Marina Tanasova¹. ¹Michigan Technological University, Houghton, MI.

**Background:** Current cancer imaging agents are limited in their ability to distinguish cancers from normal cells (low cancer-selectivity) and identify cancers at different stages of development (low cancer-specificity). This limitation makes biopsy mandatory for diagnosis and continuous treatment monitoring. Analysis of biopsy samples may also have some ambiguity in clearly identifying malignant and metastatic cells, resulting in cases of mischaracterization and overdiagnosis. Hence, cancer-selective and cancer-specific imaging agents are needed. Distinguishing cancer types and stages can be achieved by addressing differences in their nutrient uptake, manifested as changes in the expression of facilitative sugar transporters (GLUTs). Here, we present a novel approach to target the enhanced metabolism in breast cancers with sugar-like fluorescently labeled probes – ManCous – engineered for specific uptake by fructose transporter GLUT5. The differential accumulation of these probes in cancer cells parallels the differential activity of GLUT5 and results in active fluorescence accumulation within cancers with the highest levels observed in premalignant phenotypes.

**Results:** Locking fructose conformation in the furanose form was found to provide a sugar-like mimics recognized explicitly by GLUT5. The corresponding coumarin conjugates – ManCous (Figure 1A) – were found to exhibit GLUT5-specific uptake and work as reporters of GLUT5 activity in cells. Differential activity of GLUT5 in cells was found to parallel the differences in the uptake of ManCous. Significant differences in accumulation of ManCou-induced fluorescence were observed between normal and cancer cells and between cancer phenotypes (Figure 1A). Namely, an 8-fold difference in ManCou accumulation was observed between normal and adenocarcinoma MCF7 cells, and 70-fold difference was observed between normal and premalignant MCF10aNeoT cells. The uptaken ManCou were found to be metabolized by hexokinase to form phosphorylated analogs and effectively compete with glucose for hexokinase II (Figure 1B). The probes were found to be non-cytotoxic at concentrations below 100 µM, with higher cytotoxicity towards cancer cells at probe concentrations above 100 µM.

**Conclusions:** The dependence of breast cancer cells on fructose provides a firm basis for developing imaging approaches to discriminate between normal and cancer cells as well as potentially between cancer phenotypes. While current probes are restricted to in-vitro imaging, further probe evolution is expected to lead to new in vivo agents, owing to a proper modification of the scaffold with the relevant radioactive (PET) or other imaging entity and retention of transporter specificity. The development of transporter-specific GLUT5 affinity probes could further contribute to enhancing the impact of fructose uptake inhibition for approaching cancer-specific therapies.
Akt inhibition associated with change in immunophenotype of tumor microenvironment (TME) in breast cancer (BC)

Douglas K Marks¹, Robyn D Gartrell¹, Qingfei Pan¹, Margueritta El Asmar¹, Thomas D Hart², Camden L Esancy¹, Yan Lu¹, Jiyang Yu¹, Hanina Hibshoosh¹, Eileen Connolly¹, Kevin Kalinsky and Yvonne M Saenger¹. ¹Columbia University Irving Medical Center, New York, NY; ²Columbia University, New York, NY and ³St. Jude Children's Research Hospital, Memphis, TN.

Background: The PI3K/Akt/mTOR pathway is a known oncogenic pathway in BC. In addition, this pathway has demonstrated capacity to modulate host immune activity and may indirectly affect tumorigenesis. Clinicopathologic studies have demonstrated that lymphocyte density within the TME is predictive of chemosensitivity and improved prognosis in BC, while myeloid infiltration may play a deleterious role. To define the impact of Akt inhibition on the TME, we analyzed tumor tissue from patients (pts) with early-stage BC treated with single agent MK-2206, an Akt inhibitor, enrolled on a presurgical trial (NCT01319539).

Methods: Quantitative immunofluorescence (qmIF) was performed for CD3, CD8, CD4, FOXP3, CD68, Pancytokeratin on 4uM sections from biopsy and surgical specimens of MK-2206 (n=5) and control (n=5) pts. Images were analyzed using Vectra/inForm software (PerkinElmer), allowing for multiparameter phenotyping. Transcriptomic analysis was performed on surgical specimens to assess if differences exist in mRNA expression of tumor-associated and immune genes between pts treated with MK-2206 (n=5) and untreated matched controls (n=5) (nanoString). Statistical analysis was performed using t-Test, NetBID, and multiple comparison analysis by Benjamini-Hochberg. Gene set enrichment analysis (GSEA) was performed within R with gene sets from Molecular Signatures Database (Hallmark, Reactome, GO).

Results: On qmIF analysis, MK-2206 treated pts exhibited a significant increase in median cytotoxic T-cell (CD3+CD8+, CTL) density between pretreatment biopsy and surgical excision specimens, as compared to the control pts (87% vs.0.2%, p < 0.05). Mean macrophage density (CD68+) was numerically lower in surgical specimens of pts who received MK-2206 vs. control pts, although CD68+ infiltration was overall low (p=ns). mRNA expression supports in vivo activity of MK-2206 with lower expression levels of cell cycle, proliferation and anti-apoptotic genes (e.g. CTNNB1, CCND2, BAX) and greater expression of pro-apoptotic genes (e.g. BAD) associated with MK-2206 treatment (raw p-value <0.05). Additionally, greater mRNA copy number of IGF1R, a receptor tyrosine kinase (RTK) previously identified as upregulated in BC in the context of Akt inhibition, was found in post-MK-2206 surgical specimens as compared to control, non-MK-2206 specimens (raw p-value <0.05). MK-2206 was also associated with reduced expression of myeloid markers (e.g. CSF1R, CD163) (raw p-value <0.05). By GSEA, canonical gene sets related to interferon signaling were increased in post-MK-2206 specimens as compared to non-MK-2206 specimens, whereas monocyte chemotaxis genes were decreased in treated pts (adj p-value <0.05). RT-PCR is currently underway to compare biopsy and surgical specimens for a subset of RTK, immune and apoptosis related genes identified above.

Conclusion: mRNA and qmIF analysis suggest that Akt inhibition, may increase interferon signaling, CTL density, and decrease myeloid infiltration. Thus, Akt inhibition may promote a favorable TME. At present, there are both FDA approved and investigational agents that target the PI3K/mTOR pathway. Further investigation is warranted to understand the impact of Akt inhibition on the TME and potential therapeutic implications.
Markers of PI3K/Akt, ER & AR pathways and Ki67 expression in relation to tamoxifen outcome in ER+ breast cancer

Christine Campbell¹, John Mathew², Ian Ellis³, Pauline Finlay⁴, Andrew Green⁵, Ian Bradbury¹, Signe Borgquist⁶, Karin Elebro⁶, Oliver Politz⁷, Andrea Haegebarth⁷, Julia MW Gee⁴ and John FR Robertson³. ¹Frontier Science Scotland, Inverness-SHIRE, United Kingdom; ²Peterborough City Hospital, Peterborough, United Kingdom; ³Nottingham University Hospital, Nottingham, United Kingdom; ⁴Cardiff University, Cardiff, United Kingdom; ⁵Aarhus University, Aarhus, Denmark; ⁶Skåne University Hospital, Malmö, Sweden and ⁷Bayer, Berlin, Germany.

**Aim:** To select tumor biomarkers, included in the AKT pathway, able to predict response to tamoxifen (TAM) in patients with estrogen receptor (ER) positive breast cancer.

**Patients & Methods:** 157 endocrine treatment naïve patients with known ER and HER2 status were treated with TAM: tumour tissue was available either as tissue microarrays (TMA) (n=107) or core biopsies (n=50). After removal of duplicates, ER(-) BCs, & patients without full outcome data 103 patients were available. Ten biomarkers were evaluated by immunohistochemical staining (% positivity and/or H-Score): ER, HER2, Ki67, & phosphorylated forms of MAPK, AKT, ER (Ser118), PRAS40, and IGF1R, as well as pTEN & also androgen receptor (AR) expression. TMA cores were collected from three tumor sites, two central and one peripheral. Tumors were also analysed for AKT1 E17K somatic mutation using BEAMing technology. Patient outcome was assessed by clinical benefit (CB) rate & survival analyses (Time To Progression (TTP) and Time To Death (TTD)). Biomarkers were selected by regression trees to be included in multivariate models for clinical outcomes. False Discovery Rate (FDR) was applied to univariate results. Combinations of pAKT & pPRAS40, Ki67 & ER and ER/AR ratio-were also analysed.

**Results:**

**Type of Biopsy (Core versus TMA):** Generally % positivity was lower in TMAs than cores, for HER2, pER118, pIGF1R and cytoplasmic pAKT and pPRAS40. pAKT, pMAPK and Ki67 were largely unaffected by biopsy type. After FDR testing, significant differences remained for pER118 (p=0.002), pIGF1R (p<0.001), pPRAS40 (p<0.001) and HER2 (P=0.005) positivity levels.

**Biopsy Location (TMAs):** There was no significant difference in % positivity between central & peripheral tumor sites for all biomarkers examined. After FDR correction modest differences were seen for HER2 & pER118 (both p=0.044) only between the two central samples.

**IHC endpoints versus clinical outcome:** Univariate analyses identified only lower levels of pTEN and higher levels of Ki67 (% positivity) as predictive of poor outcome (TTP & TTD) following TAM treatment. In the luminal A (ER+/HER2-) subgroup only Ki67 was predictive of poor outcome (p=0.012). The predictive power of Ki67 for TTP was not improved by combination with pTEN or ER. An inverse ER H-Score association with TTP was confined to the ‘luminal A’ cohort.

AR was not predictive. 71 patients had AR/ER ratio: 61 had ratio <2 (42 had CB & 19 no CB), and 10 had ratio ≥2 (3 CB & 7 no CB) (p<0.02). There was no significant difference in TTP or TTD by AR/ER ratio.

Only 2 /146 (<2%) tumors had AKT1 E17K mutations.

**Conclusions:** Biomarker staining cannot be assumed to be the same in TMAs & core biopsies: such data should be combined with caution. Importantly however, there was no evidence of difference in Ki67 between TMA & core samples. There is no evidence to suggest that biomarker staining (including Ki67) at different tumor sites shouldn't be combined, or that ranking of scores differs across such sites. The findings confirmed previous reports that Ki67 & reduced level of PI3K /AKT pathway regulator pTEN can predict resistance to TAM in ER+ BCs. The AKT mutation rate was low.
BRG1-SOX4 mediates a novel and essential signaling network that activates PI3K/Akt signaling in TNBC

Michael L Gatza¹, Steven P Angus², Christen A Khella¹, Kevin Tong¹, Mike Verzi¹ and Gaurav A Mehta¹. ¹Rutgers Cancer Institute, New Brunswick, NJ and ²Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC.

**Background:**
Triple negative (TNBC) breast cancer, which is largely synonymous with the basal-like molecular subtype, is an aggressive malignancy that accounts for nearly 1 in 4 breast cancer related deaths and disproportionately affects younger women and women of African American decent. Given the lack of drug-able targets expressed by TNBC tumors, few therapeutic options exist beyond currently utilized cytotoxic therapies, and the overall prognosis for these patients remains poor. While TNBC tumors are characterized by high PI3K signaling, clinical trials targeting this pathway have had limited success. Therefore, identifying mechanisms driving key oncogenic pathways, including PI3K, is paramount to understanding the transformation process and enabling the development of rational, personalized therapeutic regimens.

**Methods:**
We utilized a PI3K gene expression signature as a conceptual framework to analyze genome-wide mRNA expression and DNA copy number data from human breast tumors to identify genetic drivers of PI3K/Akt signaling. Kinome profiling was used to identify changes in the drug-able kinome regulated by these genes and in vitro studies were used to delineate mechanisms by which identified genes mediate oncogenic PI3K signaling in TNBC.

**Results:**
Integrative proteogenomic analyses of orthogonal genome-wide data from ~3,000 human tumors from the TCGA and METABRIC studies identified amplification and overexpression of the oncogenic transcription factor SOX4 as well as the SWI/SNF ATPase BRG1 in tumors with high PI3K activity. These alterations were predominantly expressed in TNBC or basal-like breast tumors. Chromatin immunoprecipitation followed by DNA sequencing (ChIPseq) as well as shRNA-based studies confirmed that BRG1 regulates SOX4 expression in TNBC cell lines. Analyses of data from a genome-wide RNA interference (RNAi) screen in 27 breast cancer cell lines further indicated that SOX4 is essential in cell lines with high PI3K activity and this was confirmed by colony formation and cell proliferation assays. Importantly, in vitro analyses confirmed that both BRG1 and SOX4 regulate Akt phosphorylation and down-stream signaling. Profiling of the drug-able kinome in SOX4 depleted cell lines compared to control cells using Multiplexed kinase Inhibitor Beads couple with quantitative Mass Spectrometry (MIB/MS) identified 21 drug-able kinases regulated by SOX4 activity including TGFBR2 which has been previously shown to regulate PI3K activity. RNA sequencing (RNAseq) and RT-PCR analyses confirmed that SOX4 mediates TGFBR2 mRNA levels and co-immunoprecipitation experiments in conjunction with ChIP assays demonstrated that BRG1 and SOX4 form a complex at the TGFBR2 promoter and enhancer region to regulate TGFBR2 expression.

**Conclusions:**
In this study, we demonstrated that BRG1-SOX4 constitutes a novel and essential signaling pathway which promotes PI3K/Akt activity through TGFβ signaling in TNBC/basal-like breast cancer and leads to activation of additional, drug-able kinases. Given the essentiality of BRG1 and SOX4, our data suggest that targeting this interaction and/or the down-stream components of this pathway may represent a novel therapeutic strategy in TNBC.
A novel druggable target upstream of Notch: MEK5/ERK5 signaling regulates Jagged-1 and Notch1 expression in triple negative breast cancer stem cells

Deniz A Ucar, Margarite D Matossian, Van T Hoang-Barnes, Fokhrul M Hossain, Mohit Gupta, Hope E Burks, Thomas D Wright, Jane Cavanaugh, Patrick Flaherty, Matthew E Burow and Lucio Miele. 1LCRC, New Orleans, LA; 2Tulane Medical School, New Orleans, LA; 3Duquesne University, Pittsburgh, PA and 4NIH, Frederick, MD.

Triple negative breast cancer (TNBC) is a molecularly heterogeneous, clinically aggressive disease group that is highly prevalent among African-Americans and younger patients. Standard chemo/radio therapy often produces clinical responses, but recurrence and metastasis are unfortunately common. Metastatic disease is generally incurable. Chemo/radiotherapy has been shown to induce EMT and enrich a chemo-resistant cancer stem-like cell (CSC) population in TNBC. CSCs are thought to drive disease recurrence. Notch signaling is critical for maintenance of TNBC CSC. Expression of Notch1 and its ligand Jagged1 are correlated with poor prognosis. Efforts to pharmacologically target Notch with Gamma Secretase Inhibitors (GSIs) have been impaired by the systemic toxicity of the GSIs, and by the fact that Notch1 also plays a key role in anti-tumor adaptive immunity. Therapeutic agents that indirectly and selectively target Notch signaling in breast cancer cells would be a potentially attractive strategy. However, no such agents have been identified to date. We have found that the MAPK5-ERK5 kinase pathway, which contains at least two druggable targets, functions as a master regulator of Notch signaling in TNBC cells. ERK5 knockout TNBC cells have dramatically decreased expression of Notch receptors, ligands and transcriptional targets. In vivo, these cells form barely detectable tumors that do not metastasize and express lower levels of Notch1 and its ligand Jagged1. Using in silico screening, we identified a class of compounds that selectively target MAP2K5 (MEK5) and decrease the phosphorylation of MAPK7 (ERK5). We selected compound SC-181 for further study. Consistent with ERK5KO cells, pharmacological suppression of ERK5 phosphorylation with SC-181 decreased Notch1 and Jagged1 mRNAs and proteins. SC-181 reversed EMT and reduced the CD44hi/CD24lo CSC population in TNBC cells, but had no effect on T-cell proliferation. SC-181 decreased the number and size of mammospheres in a concentration-dependent manner. Overexpression of the Notch1 intracellular domain (N1IC) in ERK5KO cells rescues their phenotype, dramatically increasing the CSC fraction and promoting EMT. Our results suggest that targeting the MEK5-ERK5 pathway is a promising new strategy to selectively modulate Notch signaling in TNBC CSC without compromising tumor immunity.
S100A7 enhances triple negative breast cancer growth and metastasis by cross-talk with resistin

Sanjay Mishra1, Dinesh K Ahiwar1, Rajni Kant Shukla1, Nabanita Chatterjee1 and Ramesh Ganju1. 1The Ohio State University, Columbus, OH.

Triple negative breast cancer (TNBC) represents ~20% of all breast cancer cases and is highly refractory to existing therapies. Although, a number of putative functions have been proposed for S100A7, but its crosstalk with resistin in TNBC pathogenesis remains to be defined. S100A7/RAGE signaling has been shown to play an important role in inflammation-mediated breast cancer pathogenesis. S100A7/psoriasin, a member of the epidermal differentiation complex, is widely overexpressed in invasive estrogen receptor (ER)α-negative breast cancers. Thus, the objective of this study is to explore the cross-talk between S100A7 and resistin in TNBC cells. In this study, we observed that the treatment or overexpression of S100A7 increased the expression of resistin, cPLA2 and FASN expressions in TNBC cells. The overexpression/downregulation of S100A7 with exogenous resistin in TNBC cells also showed the marked changes in their migrating, sphere forming and colony forming abilities. The treatment of resistin also increases the effect of S100A7-mediated expansion of breast cancer stem cells (BCSCs) by increasing the ALDH activity and CD44+CD24- subpopulations. The in-vivo effects of resistin on breast tumor growth and metastasis were also analyzed by using MDA-MB-231 vector and S100A7 overexpressed MDA-MB-468 vector and S100A7 knock-down cells by using Xenograft NOD/SCID Il2rg null (NSG) mice model. Here, we have found that the treatment of resistin increased the tumor growth and metastases mediated by S100A7 by modulating the different myeloid cells populations. We have also shown that the S100A7 overexpressed MDA-MB-231 cells were much more sensitive to FASN and cPLA2 inhibitors as compared to vector control cells. The in-silico analyses also showed the clinical significance of S100A7 and resistin in TNBC pathogenesis. Collectively, these findings suggest the novel cross-talk in between S100A7 and resistin in TNBC pathogenesis and how resistin, cPLA2 and FASN could be used as potential therapeutic targets to inhibit the S100A7-mediated TNBC progression and metastasis.
PTEN expression at the nexus of oncogenic signals in TNBC: Testing combination of p110beta-isoform-specific inhibitor with five PARP inhibitors

Nandini Dey¹, Jennifer H Carlson¹, Pradip De¹ and Brian Leyland-Jones¹. ¹Avera Cancer Institute, Sioux Falls, SD.

Background: TNBC is the most aggressive form of BRCA-associated BC subtype. The loss of PTEN is a common “first event” associated with basal-like subtype (Martins et al., 2012) and this mode of PI3K-pathway activation (deletion/mutation/loss of PTEN) occurs more frequently (35%) than PIK3CA (5-10%) mutations in TNBC (Ellis & Perou, 2013). Several reports suggest upregulation of PI3K/AKT mediated by PTEN loss depends on the PI3Kbeta-isoform. PARP1 is identified as a target of BRCA-defined cancers. Inhibitors of PARP1 have been recently approved by the FDA as targeted agents in BRCA-defined breast cancers. Failure to repair damaged DNA upon PARP inhibition causes accumulation of DNA double-strand breaks and leads to apoptosis of cancer cells. Also, nuclear PTEN controls DNA repair (Bassi et al., 2013). Here we hypothesized that a combination of PARP inhibitor with p110beta-isoform-specific inhibitor would sensitize the effect of PARP inhibitor(s) in PTEN-deprived TNBC model.

Methods: We tested five PARP inhibitors, Talazoparib (BMN673, B), Niraparib (N), Olaparib (O), Rucaparib (R) and Veliparib (V) in combination with p110beta specific inhibitor, AZD6482. Four PTEN-null TNBC cell lines (BRCA WT/null), MDA-MB468, HCC70 (p.F90fs*9), BT549 (p.V275fs*1) and SUM149 cell lines were used for the study. Proliferative, apoptotic and PARylation signals following drug combinations were demonstrated by WB in a dose and time-dependent manner. Pro-apoptotic and anti-proliferative effects were verified using complementary 3D ON-TOP assay, real-time proliferation (Incucyte), AnnexinV and cl-caspase3 analyses. As an internal control, we also compared anti-proliferative signals of GDC-0032 (p110 beta sparing inhibitor) and GDC-0941 (pan PI3K inhibitor) with that of AZD6482 at 3/6 hours in MDA-MB468 and SUM149 cells. Mode of apoptosis was tested using triple fluorescence staining in live cells. Results: A dose of 500 nM BMN673 alone was effective in slowing cell proliferation and induced apoptosis. AZD6482 (5-10 uM) did not have anti-proliferative or pro-apoptotic effects at 48 and 72 hours. When compared, combinations of different PARPi (100nM of B, 1uM of N, 10uM of O, 10uM of R and 10uM of V) with AZD6482 abrogated 3D growth in BT549 and MDA-MB468 TNBC cells in a time-dependent manner. The effect of PARP inhibitor was tested by PAR signals which were abrogated either alone or in combination with carboplatin in both BRCA1/2 WT and mutated cells. The most pronounced anti-tumor effect was observed with the combination of B and AZD6482 which was mechanistically explained by the robust increase of AnnexinV positive cells following a single 500nM dose of B at both 48 and 72 hours. Pan PI3K inhibitor, GDC-0941, and AZD6482 blocked the activation of PI3K and its downstream effectors in contrast to p110 alpha-specific inhibitor, GDC-0032 in MDA-MB468 and SUM149 cells. Summary: We demonstrated a remarkable sensitivity of tumor cells to PARP inhibition in PTEN-defined TNBC models and identified PTEN-nullness as a potential predictive biomarker for a possible co-targeting of the PI3K pathway to further sensitize TNBC to PARP inhibitors.
Introduction: several retrospective studies suggest that βAR blocking drugs (BB) are associated with improved survival in patients with a wide range of cancers. Recently, we retrospectively showed an association between BB intake and improved progression free survival in patients with HER2 negative advanced breast cancer (BC), particularly striking in triple-negative disease (TNBC) (Reference). Based on this finding we decided to conduct an in silico study in which we have interrogated βARs in a publicly available BC sample database and the Translational Oncology Research Lab (TORL) translational platform with a genomic, transcriptomic and proteomic approach. Methodology: genomic and transcriptomic data sets for βAR 1, 2 and 3 were retrieved from cBioPortal considering all BC samples available with this information in The Cancer Genome Atlas (TCGA). Transcriptomic and proteomic data sets from 48 BC cell lines obtained from TORL were queried for βARs as well and used with validation and exploratory intent. Mutations, amplifications and deletions were queried in DNA; gene expression profiles were interrogated using RNAseq data together with protein expression by RPPA. Average expression, log ratio and fold change in mRNA and Reverse Phase Protein Array (RPPA) quantitative assessments for corresponding proteins were noted. BC cell lines with top 10 mRNA and protein levels of βAR 1, 2 and 3 were identified. Results: CBioPortal DNA data shows β AR1 amplified in 1-10% and deleted in 0,4%; β-AR2 amplified in 1-3% and deleted in 0,1%; β-AR3 amplified in 15-20% and deleted in 2% of the BC samples. CBioPortal mRNA data shows β-AR1 is upregulated in 2.7% (mostly Progesterone Receptor negative BC); βAR2 is upregulated in 4% (mostly TNBC); βAR3 is upregulated in 4% (mostly HER2 negative BC) in BC samples. TORL cell line panel shows that βARs are heterogeneously expressed between the BC cell lines (fold change range: βAR 1 2.015-3.636; βAR 2 2.545-8.248; βAR3 1.809-2.444). Within the 10 BC cell lines with highest βAR1 and βAR2 expression, 7(COLO-824, HCC1937, BT-549, BT-20, HCC1599, HCC1143, HCC1806) and 6 (184A1, MDA-MB-231, 184B5, HCC1806, MCF-10A and MDA-MB-468) of them respectively correspond to the basal BC subtype. RPPA identifies caveolin 1, PAI 1, EGFR and Bax as the proteins with the higher co-expression with βAR1 and βAR2. Conclusions: DNA alterations are infrequent in βARs in BC samples. Transcriptional mRNA data from BC samples shows βARs mostly expressed in non-luminal BC subtypes, being βAR 2 the one with highest expression. In silico data results from BC cell line panel show βAR 1 and βAR 2 are highly expressed in basal BC subtype. The above data suggest that βAR, and βAR 2 in particular could be a relevant target to explore in in vivo BC models.

Preclinical evaluation of the PI3Kα/δ inhibitor, copanlisib in HER2+ breast cancer: A proof of concept study

Pradip De¹, Jennifer H Carlson¹, Nandini Dey¹ and Brian Leyland-Jones¹. ¹Avera Cancer Institute, Sioux Falls, SD.

**Purpose:** The PI3K-AKT-mTORC1/C2 pathway is frequently activated in HER2+ breast cancer and upregulation of this pathway is a key mechanism of trastuzumab resistance. However, attempts to indirectly target this pathway by using the allosteric mTOR inhibitor everolimus have had limited clinical success. Here, we present the results of a preclinical study of the PI3Kα/δ (dominant) inhibitor copanlisib alone and in combination with T-DM1, in HER2 amplified cell lines including a model with acquired resistance to trastuzumab.

**Method:** Anti-proliferative, apoptotic, cell cycle, and intracellular signaling effects of copanlisib alone and in combination with T-DM1 were evaluated in a panel of HER2 amplified (ER+ or ER-), and HER2 amplified/PIK3CA mutated cell lines, as well as trastuzumab-resistant breast cancer cell lines.

**Results:** 1) Copanlisib inhibited PI3K, mTOR and their downstream signaling molecules in HER2 amplified/PIK3CA WT or PIK3CA mutated as well as in trastuzumab-resistant cell lines, 2) interestingly, copanlisib also inhibited RAS-MAPK signaling in the earlier time points, 3) copanlisib caused a strong differential growth inhibition in HER2 amplified BC cell lines by 3D-ON-TOP clonogenic assay and real-time monitoring in an IncuCyte Zoom. Inhibition was greater when copanlisib was combined with T-DM1, 4) administration of copanlisib induced cell cycle G0/G1 arrest and resulted in increased apoptosis in a dose-dependent manner, 5) unlike everolimus copanlisib blocked HIF1α accumulation in hypoxic condition and this blocking effect was reversed by prior treatment with the proteasome inhibitor, carfilzomib and 6) copanlisib also attenuated HER2 amplified cell migration, an important phenotypic feature for metastasis.

**Conclusions:** Copanlisib is highly effective (blocks proliferation, induces apoptosis, and inhibits PI3K and its downstream signaling targets) in HER2 amplified breast cancer cell lines including trastuzumab-resistant and PIK3CA mutated cell lines. The addition of copanlisib to T-DM1 might represent an improved treatment strategy for patients with refractory metastatic HER2+ breast cancer.
Autocrine motility factor signaling pathway promotes aggressive behavior and migration in breast cancer

Cassie Liu1,2, Jeffrey D Price1,2, Dulce Maroni1,2, Jadd M Stevens3, Amaris Z VanDyke3, Pamela A Althof3, Pinaki Mondal1,2, Jennifer N Sanmann3 and Sarah P Thayer1. 1University of Nebraska Medical Center, Omaha, NE; Fred and Pamela Buffett Cancer Center, Omaha, NE and 3Human Genetics Laboratory, Munroe-Meyer Institute for Genetics and Rehabilitation, University of Nebraska Medical Center, Omaha, NE.

Background: Autocrine motility factor (AMF) is secreted by cancer cells and acts in an autocrine or paracrine fashion to bind to its receptor, AMFR, at the cell surface of tumor cells. The AMF-AMFR pathway has been shown to promote proliferation, anti-apoptosis, motility and migration, invasion, and metastasis pathways in various cancers. However, our understanding of the AMF-AMFR pathway in breast cancer is limited. We propose that the AMF signaling pathway is an unexplored mechanism for breast cancer tumor aggression and its receptor, AMFR, may be a potential therapeutic target.

Methods: Tumor tissue obtained from consented female (n = 31) and male (n = 1) patients were analyzed by the Affymetrix Oncoscan™ genome-wide microarray platform and examined for somatic copy-number alterations (SCNAs) of AMFR. cBioPortal was used to investigate SCNA of AMFR and gene expression of AMF on primary breast cancer tumors from METABRIC (n = 1,784) and TCGA Pan-Cancer Atlas (n = 981) datasets. In vitro, AMF and AMFR gene expression in luminal A (MCF-7) and triple-negative breast cancer (MDA-MB-231) cell lines were assessed by qPCR. Cell migration assays were performed on MDA-MB-231 cells to investigate their migration towards AMF with AMFR present or knocked down by siRNA.

Results: Microarray analysis of 32 tumors revealed that a single-copy loss of AMFR occurred 79% of the time in luminal A tumors (n = 19); 67% of the time in luminal B tumors (n = 6); 33% of the time in ER+, PR+, HER2+ tumors (n = 3); and 0% of the time in triple-negative breast cancer (TNBC) tumors (n = 4), suggesting that the loss of AMFR results in less aggressive tumors that have good overall prognosis. To extend our findings to a larger patient cohort, SCNA analysis of the METABRIC and TCGA Pan-Cancer Atlas datasets revealed that single-copy loss of AMFR occurred in 64.53% and 68.14% of luminal A tumors, 58.51% and 59.90% of luminal B tumors, 23.62% and 48.72% of HER2 overexpression tumors, and 29.80% and 39.77% of TNBC tumors, respectively. Therefore, AMFR appears most frequently deleted in the tumor genomes of good prognosis breast cancer molecular subtypes (luminal tumors). Gene expression analysis of AMF in the METABRIC (using z-scores) and TCGA Pan-Cancer Atlas datasets revealed that single-copy loss of AMFR occurred in 64.53% and 68.14% of luminal A tumors, 58.51% and 59.90% of luminal B tumors, 23.62% and 48.72% of HER2 overexpression tumors, and 29.80% and 39.77% of TNBC tumors, respectively. Therefore, AMFR appears most frequently deleted in the tumor genomes of good prognosis breast cancer molecular subtypes (luminal tumors). Gene expression analysis of AMF in the METABRIC (using z-scores) and TCGA Pan-Cancer Atlas datasets revealed median mRNA expressions of -0.3351 and 4862 in luminal A tumors, -0.05415 and 5841 in luminal B tumors, 0.5758 and 9390 in HER2 overexpression tumors, and 0.754 and 8798 in TNBC tumors, respectively, suggesting that the AMF-AMFR pathway is more active in aggressive breast cancers. Similarly, we observed that AMF and AMFR are transcriptionally overexpressed by 7-fold and 16-fold, respectively, in the TNBC cell line MDA-MB-231 compared to the luminal A breast cancer cell line MCF-7. When AMFR is knocked down in MDA-MB-231 cells, focused migration towards AMF is abolished.

Conclusion: AMF-AMFR pathway activity correlates with aggressive cancer cell behavior and enhanced migration in breast cancer. Single-copy loss of AMFR in tumor genomes is associated with less aggressive tumors with better overall prognosis. AMFR may be an attractive therapeutic target.
A cholesterol-derived oncometabolite and glucocorticoid receptor signaling in triple negative breast cancer cell proliferation

Arnaud Mallinger¹², Florence Dalenc¹²³, Marc Poirot¹² and Sandrine Silvente-Poirot¹². ¹Cholesterol Metabolism and Therapeutic Innovations, Cancer Research Center (CRCT), UMR 1037, Toulouse, France; ²Université Paul Sabatier, Toulouse, France and ³Institut Claudius Regaud, Institut Universitaire du Cancer-Oncopole, Toulouse, France.

**Rationale:** A role for cholesterol in the etiology of cancers has been suspected. Our recent data have shown that it is the metabolism of 5,6-epoxide cholesterol (5,6-EC) that is deregulated in breast cancers (BC), and this metabolism controls BC development (Voisin et al, PNAS 2017). Indeed, in normal breast tissues, the 5,6-ECα and β are transformed by the cholesterol epoxide hydrolase (ChEH) into cholestane triol (CT). In BC including triple-negative subtype (TNBC), CT is further transformed into the oncometabolite 6-oxo-cholestan-3β,5α,5α-diol (OCDO) by the 11β-hydroxysteroid dehydrogenase-type 2 enzyme (11βHSD2). 11βHSD2 is known to regulate glucocorticoid metabolism by converting the active glucocorticoid receptor agonist cortisol into inactive cortisone. We established that OCDO promotes BC progression by binding to the glucocorticoid receptor (GR). Patient BC samples showed significant increased OCDO levels and greater ChEH and 11βHSD2 protein expression compared with normal breast tissues and 11βHSD2 and ChEH overexpression correlated with a higher risk of patient death, highlighting that the biosynthetic pathway producing OCDO is of major importance to BC pathology. Interestingly, data from the literature indicate that GR overexpression is correlated with poor progression-free and overall survival in patients with TNBC.

**Objective:** The aim of this study was to decipher the signaling pathways inducing the pro-proliferative activity of OCDO in TNBC cells.

**Material and methods:** OCDO was from Steraloids. Cortisol, Dexamethasone and SP600125 (SP) were from Sigma-Aldrich. **Culture:** MDA-MB231, ShC MDA-MB231 and ShGR MDA-MB231 cells were grown in DMEM supplemented with 10% FBS and 2 mM L-glutamine. **PCR quantitative.** qRT-PCR was performed with an iCycler iQreal-time PCR detection system using SYBR Green. RNA expressions of genes of interest were determined using the ∆∆CT method. **Cell Cycle Analysis.** Cell cycle analysis was performed by flow cytometry analyzer. **SPR Assays.** Binding studies were performed on a BIAcore T200 optical biosensor instrument. GST-tagged LBD of human GR (Thermo Fisher Scientific) was covalently coupled to the chip surface using amine coupling (CM5) sensor chips. A low mass weight–multiple-cycle kinetics analysis, to determine affinity constants, was carried out by injecting different concentrations of the indicated ligand (6.25 µM–100 µM).

**Results:** We established that OCDO binds to the GR, activates its translocation into the nucleus and the transcription of genes under the control of the AP-1 complex, while cortisol or dexamethasone represses their transcription. We showed that OCDO stimulates cell cycle progression by increasing the percent of the G2/M phase. OCDO increases the expression of cyclin D1 and c-myc proteins and the phosphorylation of c-jun forming the AP1 complex. All these effects were abolished when GR expression is knocked-down or when tumor cells are treated with OCDO and SP600125, an inhibitor of the c-Jun N-terminal Kinase pathway (JNK). These data indicate that OCDO mediates cell cycle progression by acting through the GR and by activating the JNK pathway and the oncoprotein c-jun.

**Conclusion:** Targeting this oncometabolism and GR signaling may be novel strategies to treat TNBC.
Genetic background determines the algorithm of effectiveness of targeted drugs of RAS and PI3K pathways in TNBC: Testing a combination of MEK 1/2 inhibitor with mTOR kinase inhibitor or AKT inhibitor

Jennifer H Carlson¹, Pradip De¹, Nandini Dey¹ and Brian Leyland-Jones¹. ¹Avera Cancer Institute, Sioux Falls, SD.

Introduction: Most TNBC patients with single-agent targeted therapy in multiple clinical trials develop resistance, leading to disease progression, posing a major challenge in clinical management of mBRCA. In TNBC patients there remains a lack of obvious predictive biomarkers to guide targeted therapy. Although signaling mechanisms of resistance may be either intrinsic or acquired, the role of driver pathways are known be associated with oncogenic evolution of tumor cells to a resistant state. As the PI3K-AKT-mTOR1/2 (PAM) pathway is activated in TNBC (due to alterations in EGFR, 50%; PTEN, 40%; and PIK3CA, 5-10%), the PAM pathway is a candidate for potential molecular targeting of anti-cancer therapeutics. Despite the involvement of PI3K pathway activation in TNBC tumors, single agent PI3K inhibitors show modest clinical activity. Literature references suggest extensive cross-talk exists between the (PAM) and the RAS-RAF-MEK-ERK (MAPK) pathways. Here we tested the efficacy of a combination of MEK 1/2i (AZD6244, GDC0973) with mTOR kinasei (AZD2014, TAK228) or AKTi (AKT5363) in TNBC models.

Methods: TNBC cell lines with alterations in KRAS/RAF (MDA-MB231), BRCA-deficient PTEN-loss (SUM149), PTEN-loss (MDA-MB468) and PIK3CA mutation (BT20) were used. Proliferation, apoptosis, cell cycle and 3D clonogenic growth were tested following drug treatment alone or in combination. Signaling events in the respective pathways following drug treatment were interrogated by WB.

Results: MEKi led to a brief proliferation inhibition in MDA-MB231 cells. A combination of MEKi and mTORi was additive in decreasing short term proliferation and 10 day 3D growth. AKTi alone had limited effect on 3D growth but in combination with MEKi was profoundly inhibitory. A limited effect of MEKi was observed in BT20 cells; blocking 2D and 3D growth, while a profound effect of MEKi was observed in combination with mTORi (to a lesser extent with AKTi). In MDA-MB468 cells, MEKi did not have an initial appreciable effect (proliferation and G1 arrest), though 3D growth was significantly reduced at 10 days following drug alone or in combination with AKTi. SUM149 cells had G1 arrest with no appreciable change in 3D growth following MEKi. In contrast, single agent mTORi and AKTi reduced 3D growth. MEKi and mTORi doublet slowed proliferation, increased apoptosis and disrupted 3D growth. No single agent treatment with AKTi or mTORi disrupted colony formation however either agent in combination with MEKi blocked 3D growth. Single agents treatments were mostly cytostatic with no increase in apoptosis while a doublet of MEKi plus mTORi induced significant apoptosis. A combination of MEKi with PI3K pathway specific inhibitor significantly blocked phosphorylation of downstream effector molecules. Upregulation of ERK signals following PAM pathway inhibitors were abrogated by prior addition of MEKi. Summary: Combined blockade of the PAM and MAPK pathways (AKTi or mTORi) plus MEK1/2 inhibitor were more effective in attenuating molecular signals. This combination showed enhanced efficacy in TNBC cell models with specific PAM and or MAPK pathway alterations.
Role of nucleus-specific intergenic long noncoding RNA-1476 in estrogen-dependent transcription in cancer

Ramesh Choudhari¹, Alana L Harrison¹, Celeste N Carrillo¹ and Shrikanth S Gadad¹. ¹Texas Tech University of Health Sciences Center, El Paso, TX.

Long noncoding RNAs (lncRNAs) are emerging as key regulators of diverse cellular processes, but their roles in cancer biology are just beginning to be elucidated. Previous work using Global Run-On sequencing (GRO-seq) to study the transcriptome of MCF-7 breast cancer cells identified a large number of unannotated noncoding RNAs. Integration of RNA-seq data from subcellular fractionated RNA (i.e., cytoplasm, nucleoplasm, and chromatin-associated) with GRO-seq data using a novel bioinformatics pipeline has yielded a comprehensive catalog of >1900 polyadenylated lncRNAs in MCF-7 cells, about half of which have not been annotated previously and about a quarter of which are estrogen-regulated. Analysis of RNA-seq data from hundreds of samples representing 13 different cancer and normal tissue types, revealed that many lncRNAs are differentially expressed in various cancers. Furthermore, a large number of lncRNAs show distinct expression patterns across molecular subtypes of cancer. In functional assays, Kaplan Meier analysis of selected lncRNA, such as lncRNA 1476, predicts clinical outcome in ER-positive cancer and is transcriptionally upregulated in MCF-7 cells upon estrogen treatment. LncRNA1476 has now been fully annotated (transcription start and stop site, 5’ cap, polyA tail, and exon/intron structure), and cloned. Molecular analyses indicate that lncRNA1476 plays a critical role in ER-dependent pathway. Collectively, our results suggest that lncRNAs are essential in controlling biological processes.

Human papillomavirus (HPV) DNA detection in breast cancer by liquid biopsy: Something new on the horizon?

Sara Bravaccini¹, Sara Ravaiolí¹, Andrea Rocca¹, Roberta Maltoni¹, Carlotta Cristalli², Elena Marasco², Sabrina De Carolis², Monica Cricca² and Massimiliano Bonafè¹,². ¹Istituto Scientifico Romagnolo per lo Studio e la Cura dei Tumori (IRST) IRCCS, Meldola, FC, Italy and²Alma Mater Studiorum, University of Bologna, Bologna, Italy.

**Background**
The presence of human papillomavirus (HPV) DNA in breast cancer (BC) tissues has been widely investigated in recent years. HPV DNA has been detected in ductal lavage fluids and in serum-derived extracellular vesicles of patients with benign or in situ breast lesions. However, there are no data attesting to its presence in liquid biopsies of different BC subtypes or to its impact on prognosis.

**Methods**
We analyzed a total of 72 serum samples for the presence of circulating HPV DNA, of which 20 were from luminal A BC (5 relapsed, 15 non relapsed), 17 from luminal B BC (5 relapsed, 12 non relapsed), 15 from triple-negative BC (6 relapsed and 9 non relapsed), 12 from HER2-positive BC (3 relapsed, 9 non relapsed) and 8 from healthy subjects. Circulating DNA was extracted and purified from 500 µl of serum by Qiamp DNA minikit (Qiagen, Milan, Italy) according to the manufacturer’s instructions. HPV DNA was assessed by a high-throughput MALDI-TOF mass spectrometry-based method (Mass Array Platform, Agena Bioscience, Hamburg, Germany). The DNA target sequence was amplified by a multiplex PCR with HPV E6 or E7 gene-specific primers. A primer for primer extension annealing to the amplified product was extended at its 3′ terminal base for each HPV type.

**Results**
HPV DNA was detected in 5 BC patients but in none of the healthy controls. None of the serum samples analyzed showed HPV DNA types 16 or 18. Four of the 5 BC cases had high-risk HPV DNA (type 39, 45, 52, 59) and one had low-risk HPV DNA (type 73).

TN, triple negative; CIN 1: low-grade cervical intraepithelial neoplasia

The 4 patients with high risk HPV DNA had low-grade cervical intraepithelial neoplasia (CIN 1) detected by Pap smear prior to the diagnosis of BC. No relation was found between HPV infection and tumor subtype or prognosis. Our in vitro studies also revealed the active release of HPV DNA into the extracellular vesicle compartment of cervical cancer cells.

**Conclusions**
Our findings support the feasibility of HPV DNA evaluation by liquid biopsy in BC. They also suggest that circulating HPV DNA in BC patients might be of cervical tissue origin and that the presence of HPV DNA in BC may be a consequence of its spreading from virus-infected tissue such as that of the uterine cervix.
Chemotherapy-induced metastasis: Mechanisms and translational opportunities

Background: Chemotherapy has become essential in the care of patients with advanced breast cancer. However, as we have previously discovered, chemotherapy may induce pro-metastatic changes in the breast cancer microenvironment by promoting the assembly and function of cancer cell intravasation sites called tumor microenvironment of metastasis (TMEM), and by increasing the proportion of the highly-invasive MenaINV-HI tumor cells that utilize TMEM sites for hematogenous dissemination. Consequently, chemotherapy-treated animals demonstrate increased numbers of circulating-tumor cells and micrometastases. Since the formation of metastases depends on both the presence of functional doorways for dissemination (TMEM) and cancer cells capable of using these doorways (MenaINV-HI tumor cells), we investigated the cellular and molecular contexts required for chemotherapy-mediated induction of TMEM function and MenaINV expression. Since TMEM function depends on Tie2 expressing macrophages and MenaINV expression is inducible by cancer cell-macrophage contact, we focused on inhibiting Tie2 receptors and chemotherapy-induced macrophage influx to inhibit chemotherapy-induced metastasis.

Materials and Methods: We used spontaneous models of mouse breast carcinoma (MMTV-PyMT) and patient-derived xenografts treated with chemotherapy with or without co-treatment with either Tie2 inhibitor (rebastinib), inhibitors of Cxcr4+ macrophage chemotaxis (Cxcl12 inhibitors) or macrophage depletion agents (clodronate). Pro-metastatic endpoints were measured by intravital imaging, multichannel immunofluorescence and standard metastasis dissemination assays.

Results: We demonstrated, using multiple methods of macrophage suppression, that chemotherapy-mediated induction of MenaINV-HI tumor cells depends on the presence of macrophages. In particular, depletion of either the entire macrophage lineage using clodronate liposomes or the use of specific inhibitors of the Cxcl12/Cxcr4 chemotactic pathway, resulted in a significant suppression of the MenaINV-HI cancer cell subpopulation in all mammary tumors examined. Moreover, inhibition of Tie2 by rebastinib blocked TMEM function and decreased the number of circulating tumor cells and metastatic foci, despite the chemotherapy-mediated induction of MenaINV-HI tumor cells.

Conclusions: Our data indicate that both the MenaINV-HI disseminating cancer cell population and the TMEM doorways are necessary but not individually sufficient for metastasis. As such, suppression of either the MenaINV-HI population or TMEM function can suppress chemotherapy-induced metastasis, thus providing a target to improve clinical care and eliminate non-beneficial effects of chemotherapy.
Age-related genetic and epigenetic changes in estrogen-receptor positive breast cancer

Eugene F Schuster1,2 and Mitchell Dowsett1,2. 1Breast Cancer Now Research Centre at The Institute of Cancer Research, London, United Kingdom and 2Ralph Lauren Centre for Breast Cancer Research at the Royal Marsden Hospital, London, United Kingdom.

**Background:**
Age is the main risk factor for developing breast cancer (BC) in women. The increase in incidence with age is dominated by estrogen receptor positive (ER+) BC despite the >90% reduction of estrogen levels during menopause and later life. Recent models suggest the lifetime risk of BC is correlated with the number of stem cell divisions with random mutations arising during each division and driving cancer development. However, only two genes are mutated in more than 20% of BC while several recurrent copy number alterations (CNAs) occur in more than 50%. New models of age-related risk factors need to be developed that incorporate mutations, CNAs, epigenetics, and other biological factors. As data of this type is limited in normal breast tissue, factors correlated with age of diagnosis in ER+ BC were identified to understand which variables changed with age and might impact risk of developing BC.

**Methods:**
*In silico* analysis of public databases was used to identify factors in ER+ primary BC and normal adjacent tissue (NT) that are correlated with age of diagnosis including DNA mutations, CNAs, DNA methylation and gene/protein expression (TCGA n=599ER+,113NT; METABRIC n=1435ER+,144NT).

**Results:**
DNA mutations accumulated with age in ER+ BC with the median mutation count below 28 in primary tumors diagnosis in patients <50yr and rising to more than 43 in patients >80yr. However, the two most frequently mutated genes (*PIK3CA* and *TP53*) showed no significant correlation with age. As previously reported, *GATA3* mutation rate was nearly twice as high in younger patients (<50yr=0.25,>80yr=0.12). There was little evidence of a general accumulation of CNAs with age, but there were higher rates of gain in 16p (<50yr=0.42,>80yr=0.51) and loss of 1p (<50yr=0.18,>80yr=0.37) in older patients and lower rates of loss in 6q (<50yr=0.34,>80yr=0.24). The most significant correlations with age related to *ESR1* including expression of *ESR1* mRNA (*rho*=0.39,*P*=1.2e-23 Spearman), ERα protein (*rho*=0.35,*P*=1.7e-15 Spearman), and demethylation of *ESR1* promoter (*rho*=-0.36,*P*=1.6e-13 Spearman). The levels of the activated form of ERα (pS118) also correlated with age but to a much lesser extent than total ERα (*rho*=0.12,*P*=0.01 Spearman). Demethylation and expression of ESR1 were highly correlated (*rho*=-0.50,*P*<1e-16 Spearman). Analysis of data from NT revealed correlation of age of diagnosis, expression of ESR1 (*rho*=0.34,*P*=0.001 Spearman) and demethylation of the *ESR1* promoter (*rho*=-0.22,*P*=0.03 Spearman) but not with ERα expression (*rho*=0.32,*P*=0.19 Spearman) although only 19 NT had protein data.

**Conclusions:**
Analysis of DNA mutations and CNAs fit previous theoretical models with both the result of stochastic processes. In these models, the low impact on fitness from individual mutations allows the accumulation over time while the high fitness costs of CNAs prevent accumulation and are likely acquired in a single catastrophic event. The ability of ER+ BC to progress in the presence of very low postmenopausal estrogen levels may be partly explained by demethylation leading to higher *ESR1* expression and maintenance of ERα activation. In theory, changes in expression and demethylation can be targeted to reduce the age-related increase in risk for developing BC.
Clinical implication of APOBEC3A and 3B in Korean patients with breast cancer

Hye Sung Won¹, Der Sheng Sun¹, Yoon Ho Ko¹, Sun Hyong You¹, Yong Seok Kim¹ and Jeong Soo Kim¹. College of Medicine, The Catholic University of Korea, Seoul, Korea.

**Background:** Apolipoprotein B mRNA-editing enzyme, catalytic polypeptide-like (APOBEC) family is known to function in innate immune system that protects against retrovirus by deaminating cytosine to uracil in single-stranded DNA. APOBEC family has emerged as an endogenous mutator to contribute to the mutation burden in many cancers. We aimed to evaluate the expression of APOBEC3A (A3A), 3B (A3B) mRNA and APOBEC3A-3B deletion polymorphism in Korean breast cancer patients and investigate the correlation between their expression and clinicopathological characteristics.

**Methods:** One hundred thirty-eight patients who underwent surgery for breast cancer in Uijeongbu St. Mary's Hospital between January 2013 and December 2016 were evaluated. RNA and DNA were extracted from 138 breast cancer tissues and 10 adjacent normal breast tissues. The levels of A3A and A3B mRNA transcripts were determined using real-time quantitative PCR. Insertion and deletion PCR assays were performed to detect the APOBEC3A-3B deletion allele. Mutation hotspots in exon 2-11 of TP53 and exon 9/20 of PIK3CA were evaluated using direct sequencing method.

**Results:** The expression of A3B was increased in breast cancer tissues than in normal breast tissues. The median A3B mRNA expression levels in both triple-negative breast cancer and human epidermal growth factor 2-positive breast cancer were significantly higher than in hormone receptor-positive breast cancer. Old age and high ki-67 expression were associated with increased expression of A3A and A3B. Advanced stage, presence of lymph node involvement, and high histological grade were associated with increased expression of A3A. The APOBEC3B deletion allele was found in 78 (56%) tumor samples. There was no significant association between A3A, A3B mRNA levels and the presence of APOBEC3B deletion allele. There was no difference in clinicopathological characteristics according to the presence of APOBEC3B deletion allele except histological grade. The frequency of high histological grade was significantly higher in tumors with APOBEC3B deletion allele than tumors without APOBEC3B deletion allele. TP53 mutations were identified in 12 (8.7%) cases and PIK3CA mutations were identified in 31 (22.5%) cases. There were no significant differences in the levels of A3A and A3B mRNA expression by TP53 mutation status. The presence of a PIK3CA mutation was significantly associated with lower A3A expression.

**Conclusions:** The levels of A3B mRNA expression showed a difference according to breast cancer subtype, and triple-negative breast cancer showed the highest levels of A3B mRNA expression. The high levels of A3A and A3B mRNA expression were associated with an aggressive phenotype including high proliferation index. The APOBEC3A-3B deletion polymorphism was found in about half of the patients, but there was no difference in clinicopathological factors according to the presence of APOBEC3B deletion allele except histological grade.
The WNT pathway gene, LBH, is critically required for breast carcinogenesis by promoting tumor initiation and survival

Koteswararao Garikapati¹, Pingping Chen¹, Kilan Ashad-Bishop¹ and Karoline Briegel¹. ¹Braman Breast Cancer Institute at Sylvester Comprehensive Cancer Center; Miller School of Medicine, University of Miami, Miami, FL.

Background: Cancer stem cells (CSCs) are a small subset of tumor cells with stem cell properties that drive tumor initiation, treatment resistance, and metastasis, thereby leading to rapid disease relapse. However, no cancer stem cell specific treatments are currently available in the clinic. Thus, there is a need to identify novel cancer stem cell-specific molecular targets. LBH (Limb-Bud and Heart), is a poorly characterized transcription co-factor in the WNT pathway, a signaling network that is key to normal stem cell control and cancer stem cell transformation. We previously identified LBH as a basal mammary stem cell specific marker critically required for stem cell self-renewal and maintenance during normal mammary gland development. Significantly, LBH is also abnormally over-expressed specifically in worst prognosis basal-like breast cancers, a treatment-resistant breast cancer subtype that is enriched in cancer stem cells. Moreover, high inter-tumor LBH expression levels correlate with reduced metastasis-free patient survival and increased chemo-resistance. However, the role of LBH in breast carcinogenesis is not known.

Results: To identify the potential role of LBH in breast carcinogenesis, we abrogated LBH expression in breast cancer cell lines with high CSC populations (HCC1395, MDA-MB-231) using shRNA and CRISPR/Cas technologies. Conversely, we stably introduced LBH into more differentiated breast cancer cell lines with low CSC populations (MCF7, BT549). We found that LBH depletion significantly reduced, while LBH overexpression increased in vitro tumor sphere formation and clonogenic ability, suggesting LBH promotes a CSC phenotype. Modulation of LBH expression did not change proliferation rates, indicating the CSC promoting effects of LBH were not due to increased cell proliferation. However, LBH reduced apoptosis rates and increased tumor cell survival. Importantly, loss of LBH markedly decreased in vivo tumor initiation and metastatic potential of triple negative breast cancer cells, which are important functions of CSC. The underlying mechanisms will be discussed.

Conclusions: Collectively our results suggest that LBH is required for breast CSC self-renewal and maintenance. Thus, LBH inhibition may have value for future CSC-targeted anti-cancer therapy.
Evaluation of pan-HER and c-MET inhibitors tested ex vivo in primary HER2- breast cancer cells with hyperactive c-MET and ErbB family signaling

Lance G Laing¹, David J Burns¹, Salmaan Khan¹, Ian A MacNeil¹, Benjamin E Rich¹, Samantha M Kharbush¹, Sajjad M Soltani¹ and Brian F Sullivan¹. ¹Celcuity Inc., Minneapolis, MN.

**Background:** To elucidate the role of c-Met signaling and its involvement with ErbB signaling as a cancer driver, a new assay using an impedance biosensor, the CELx multi-pathway signaling function (CELx MP) test, was developed. The CELx MP Test measures ex vivo real-time live cell response to specific ErbB and c-Met agonists to diagnose breast tumors with hyperactive HER1, HER2, HER3, HER4, and c-MET signaling activity. A recent study quantified c-MET and ErbB-driven signaling activity in epithelial cell samples derived from fresh breast tumor specimens obtained from 74 HER2- breast cancer patients. Of the cell samples tested, 20 of 74, (27.0%; 95% CI=18%-38%) had both hyperactive c-MET signaling and at least one hyperactive ErbB-family receptor signaling. Using primary breast cancer cells with hyperactive c-MET and ErbB signaling and the CELx MP test, the current study set out to: 1) determine the IC₅₀ values of six pan-HER and five c-MET inhibitors; and 2) characterize the efficacy of combinations of each pan-HER inhibitor with each c-MET inhibitor.

**Methods:** Epithelial cells from six HER2- tumor specimens with hyperactive c-MET and ErbB-driven signaling were obtained. Real-time live cell response to specific ErbB and c-Met agonists (NRG1b, EGF, or HGF) alone and in combination, with or without one of six pan-HER antagonists (neratinib, lapatinib, ibrutinib, dacomitinib, sapitinib, poziotinib) or one of five c-MET antagonists (tepotinib, cabozantinib, crizotinib, capmatinib, or savolitinib) was quantified using an xCELLigence RTCA impedance biosensor. Each individual drug IC₅₀ was determined using a 1000-fold, 5-point, dose response curve with a single fixed concentration of a corresponding agonist. For the drug combination efficacy studies, fixed concentrations of the agonist mixture and clinically relevant concentrations of combinations of the antagonists were used to determine the percentage inhibition of the ErbB and c-MET signaling.

**Results:** The IC₅₀ values for the individual c-MET and pan-HER inhibitors ranged from 3.10nM - 28nM and 2.67nM – 137.27nM, respectively. In the drug efficacy studies, an average of at least 80% of the ErbB and c-MET signaling activated by NRG1, EGF, and HGF co-stimulation was inhibited by each combination of c-MET and pan-HER inhibitors.

**Conclusions**: The CELx MP test using live cells measures IC\textsubscript{50} values comparable to those derived using cell-free methods. Every combination of pan-HER and c-MET inhibitors provided comparably high (at least 80%) levels of inhibitory effect *ex vivo*. This suggests the sub-group of HER2- breast cancer patients diagnosed with coincident hyperactive c-MET and ErbB signaling by the CELx Test may respond to virtually any pan-HER and c-Met inhibitor combination. Studying combinations designed to minimize drug toxicities without sacrificing efficacy should thus be possible.
Effects of a soy isoflavone in breast cancer treatment

Minami Hatono1, Hirokuni Ikeda1, Naruto Taira1, Yoko Suzuki1, Yukiko Kajiwara1, Kengo Kawata1, Yuko Takahashi1, Takahiro Tsukioki1, Mariko Kochi1, Takayuki Iwamoto1, Tadahiko Shien1 and Hiroyoshi Doihara1. 1Okayama University Graduate School of Medicine, Dentistry, and Pharmaceutical Sciences, Okayama City, Japan.

Background: Isoflavones are phytoestrogens that may be effective in preventing osteoporosis, reducing cardiovascular events, and improving menopausal symptoms such as hot flash due to their estrogen-like actions. Isoflavones are currently used as a supplement for improving symptoms of menopause. Epidemiological studies have shown that ingestion of soy products may also reduce the risk of breast cancer, and antitumor effects on hormone receptor (HR)-positive breast cancer cells have been shown in vitro for equol, an isoflavone metabolite. Equol binds to estrogen receptors (ERα, β) and is thought to antagonize ERα-estradiol binding in the presence of estradiol. Since equol shows an antiestrogenic effect, similar to that of the hormonal agent tamoxifen, it is thought that equol acts as a selective estrogen receptor modulator (SERM), but the mechanism is still unclear. In this study, we evaluated the antitumor effects of equol alone and in combination with existing therapeutic agents in HR-positive breast cancer cells, and examined the mechanism of these effects.

Methods: The antitumor effects of equol alone and in combination with hormone drugs (4-hydroxytamoxifen (Tam), fulvestrant (Ful)) and chemotherapeutic agents (paclitaxel (Ptx), doxorubicin (Dox)) were examined using a MTS assay. Combination indexes (CIs) were determined in HR-positive MCF-7, T-47D, and ZR-75-1 cell lines. The mechanisms of the drug effects were evaluated by Western blot for assessment of changes in chemoresistance factors at the protein level.

Results: In MCF-7, T-47D and ZR-75-1 cells, there was a concentration-dependent antitumor effect of equol and of the other hormonal agents. CIs showed an antagonistic effect of equol with Tam and a synergistic effect with Ful in all cell lines. Equol also had an antagonistic effect with the two chemotherapeutic agents, with the strongest antagonism occurring at a low dose of equol. Western blot showed that ER, PgR, Cyclin D1 and Bcl-2 were upregulated via ER at a low concentration of equol, similarly to the effect of 17-β-estradiol (E2), and ER, PgR, Cyclin D1 and Bcl-2 were downregulated at a high concentration, similarly to the effect of Tam. In addition, ER, PgR and cyclin D1 were downregulated with the combination of equol and Tam, while the expression of Bcl-2, a chemoresistance factor, increased.

Conclusion: These results suggest that equol has a concentration-dependent antitumor effect in HR-positive breast cancer cell lines and may antagonize the effect of existing therapeutic agents (hormone drugs and chemotherapeutic agents). In particular, it was considered that in combination of equol and Tam, the apoptosis inducing action of each drug was attenuated and antagonistic effect was shown.
Differential expression and localization of beta-catenin and HSP27 after cisplatin/doxorubicin treatment in triple negative breast cancer cells

Gisela E Pennacchio\textsuperscript{1,2,3}, Maria E Cordoba\textsuperscript{1}, Martín E Guerrero-Gimenez\textsuperscript{1,2}, María M Montt-Guevara\textsuperscript{4}, Dario Cuello-Carrion\textsuperscript{1}, Silvina B Nadín\textsuperscript{1}, María L Vargas Roig\textsuperscript{1,2} and Mariel A Fanelli\textsuperscript{1}. \textsuperscript{1}Institute of Medicine and Experimental Biology of Cuyo, (IMBECU) CONICET, Mendoza, Argentina; \textsuperscript{2}Faculty of Medical Sciences, National University of Cuyo, Mendoza, Argentina; \textsuperscript{3}Faculty of Medical, Mendoza University, Mendoza, Argentina and \textsuperscript{4}Molecular and Cellular Gynecological Endocrinology Laboratory (MCGEL), University of Pisa, Pisa, Italy.

The treatment of triple-negative breast cancers (TNBC) involves the administration of the conventional chemotherapeutic drug doxurubicin, given the lack of specific targeted agents. Novel therapeutic strategies, such as cisplatin, are currently being tested for these patients. Many studies have demonstrated that aberrant Wnt/\(\beta\)-catenin signaling serves a role in the development of breast cancer, while others have concluded that abnormal regulation of Wnt pathway induces tumor cell chemoresistance. The small heat shock protein 27 (HSP27) is overexpressed in human breast cancer cells. As a result, cancer cells may suppress apoptosis and develop resistance to antineoplastic agents, such as doxorubicin. The present study sought to examine the role of the Wnt/\(\beta\)-catenin and HSP27 signaling pathway in response to cisplatin (CisPt)/ doxorubicin (Doxo) treatment in human triple-negative (TN) breast cancer cell lines.

**Material and Methods:** MDA-MB231 (TN) and MCF10A cell lines were used. Cell viability was measured using MTT assay and IC\(_{50}\) values were obtained after 48 h of CisPt or Doxo exposition. Cellular senescence was assayed by measuring SAbeta-galactosidase (SA-beta-Gal) activity. Total and active \(\beta\)-catenin, HSP27, phospho HSP27, GSK3\(\beta\), phospho GSK3\(\beta\), p38 and phospho p38 expressions were measured by western blot and immunofluorescence. Apoptosis was measured by cleaved Caspase-3 immunofluorescence.

**Results:** MDA-MB231 cells showed higher IC\(_{50}\) values for CisPt and Doxo than the MCF10A cell line. Increased numbers of senescent cells (larger and flatter) were observed in both MDA-MB231 and MCF10A cells exposed to the IC\(_{50}\) dose of Doxo. In MDA-MB231 cells, CisPt treatment induced caspase-3 cleavage. In MDA-MB231 cells, the expression of \(\beta\)-catenin, active \(\beta\)-catenin, total and phospho-GSK3\(\beta\) and total HSP27 significantly decreased in the CisPt group (p<0.05). No changes were observed in Doxo-treated group. In MCF10A cells, the expression levels of total and active \(\beta\)-catenin did not modify with CisPt treatment, but in the Doxo group the protein have a tendency to increase. Also in MCF10A Doxo treatment significantly decreased the expression of GSK3\(\beta\) in comparison with control (p<0.05). In contrast, CisPt administration significantly increased phospho-GSK3\(\beta\) expression respect to the control group (p<0.05). Interestingly, in MDA-MB231 cells the nucleolus appeared disaggregated and active \(\beta\)-catenin increased at this subcellular localization after CisPt and Doxo treatment, in contrast, total \(\beta\)-catenin was preferentially localized in the Golgi.

**Conclusions:** CisPt treatment was associated with absence of senescence, and decreased expression of \(\beta\)-catenin and HSP27. While in Doxo-treated cells, senescence phenomenon was related to stable levels of \(\beta\)-catenin and increased expression of HSP27. The differential expression and localizations of \(\beta\)-catenin and HSP27 could be related to a differential cellular response depending on the cytotoxicity mechanism of chemotherapeutic agent used, that in turns affect the cell fate decision. Our preliminary data indicate that \(\beta\)-catenin and HSP27 may be potential therapeutic targets in TNBC. G.E.P. and M.E.C. contributed equally to this work.
An assessment of the potential role of intracellular Ca\(^{2+}\) store regulators in breast cancer cells

Alice HL Bong\(^1\), Sarah J Roberts-Thomson\(^1\), Michael JG Milevskiy\(^2\) and Gregory R Monteith\(^{1,3}\). \(^1\)School of Pharmacy, University of Queensland, Brisbane, Queensland, Australia; \(^2\)The Walter and Eliza Hall of Medical Research, Parkville, Victoria, Australia and \(^3\)Mater Research Institute, Brisbane, Queensland, Australia.

**Background:** Calcium (Ca\(^{2+}\)) regulates many crucial cellular processes including cell survival, proliferation and death. Endoplasmic reticulum (ER) Ca\(^{2+}\) store levels are critical in the death-inducing effects of some anti-cancer agents. Modulators of ER Ca\(^{2+}\) signalling, such as neuronal calcium sensor-1 (NCS-1) may therefore represent new therapeutic opportunities to enhance the effect of some anti-cancer agents. NCS-1 is associated with poorer survival in breast cancer patients. However, the expression of NCS-1 in specific breast cancer molecular subtypes and its potential role in intracellular Ca\(^{2+}\) signalling in breast cancer cells has not been fully explored.

**Aim:** To assess expression of NCS-1 in breast cancer molecular subtypes and assess the effect of silencing NCS-1 on intracellular Ca\(^{2+}\) homeostasis and on sensitivity to doxorubicin treatment in MDA-MB-231 breast cancer cells.

**Methods:** NCS-1 levels were assessed in breast cancer molecular subtypes based on PAM50 subtyping using the TCGA public breast cancer database. Intracellular Ca\(^{2+}\) changes as a consequence of siRNA-mediated silencing of NCS-1 were evaluated using a Fluorescence Imaging Plate Reader (FLIPR) in MDA-MB-231 cells expressing the genetically-encoded Ca\(^{2+}\) indicator GCaMP6m. The effect of NCS-1 silencing on MDA-MB-231 cells treated with doxorubicin (0.03 and 1 µM, 24 h) was evaluated by cell nuclear enumeration (Hoechst 33342 staining) and the percentage of dead cells (propidium iodide staining). Images were acquired using an automated epifluorescence microscope (ImageXpress Micro).

**Results:** Levels of NCS-1 were higher in the basal molecular subtype compared to other molecular subtypes. NCS-1 silencing promoted cell death induced by 1 µM doxorubicin. NCS-1 silencing had no major effect on cytosolic free Ca\(^{2+}\) levels as a result of either IP3-mediated Ca\(^{2+}\) store release with the purinergic receptor activator ATP or the protease activated receptor activator trypsin. However, NCS-1 silencing suppressed constitutive Ca\(^{2+}\) influx in MDA-MB-231 breast cancer cells. The expression of NCS-1 was positively correlated with the Ca\(^{2+}\) entry channel Orai1 in breast cancers on the TCGA database. Orai1 is associated with increased migration and invasiveness in some breast cancers.

**Discussion:** These studies suggest that elevation in NCS-1 is a feature of breast cancers of the basal molecular subtype and that NCS-1 is a regulator of the cytotoxic effects of doxorubicin. Further studies are required to determine if this effect is related to changes in constitutive Ca\(^{2+}\) influx that may be mediated via Orai1.
The effect of a subcutaneous combination of testosterone (T) and anastrozole (Ai) (HAVAH T+Ai) on volumetric mammographic breast density (MBD); an open labelled cohort study

Stephen N Birrell¹, Daniella Dougherty², Suzanne B Good³, Nicholas J Birrell¹ and Paul Rolan². ¹HAVAH Therapeutics Pty Ltd, Toorak Gardens, South, Australia; ²The University of Adelaide, Adelaide, South Australia, Australia and ³Wellend Clinic, Toorak Gardens, South Australia, Australia.

MBD is the single greatest modifiable risk factor for the development of breast cancer; this risk can be lessened by reducing MBD. Previous studies suggest breast cancer risk is reduced in women treated with subcutaneous HAVAH T+Ai. As well, HAVAH T+Ai has been suggested to be effective in managing hormone deprivation symptoms in women who have had breast cancer and in perimenopausal women with hormonal dysfunction.

HAVAH T+Ai alters the androgen/estrogen (A/E) ratio in breast tissue by delivering more bioavailable T in the presence of Ai to tissue known to contain high levels of 5alpha-reductase and aromatase, respectively facilitating production of the potent androgen dihydrotestosterone and diminishing conversion of T to estradiol. Alteration of the A/E ratio in favor of an androgenic environment reduces MBD. This study evaluates the effect of HAVAH T+Ai on volumetric MBD.

Methods: 652 women attending Wellend Health Clinic (a clinic that manages perimenopausal symptoms and/or high risk of breast cancer) received HAVAHT+Aï and evaluated for MBD change as determined by a fully-automated volumetric density analysis (VolparaDensity). Women received a HAVAH T+Aï subcutaneous implant every 3-4 month containing 1mg/kg T and a fixed dose of Ai 1-4mg. 142 women had 2 or more mammograms within the analysis period and were included in the final analysis. A restricted analysis set (RAS) of 89 of these women were compared with a matched 65 women undergoing mammographic screening for high risk, but not receiving hormonal therapy. Safety and tolerability data were collected and analyzed.

Results:
Least squares mean estimated (LSME) change in % volumetric breast density (%VBD), by cumulative testosterone dose and time from first implant.

**Comparison with control group:** Analysis of RAS (n=89) versus untreated controls (N=65) revealed statistically significantly different from zero for both %VBD and AVBD between the 2 groups, respectively 2.36%, (95% CI on the difference, from 1.15 to 3.56) and 18.0cm³, (95% CI on the difference, from 4.8 cm³ to 31.1cm³).

**Summary of safety:** The treatment was well tolerated with no serious adverse events.

**Conclusions:** HAVAHTAi™ therapy significantly reduces volumetric MBD with good safety and tolerability. An accumulative dose of greater than 700mg of T and 30mg of Ai over 2-3 years is required to achieve a similar reduction in MBD as that demonstrated with tamoxifen as a preventative agent for breast cancer.
Development of a first-in-class small molecule inhibitor (EC359) targeting oncogenic LIF/LIFR signaling for the treatment of triple negative breast cancer

Suryavathi Viswanadhapalli¹, Yiliao Luo¹, Gangadhara R Sareddy¹, Bindu Santhamma², Mei Zhou¹, Mengxing Li¹, Uday P Pratap¹, Kristin Ann Altweeg¹, Xiaonian Li¹, Uma Srinivasan¹, Shihong Ma¹, Annabel Chang¹, Alejandra Chávez Riveros³, Kam Y Zhang¹, Kalarikal V Dileep⁴, Xinlei Pan⁵, Ramachandran Murali⁵, Marek Bajda⁶, Ganesh Raj⁷, Andrew Brenner¹, Vijaya Manthati², Manjeet Rao¹, Rajeshwar R Tekmal³, Hareesh B Nair⁵, Klaus J Nickisch² and Ratna K Vadlamudi¹. ¹UT Health and Mays Cancer Center, San Antonio; ²Evestra, Inc., San Antonio; ³Instituto de Química, Ciudad de, Mexico; ⁴RIKEN Center for Biosystems Dynamics Research, Yokohama, Japan; ⁵Cidars-Sinai Medical Center, Los Angeles; ⁶Jagiellonian University, Cracow, Poland and ⁷UT Southwestern, Dallas.

**Background:** Leukemia inhibitory factor (LIF) and its receptor LIFR are over-expressed in multiple solid tumors and play a key role in tumor growth, progression, and resistance to standard anti-cancer treatments. Triple-negative breast cancer (TNBC) lacks targeted therapies and represents a disproportional share of breast cancer (BCa) mortality. TNBC exhibits autocrine stimulation of the LIF/LIFR axis and overexpression of LIF is associated with poorer relapse-free survival in BCa patients. LIF signaling also promotes maintenance of stem cells. Therefore, targeting the LIF/LIFR axis may have therapeutic utility in TNBC.

**Methods:** We rationally designed a small organic molecule (EC359) that emulates the LIF/LIFR binding site and functions as a LIFR inhibitor from a library of compounds. In silico docking studies were used to identify the putative interaction of the EC359 and LIF/LIFR complex. Direct binding of EC359 to LIFR was confirmed using surface plasmon resonance (SPR) and microscale thermophoresis technique (MST) assays. In vitro activity was tested using Cell-Titer Glo, MTT, invasion, and apoptosis assays. Mechanistic studies were conducted using Western blot, reporter gene assays, and RNA-seq analysis. Xenograft, patient-derived xenograft (PDX), and patient-derived explant (PDEX) models were used for preclinical evaluation and toxicity.

**Results:** Molecular docking studies showed that EC359 interacts at the LIF/LIFR binding interface. SPR and MST studies confirmed direct interaction of EC359 to LIFR. EC359 reduced the growth of TNBC cells with high potency (IC50 50-100nM) and promoted apoptosis. Further, EC359 treatment reduced invasion and stemness of TNBC cells. EC359 activity is dependent on the expression levels of LIFR and showed little or no activity on TNBC cells that have low levels of LIFR or ER+ve BCa cells. Further, EC359 significantly reduced the viability of cisplatin and taxane-resistant TNBC cells and enhanced the efficacy of HDAC inhibitors. Mechanistic and biochemical studies showed that EC359 interacts with LIFR and effectively blocking LIF/LIFR interactions. EC359 also blocked LIFR interactions with other LIFR ligands such as oncostatin M, ciliary neurotrophic factor, and cardiotrophin-1. EC359 treatment attenuated the activation of LIF/LIFR driven pathways including STAT3, mTOR, AKT, and MAPK. RNA-seq analysis identified regulation of apoptosis as one of the important pathway modulated by EC359. In TNBC xenograft and PDX assays, EC359 significantly reduced tumor progression. Further, using human primary BCa PDEX cultures, we demonstrated that EC359 has the potential to substantially reduce the proliferation of human BCa. Pharmacologically, EC359 exhibited high oral bioavailability and long half-life with a wide therapeutic window.

**Conclusions:** EC359 is a novel targeted therapeutic agent that inhibits LIF/LIFR oncogenic signaling in TNBC via a unique mechanism of action. EC359 has the distinct pharmacologic advantages of oral bioavailability, in vivo stability, and is associated with minimal systemic side effects. (DOD BCRP grant #BC170312)
Insulin receptor isoform signaling in breast cancer

Xihong Zhang¹, Jie Ying Chan¹, Yan Pan², Christopher Dong¹ and Douglas Yee¹. ¹Masonic Cancer Center, University of Minnesota, Minneapolis, MN and ²Peking University, Beijing, China.

Recent data shows that insulin receptor (IR) and the type I insulin-like growth factor receptor (IGF1R) play important roles in breast cancer cell biology. Targeting only IGF1R has not been successful perhaps due to compensation by IR. IR exists in two isoforms, fetal isoform IR-A is a splice variant of IR which excludes exon 11. The adult/metabolic isoform IR-B is the predominant species expressed in normal tissues, while the fetal form IR-A is more highly expressed in breast cancer. IR-A mRNA in endocrine resistant cells is expressed at levels 24-fold higher than IGF1R expression (Gradishar, et al. Clin Cancer Res 22:301 2016 PMID: 26324738). In addition to its homodimer, IR-A can also dimerize with IGF1R to form a hybrid. Homodimer IR-A responds to IGF-II and insulin, while IGF1R/IR-A hybrid can also respond to IGF-I. Previous studies in our lab showed down regulation of IGFIR increases the sensitivity of breast cancer cells to insulin. To further investigate the roles of IR-A and IR-B in breast cancer biology, we cloned IR-A and IR-B isoforms into pLV-mCherry and pLJM1EGFP lentiviral expression vectors. Then MCF-7L breast cancer cells were infected with IR-A, IR-A vector control, IR-B and IR-B vector control. Both pooled and single clones were studied. Our results showed that both IR-A and IR-B were highly expressed in MCF-7L cells with the introduced IR tagged species present at a higher molecular weight confirmed by immunoprecipitation and immunoblot. The lower migrating species was endogenous IR. IR-A-pool/Clones had strong basal IR tyrosine phosphorylation, while IR-B-pool/clones did not. This basal phosphorylation did not activate downstream signaling as measured by pAKT and pErk1,2. IR-A basal phosphorylation was completely inhibited by BMS754807 (0.3µM), a dual IGFIR/IR tyrosine kinase inhibitor. Total levels of IRS1, IRS2, IGF1R, ERa, AKT and Erk1,2 levels were not changed in the over-expressing cells. Ligands-IGF-I (5nM), IGF-II (10nM) and Insulin (10nM) stimulated IGF1R/IR, IRS, AKT and Erk1,2 phosphorylation in IR-A-pool and high expression clone IR-A-G5. Cells expressing IR-A activated downstream signaling (IRS, AKT and Erk1,2) at 0.1nM insulin, while IR-A vector control cells required 1nM insulin. IR-B-pool overexpressing cells were not more sensitive to insulin compared to parental cells. Insulin significantly increased Erk1,2 phosphorylation in IR-A-G5 cell while IGF-I stimulation was minimal. In contrast, Erk1,2 phosphorylation in parental cells and vector control cells was primarily mediated by IGF-I, not insulin. IR-A overexpressing cells were stimulated in monolayer growth by insulin. These data show that IR-A expression, as seen in endocrine resistant breast cancer cells, sensitizes breast cancers to low concentrations of insulin. Thus, IR-A expression could serve as a target in breast cancer.
Enhancing abiraterone acetate efficacy in androgen receptor-positive triple negative breast cancer: Chk1 as a potential target

Thomas Grellety¹,², Céline Callens³, Elodie Richard¹, Marina Pulido⁴, Anthony Goncalves⁵, Pierre Gestraud⁶, Gaetan MacGrogan², Hervé Bonnefoi¹,² and Bruno Cardinaud¹,⁷. ¹INSERM UNIT U1218, Institut Bergonié, Bordeaux, France; ²Institut Bergonié, Comprehensive Cancer Centre, Bordeaux, France; ³Pharmacogenomic Unit, Genetics Laboratory, Institut Curie, Paris, France; ⁴Clinical and Epidemiological Research Unit, Institut Bergonié, INSERM CIC1401, Bordeaux, France; ⁵Aix-Marseille Univ, CNRS, INSERM, Institut Paoli-Calmettes, Marseille, France; ⁶Institut Curie, PSL Research University, Mines Paris Tech, Bioinformatics and Computational Systems Biology of Cancer, INSERM U900, Paris, France and ⁷Bordeaux Institut National Polytechnique, Bordeaux, France.

Purpose: Our aim was to identify predictive factors of abiraterone acetate (AA) efficacy and putative new druggable targets in androgen receptor (AR)-positive triple-negative breast cancer (TNBC) treated in the UCBG 2012-1 trial.

Material and methods: We defined AA response as either complete or partial response, or stable disease at 6 months. Using Ampliseq, we sequenced 91 general and breast cancer-associated genes from the tumor DNA samples. We analyzed transcriptomes from the extracted RNA samples on a Nanostring platform and performed immunohistochemistry (IHC) on tumor samples using tissue microarrays. We assessed AA and CHK1 inhibitors (GDC-0575 and AZD7762) efficacies, either alone or in combination, on cell lines grown in vitro and in vivo.

Results: Classical IHC apocrine markers, including AR, FOXA1, GGT1 and GCDFP15, allowed identifying AA responders and non-responders. All responders have clear apocrine features. Transcriptome analysis revealed that 31 genes were differentially expressed in the two subgroups, 9 of them being linked to proliferation and DNA damage repair. One of the most significant differences was the overexpression in non-responders of CHEK1, a gene encoding Chk1, a protein kinase that can be blocked by specific inhibitors. In vitro, AA and Chk1 inhibitor combination showed additive or slightly synergistic effect on cell viability, cell cycle, apoptosis and accumulation of DNA damages. In vivo, orthotopic xenograft experiments confirmed the efficacy of this combination therapy.

Conclusions: This study suggests that apocrine features can be helpful in the identification of AA-responders. We identified Chk1 as a putative drug target in AR-positive TNBCs.
TP-0903, an AXL kinase inhibitor, reduces inflammatory breast cancer aggressiveness and macrophage polarization through additional mechanisms that may include JAK2 and Aurora B.

Yating Cheng1,2, Yohei Funakoshi1,2, Xiaoping Wang1,2, Steven L Warner3, David J Bearss3 and Naoto T Ueno1,2. 1Morgan Welch Inflammatory Breast Cancer Research Program and Clinic, Houston; 2The University of Texas MD Anderson Cancer Center, Houston and 3Tolero Pharmaceuticals, Inc., Salt Lake City.

**Background:** Inflammatory breast cancer (IBC) is the most lethal and aggressive type of breast cancer; it accounts for 2-4% of breast cancer cases but causes 8-10% of breast cancer deaths. Novel targeted therapy to improve the outcomes of patients with IBC is urgently needed. The receptor tyrosine kinase AXL is a driver for metastasis and drug resistance in various cancers, including breast cancer. Our previous work showed that AXL signaling contributes to the aggressiveness of IBC. In addition, emerging evidence indicates that the tumor microenvironment components, particularly tumor-associated macrophages, are critical drivers of the IBC clinical phenotype and promote IBC metastasis. AXL signaling has been shown to modulate the tumor microenvironment. In the present study, we investigated the impact of TP-0903, a small-molecule AXL kinase inhibitor, with additional activity against Aurora B and Janus kinase 2 (JAK2), on IBC cells and macrophage polarization.

**Methods:** The effects of TP-0903 on IBC cell proliferation, migration/invasion, and mammosphere formation were analyzed. The effects of TP-0903 on the polarization of human monocytic cells THP-1 were tested *in vitro*. In addition, the signaling pathways involved in TP-0903-regulated M2 macrophage polarization were investigated using Western blotting.

**Results:** The half-maximal inhibitory concentration (IC50) of TP-0903 in an array of IBC cells (including SUM149, SUM190, BCX010, FC-IBC-02, MDA-IBC-3, and KPL4) ranged from 66 nM to 346 nM, suggesting a strong cell growth inhibitory effect. TP-0903 treatment decreased the migration, invasion, and mammosphere formation of IBC cells. In addition, TP-0903 inhibited both AXL signaling and Aurora B activation, which induced a G2/M cell cycle arrest in IBC cells. Based on the importance of AXL and JAK2 in the regulation of the tumor microenvironment, we showed that TP-0903 decreased expression of CD163/CD206 and the CCL17/CCL18 cytokine, and markers of M2 macrophages, suggesting that TP-0903 treatment inhibits the polarization of THP-1 cells to M2 macrophages *in vitro*. We also found that TP-0903 treatment decreased the phosphorylation of STAT6, a critical molecule in M2 polarization, and that knockdown of STAT6 expression decreased M2 macrophage polarization, indicating that TP-0903 may regulate macrophage polarization via STAT6 signaling.

**Conclusion:** Our results demonstrated the dual functions of TP-0903 targeting of both IBC cells and macrophages, possibly via the targeting of multiple kinases, including AXL and Aurora B. Examinations of the impact of TP-0903 on the cross-talk between IBC cells and macrophages *in vitro* and *in vivo* and the related mechanisms are ongoing and will be presented at the meeting.
Targeting loss of isoenzyme diversity as a novel therapeutic strategy in breast cancer

Michal Marczyk1,3, Vignesh Gunasekharan1, Vikram B Wali1, Weiwei Shi2, Gauri Patwardhan1, Tao Qing1, Lajos Pusztai1 and Christos Hatzis1. 1Yale School of Medicine, New Haven; 2OrgiMed, Shanghai, China and 3Silesian University of Technology, Gliwice, Poland.

**Background:** Several metabolic steps are mediated by distinct proteins or isoenzymes that catalyze the same reaction, providing redundancy of metabolic functions. Metabolic states are frequently altered in cancer to support survival and proliferation in hypoxic and otherwise hostile microenvironments, and metabolic re-wiring often involve loss of isoenzyme diversity. We hypothesize that targeting enzymes that have lost isoenzyme diversity in cancer, but not in normal cells, provides an opportunity to selectively target cancers. In this study, we assessed mRNA expression of all known human isoenzyme families in breast cancer and normal breast tissue and identified isoenzymes with loss of diversity within each breast cancer subtype.

**Methods:** We obtained RNAseq data from cancer and patient-matched normal breast tissues from the TCGA (N=66 HR+, N=24 HER2+, and N=15 TNBC tumors). We retrieved annotated human isoenzyme families from the ENZYME nomenclature database. We compared expression in cancer and matched normal samples from the same patient to identify isoenzymes that had i) same or increased expression of the target isoenzyme in cancer vs normal and ii) reduced expression of the complementary isoenzymes in cancer. We developed five scores that capture various elements of these characteristics and prioritized candidates as targets based on clustering and their combined ranking based on the five scores. We validated overexpression of the candidate isoenzymes relative to other isoforms in breast cancer microarray data from ArrayExpress (E-GEOD-76250: 33 TNBC, and E-GEOD-70951: 30 TNBC, 108 HR+, 10 HER2+).

**Results:** We identified 321 enzymes in the TCGA discovery cohort that correspond to 829 unique isoenzymes. Overall, 636, 483 and 429 isoenzymes were differentially expressed in HR+, HER2+ and TNBC cancers, respectively, compared to corresponding normal samples. Of these, 308 isoenzymes were differentially expressed relative to normal in all 3 subtypes. In all, 112 and 92, and 84 were selected as candidate isoenzyme therapeutic targets in HR+, HER2+ and TNBC, respectively. 23 isoenzymes prioritized in clustering step were further validated. Finally, 6 isoenzymes were validated in HR+ (ALDOA, GUSB, GYG1, MIF, P3H1, PCK2), 10 in HER2+ (ALDH1L2, ALDOA, GLYATL2, GUSB, GYG1, GYS1, MIF, P3H1, PCK2, PTGS1) and 12 in TNBC (ADSS, ALAS1, ALDH1L2, ALDOA, ART3, GLYATL2, GUSB, GYS1, HS3ST1, MIF, PCK2, SOAT1), as potential targets for breast cancer treatment. Of these, 5 potential isoenzyme targets (ALDH1L2, GUSB, GLYATL2, MIF, PCK2), which were mostly hydrolases and transferases, were further selected for ongoing experimental validation in the laboratory. Decreased expression of the complementary isoforms of these 5 targets were primarily due to DNA methylation of the genes in cancer.

**Conclusions:** We found that loss of isoenzyme diversity is a broad phenomenon in breast cancers that may be explored therapeutically. We identified several instances of “isoenzyme addiction” in which cancers depend exclusively on a single isoenzyme while downregulating via methylation the complementary isoenzymes, providing cancer-specific targeting opportunities. We are currently validating several of these targets in cell line models.

Investigating the role of focal adhesion kinase in regulating CSC activity in invasive ductal carcinoma

Simon Timbrell¹,², Hosam Aglan¹,², Angela Cramer³, Phil Foden², David Weaver⁴, Jonathan Pachter⁴, Gillian Farnie⁵, Robert Clarke¹ and Nigel Bundred². ¹Breast Biology Group, The University of Manchester, Manchester, United Kingdom; ²Academic Surgery, Manchester University Foundation Trust, Manchester, United Kingdom; ³The Christie, Manchester, United Kingdom; ⁴Verastem, Boston and ⁵Cellular Assays Group, The University of Oxford, Oxford, United Kingdom.

Background
Breast Cancer Stem-like Cells (BCSCs) have been associated with tumour development, metastasis and recurrence¹. Focal Adhesion Kinase (FAK) is a non-receptor tyrosine kinase classically known for its role in metastasis, proliferation and survival. We have previously shown FAK plays a role in regulating CSC activity in DCIS². We aimed to investigate FAK and CSC marker expression in a retrospective patient cohort. We aimed to evaluate the effects of FAK inhibition on CSC activity in Invasive Ductal Carcinoma.

Methods
Using a retrospective case-control cohort of 244 patients across a range of molecular phenotypes we evaluated FAK Immunohistochemical expression alongside CSC markers; Aldehyde Dehydrogenase 1 (ALDH1) and Integrin Alpha 6 (ITGa6). FAK expression was measured in IDC cell lines and ALDEFLUOR high expressing cells. FAK was inhibited using 0.5µM VS4718 or SiRNA and CSC activity evaluated in 5 cell lines and 25 patient samples. We determined the effects of 50mg/kg VS4718 for 4 weeks as single agent or in combination with Paclitaxel 7.5mg/kg in a ER-/PR-/HER- Patient Derived Xenograft model (PDX).

Results
Total FAK expression was associated with reduced breast cancer survival. Co-expression of FAK and either BCSC marker was associated with the poorest survival.

Hazard ratios calculated using cox-proportional hazard regression analysis.

pFAK was higher in ALDEFLUOR expressing cells and triple negative cell lines. SiRNA knockout of FAK reduced mammosphere formation, self-renewal and ALDEFLUOR expression from 1.2% to 0.2% (p<0.01, unpaired t-test) in MDA-MB-231 cells. VS4718 reduced primary mammosphere forming efficiency in all cell lines and reduced self-renewal in ER negative cell lines. FAK inhibition led to a reduction in mammosphere forming efficiency and self-renewal in 25 primary breast cancer specimens as outlined below:

FAK inhibition reduces MFE

VS4718 reduced tumour growth, Ki67 staining and CSC activity in our triple negative PDX model. VS4718 administration reduced ex-vivo mammosphere formation, tumour initiating capacity and prevented ALDEFLUOR enrichment when used in combination with Paclitaxel.

Conclusions

FAK, ALDH1 and ITGa6 are associated with increased breast cancer mortality in early breast cancer. Inhibition of FAK reduces CSC activity in vitro and in vivo in cell lines and patient samples. This data suggest that FAK inhibition may be used to reduce CSC activity in triple negative carcinoma.

Identification of oncogenic gene fusions in triple-negative breast cancer metastatic to the brain

Paula Gonzalez-Ericsson¹, Brian Lehmann¹, Bret Mobley¹, Yunn-Yi Chen², Jennifer Pietenpol¹ and Melinda E Sanders¹.
¹Vanderbilt University Medical Center/Vanderbilt Ingram Cancer Center, Nashville, TN and ²University of California at San Francisco, San Francisco, CA.

BACKGROUND: As many as 24% of breast cancer (BC) patients develop metastasis to the brain and 27% of these occur in patients with triple negative (TN) BC. The brain (#2) and lung (#1) are the most common sites of TNBC metastasis. Half of women with metastatic (m) TNBC will die within one year. Novel therapies for women with mTNBC, especially to the brain, are desperately needed. TNBCs often exhibit genomic instability, resulting in gene fusions and other chromosomal rearrangements. Such alterations are long recognized as oncogenic drivers and effective drug targets in hematologic and other solid malignancies. We aimed to identify these alterations in mTNBC with Segmental Transcript Analysis (STA), a novel population-based algorithm ranking genes based on likelihood of harboring a gene rearrangement by identifying abrupt changes in transcript expression.

RESULTS: We performed RNAseq on 25 mTNBC, 4 matched primary BC, 2 normal cerebellum and 2 normal cerebral cortex samples. TNBC subtype analysis showed an enrichment of basal-like (BL) 2 and mesenchymal (M) subtypes among mTNBC to the brain compared to primary (p) BC in the TCGA. A principal component analysis demonstrated mTNBC and their matched primaries clustered together, indicating the pairs were more closely related to each other genetically than to other mTNBCs. When the gene expression patterns of pBC were compared with their brain metastases following adjustment for contamination with normal brain tissue, an upregulation of mesenchymal genes (p63/p73 axis) and primitive/embryonic genes (NOTCH and PAX family) were noted in the brain mTNBC. We confirmed a modest to marked upregulation of p63 expression by immunohistochemistry across all TNBC subtypes, most notably in BL1 and BL2. STA found three gene rearrangements: EHF-WT1, NF1-VWDE and JAG1-Chr20. Two of these are potential driver gene rearrangements. The first, in a tumor of M subtype, results from fusion of the 5'UTR of EHF to WT1. The resulting fusion transcript is predicted to encode a truncated WT1 protein; loss of the N-terminal regulatory region of WT1 would likely cause constitutive activation. We also identified a truncating rearrangement in the Notch ligand JAG1 in a tumor of LAR subtype. JAG1 is a membrane bound ligand for the Notch receptor and the breakpoint occurs just distal to the DSL domain essential for Notch interaction. This rearrangement occurs within an intergenic chromosomal region, introduces an abrupt stop codon and generates a truncated protein lacking a transmembrane domain. An intact signal peptide should localize the protein to the endoplasmic reticulum; however, loss of the transmembrane domain would likely lead to secretion rather than membrane insertion. This alteration is predicted to constitutively stimulate Notch activity in a paracrine fashion. If the rearrangement functions in this manner, neutralizing antibodies to the N-terminal portion of JAG1 should have therapeutic efficacy.

DISCUSSION: EHF-WT1 and JAG1-Chr20 are potential driver rearrangements novel to brain mTNBC. The JAG1 rearrangement predicts constitutive production of Notch transcription factors and is potentially targetable. Continued interrogation of mTNBC for discovery of additional oncogenic fusions driving BC biology is warranted.
Sortilin targeted therapy in breast cancer with elevated progranulin expression

Background: A major challenge concerning breast cancer therapy is the occasional lack of effects using drugs that target cancer cells unspecifically. One possible explanation for this treatment failure is the existence of the small subpopulation of breast cancer stem cells that are believed to be more resistant towards conventional therapy and possesses the ability to drive tumor formation and disease progression. Cytokines secreted by nearby cells and other factors in the surrounding tumor microenvironment further stimulate the cancer cells, contributing to a heterogeneous and potentially more treatment resistant tumor. Thus, a more specific treatment approach targeting the breast cancer stem cell niche is crucial in preventing disease recurrences. In a cytokine screen, we identified progranulin as one of the main compounds secreted from cells exposed to hypoxia, leading to cancer stem cell propagation. Progranulin is involved in biological processes such as wound healing, inflammation and cancer progression. Progranulin and its receptor sortilin are known to be highly expressed in subgroups of breast cancer and are further associated with a clinically aggressive phenotype.

Methods/Results: By carrying out a number of in vitro and in vivo like screening assays, we demonstrate that progranulin influences the stem cell population in breast cancer and is responsible for spreading a cancer stem cell promoting signal to normoxic tumor areas. In breast cancer, progranulin induces a dedifferentiation process in the receiving cancer cells and expression of cancer stem cell markers together with an EMT-associated gene expression profile, leading to cancer stem cell expansion. By using siRNA and pharmacological inhibition of sortilin, we show that sortilin is a functional receptor of progranulin and is responsible for driving progranulin induced breast cancer stem cell propagation. Supporting the role of progranulin in cancer progression, administration of progranulin in immunocompromised mice induce lung metastasis in our breast cancer xenograft models. The use of different approaches for blocking sortilin, such as sortilin inhibitors, down-modulators or sortilin-targeted antibodies can prevent this dedifferentiation process, both in vitro and in vivo, making the tumor cells less aggressive and metastatic.

Conclusion: Targeting progranulin through its associated receptors is a potential therapeutic strategy for the treatment of patients with breast tumors having elevated progranulin or sortilin expression. By inhibiting the secretion based breast cancer progression, we could possibly block the formation of metastasis and cancer cell infiltration.
Oncogenic potential of Trefoil factor 3 in initiation of mammary carcinoma through suppression of p53 pathway

Ru Mei Chen¹,², Vijay Pandey³, Qing Yun Chong¹, Han Ming Poh¹,², Meng Yi Zhang¹,², Alan Prem Kumar¹,²,⁴,⁵ and Peter Edward Lobie³,⁴. ¹Cancer Science Institute of Singapore, National University of Singapore, Singapore, Singapore; ²Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore; ³Tsinghua Berkeley Shenzhen Institute, Tsinghua University Graduate School at Shenzhen, Shen Zhen, Guang Dong, China; ⁴National University Cancer Institute, Singapore, Singapore and ⁵Cancer Program, Medical Science Cluster, Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore.

Background
Oncogenic transformation is a complex multistep process where normal cells acquire the hallmarks of cancer, leading to unrestrained outgrowth of malignant clones. Trefoil Factor 3 (TFF3) is a clinically validated and functionally potent oncogene in mammary carcinoma. Elevated TFF3 expression has been consistently observed in mammary carcinoma, being involved in cancer progression. The present study investigates the potential functional role and the underlying mechanisms of TFF3 in promoting oncogenic transformation early in the onset of mammary carcinoma.

Material and method
Immortalized human mammary epithelial cells (HMECs): HMEC-hTERT, MCF10A and MCF12A, with forced expression of TFF3, were used as in vitro models and in an orthotopic xenograft model to study the oncogenic roles of TFF3. Furthermore, microarray analysis, immunofluorescence, and ubiquitination and CHX chase assays were used to examine the involvement of p53 pathway in TFF3 mediated-oncogenic transformation.

Results
Immortalized HMECs with forced expression of TFF3 exhibited the capacity of anchorage independent growth in the soft agar colony formation assay, which is a hallmark of oncogenic transformation. The forced expression of TFF3 also enhanced 3D growth of the immortalized HMECs in matrigel. Furthermore, immortalized HMECs with forced expression of TFF3 gaverise to orthotopic xenograft tumors in nude mice, which are not observed in mice injected with immortalized HMECs. These observations suggest that TFF3 stimulates the oncogenic transformation of non-malignant immortalized HMECs. In addition, the forced expression of TFF3 promoted aberrant cell proliferation, resistance to apoptosis, and increased cell migration and invasion of the HMECs, all these being important hallmarks of cancer. Here, we showed that TFF3-mediated oncogenic transformation of the immortalized HMEC-hTERT cells is dependent on p53 signaling pathway suppression. Mechanistically, TFF3 downregulated NF-κB (p65)-mediated transcription of p53 through decreasing NF-κB (p65) expression and nuclear accumulation. TFF3 also decreased p53 protein levels through post-transcriptional regulation. The forced expression of TFF3 increased MDM2 expression, resulting in an increased ubiquitin-mediated proteasomal degradation of p53. Moreover, forced expression of TFF3 decreased the cleaved form of MDM2, which is responsible for stabilizing p53 protein. Concordantly, HMECs with forced expression of TFF3 exhibited shorter p53 protein half-life as compared to vector control HMECs.

Conclusion
In summary, our study highlights the oncogenic potential of TFF3 in the initiation of mammary carcinoma through the suppression of the p53 pathway.
A novel small molecule JMX0293 inhibits the growth of triple-negative breast cancer via suppressing STAT3 and inducing apoptosis

Jiabin Dong¹, Jimin Xu², Hyejin Kim¹, Jia Zhou² and Qiang Shen¹. ¹The University of Texas MD Anderson Cancer Center, Houston, TX and ²University of Texas Medical Branch, Galveston, TX.

Approximately 30-40% of breast cancer cases are estrogen receptor negative (ENBC), including the most aggressive triple-negative subtype (TNBC) which spread early and recur frequently with a poor prognosis. ENBCs do not respond to selective ER modulators such as tamoxifen or aromatase inhibitors, and therefore, there is an urgent need of non-ER-based therapies for ENBC and TNBC. We recently developed a novel small molecule JMX0293 based on our lead drug candidate HJC0152. Both HJC0152 and JMX0293 were able to suppress cell proliferation of both ER⁺ (MCF-7, T-47D) and ER⁻ (MDA-MB-231 and MDA-MB-468) breast cancer cell lines in a dose-dependent manner, with significantly lower toxicity against normal mammary epithelial cells (MCF-10A) in vitro. JMX0293 exhibited moderately improved anti-proliferative effects against highly invasive TNBC cell line MDA-MB-231 and ER⁺ breast cancer cell line MCF-7 with IC₅₀ values of 0.92 and 2.24 µM, respectively. JMX0293 was also demonstrated to induce apoptosis of MDA-MB-231 cells dose-dependently. Mechanistically, JMX0293 inhibited STAT3 phosphorylation at Tyr705 residue, leading to the down-regulation of Bcl-2 and upregulation of apoptotic proteins including Bax, cleaved-caspase 3 and cleaved-PARP. In addition, JMX0293 reduced the ratio of Bcl-2 to Bax. In vivo, JMX0293 treatment for 2 weeks at a dose of 10 mg/kg significantly suppressed the growth of TNBC xenograft tumors in mice with minimal impact on general health and body weight. Our results suggest that JMX0293 induces TNBC cell apoptosis and contributes to its anti-proliferative effect through inhibiting transcription factor STAT3, and JMX0293 could be further characterized and optimized for developing a promising therapeutic for treating ENBC and TNBC. This work was supported by grant (R01 CA231150) from the NIH/NCI.
The role of SLC7A5 (LAT1) in endocrine therapy-resistant breast cancer

Catherine M Sevigny\textsuperscript{1}, Surojeet Sengupta\textsuperscript{1}, Zhexun Luo\textsuperscript{1}, Lu Jin\textsuperscript{1}, Dominic Pearce\textsuperscript{2} and Robert Clarke\textsuperscript{1}. \textsuperscript{1}Georgetown University, Washington, DC and \textsuperscript{2}The University of Edinburgh, Edinburgh, United Kingdom.

Endocrine therapies are commonly used to treat estrogen receptor-positive (ER+) breast cancers, which comprise 70% of all new breast cancer cases. Unfortunately, emergence of resistance to these therapies presents a major clinical challenge. Cancer cells can adapt to the dysregulation of cellular metabolism induced by endocrine therapy in order to evade cell death. Central to this adaptation is the scavenging of free-formed amino acids from the tumor microenvironment. For example, we found 109 solute carrier (SLC) mRNAs to be differentially expressed between endocrine-sensitive and resistant cells. We began our mechanistic studies of these genes with SLC family 7 member 5 (SLC7A5 or LAT1). SLC7A5 is a key component of a transmembrane transporter, which can complex with CD98 and increase the uptake of large, neutral amino acids (such as leucine or tyrosine). We used a panel of endocrine therapy-resistant (LCC9) and sensitive (MCF7; LCC1) breast cancer cells. SLC7A5 expression was upregulated by estrogen in MCF7 and LCC1 cells; this induction was blocked by fulvestrant treatment. Basal expression of the SLC7A5 protein in the absence of estrogen was 2.75-fold higher in LCC9 cells compared with MCF7 cells; SLC7A5 mRNA expression was 71-fold higher. Fulvestrant treatment did not significantly alter SLC7A5 mRNA or protein expression in LCC9 cells. Inhibiting SLC7A5 function using either a pharmacological inhibitor (JPH203), or depleting expression using siRNA, led to significant suppression of LCC9 cell growth. Cell cycle analysis revealed that SLC7A5 depletion caused cells to accumulate in the G1-phase, with a concurrent reduction of cells in S-phase. In four publicly available datasets of ER+, tamoxifen treated breast cancer patients, high expression of SLC7A5 was significantly associated with poor relapse-free survival. This study uncovers a novel adaptive mechanism in endocrine therapy-resistant breast cancer cells that is facilitated by increased expression of SLC7A5, which enables them to supplement their increased metabolic needs and promoting cell growth. Blocking the functions of SLC7A5, perhaps in conjunction with inhibition of autophagy, may therefore offer a new avenue of potential therapeutic intervention against endocrine therapy-resistant breast cancers.
Rational combination of Wee1 and BCL-2 inhibition in preclinical models of triple-negative breast cancer

Dennis M Simmons¹, Tonia E Tse¹, Kyrie Dailey¹, Sarah J Hartman¹, Stacey Bagsby¹, Todd M Pitts¹, John J Tentler¹ and Jennifer R Diamond¹. ¹University of Colorado Cancer Center, Aurora, CO.

Background:
Triple-negative breast cancer (TNBC) is an aggressive subtype distinguished by its lack of expression of receptors for estrogen, progesterone, and normal human epidermal growth factor 2 expression. TNBC is difficult to treat and is associated with a high risk of recurrence and mortality. In order to effectively treat TNBC, alternative therapeutic targets need to be identified. Wee1 is a tyrosine kinase that phosphorylates CDC2 to pause the cell cycle at the G2 checkpoint as a means to delay mitosis while DNA damage undergoes repair. Inactivation of Wee1 via adavosertib (AZD1775, MK1775), a highly selective inhibitor of Wee1, allows CDC25 to dephosphorylate the CDC2/cyclin B complex resulting in premature initiation of mitosis and, ultimately, mitotic catastrophe and apoptosis. An unbiased screen of adavosertib in combination with other targeted compounds in TNBC patient-derived xenograft (PDX) models demonstrated that the combination of adavosertib and navitoclax, an inhibitor of anti-apoptotic BCL-2 and BCL-XL proteins, had greater efficacy than the single agents alone. The purpose of this study was to investigate the combination of adavosertib and navitoclax in preclinical TNBC models, both in vitro and in vivo.

Methods:
HCC1937, CAL51, MDA-MB-231 and MDA-MB-468 cells were plated in 96-well plates and exposed to increasing concentrations of adavosertib (125nM – 1000nM), navitoclax (2500nM – 10000nM), or the combination. Cellular proliferation was assessed in real-time using IncuCyte Live Cell Analysis, followed by endpoint sulforhodamine B (SRB) assay. Combination effects were analyzed using CalcuSyn to determine combination indexes (CI). Apoptosis was assessed via the Caspase 3/7 assay. Western blotting was used to assess changes in expression of CDC2, phospho-CDC2, and BCL2. TNBC PDX models CU_TNBC_013 and CU_TNBC_014 were treated with vehicle, adavosertib (50mg/kg), navitoclax (100mg/kg), or the combination and assessed for tumor growth inhibition.

Results:
The combination of adavosertib and navitoclax resulted in greater antiproliferative effects in vitro compared to either single agent (p< 0.05). This effect was classified as synergistic with CI values <1. We observed a significant increase in apoptosis with the combination treatment as measured by Caspase 3/7 (p<0.005). The combination of adavosertib and navitoclax treatment resulted in a decrease in phospo-CDC2, and BCL2 in cell lines. In vivo, the combination treatment resulted in greater tumor growth inhibition as compared to adavosertib or navitoclax alone in the CU_TNBC_013 and CU_TNBC_014 PDX models.

Conclusions:
The combination of adavosertib and navitoclax is active in preclinical TNBC models and induces apoptosis and tumor growth inhibition. This data supports the continued development of this combination in TNBC with investigation of potential selective markers.
New targets in triple negative breast cancer: Role of Oncostatin M receptor pathway

Isabel Alvarez\(^1\), Angela Araujo\(^1\), Andrea Abaurrea\(^1\), Ricardo Rezola\(^3\), Ander Urruticoechea\(^1\), Charles Lawrie\(^1\) and María M Caffarel\(^1\). \(^1\)Biodonostia Health Research Institute, Donostia-San Sebastián, Gipuzkoa, Spain; \(^2\)Donostia University Hospital - Hospital Universitario Donostia, Donostia-San Sebastián, Gipuzkoa, Spain and \(^3\)Onkologikoa, Donostia-San Sebastián, Gipuzkoa, Spain.

**BACKGROUND:** Triple negative breast cancer (TNBC) has poor prognosis, lack of targeted therapies and are often refractory to conventional chemotherapy treatments. Therefore, finding new therapeutic targets for those tumours is an unmet need with high clinical impact. In this context, Oncostatin M receptor (OSMR) is a promising therapeutic target as it is over-expressed in this tumour subtype and its activation promotes invasiveness (Guo L, et al. 2013 Oncogene; West NR, et al. 2014 Oncogene). We previously showed that OSMR is frequently copy-number gained and over-expressed in squamous cell carcinoma, where it induces migration, invasion and metastasis (Caffarel MM, et al. 2013 Journal of Pathology; Caffarel MM, et al. 2014 Journal of Pathology; Kucia-Tran JA, et al. 2016 Brit J Cancer; Kucia-Tran JA, et al. 2018 Journal of Pathology). We now investigate the role of OSMR in breast cancer progression.

**METHODS:** To address this issue we use a wide array of tools including *in vitro* cell cultures and *in vivo* models. The expression of OSMR pathway was analysed in FFPE samples and large datasets of publicly available breast cancer samples (METABRIC, \(n=1462\); and TCGA, \(n=547\)).

**RESULTS:** OSMR and its ligand Oncostatin M (OSM) are over-expressed in basal tumours, where they associate with shorter overall survival \((p=0.015)\). While OSMR is expressed by breast cancer cells and cancer associated fibroblasts, the main source of OSM seems to be primarily macrophages. OSM treatment of breast cancer cells induces the expression of important mediators of angiogenesis and invasion. Importantly, OSMR activation accelerates tumour onset, tumour growth and metastasis in orthotopic xenografts in nude mice.

**CONCLUSIONS:** Our results support that OSMR pathway may have an important role in the initiation and progression of breast cancer and that it could be a promising candidate for therapeutic targeting in TNBC. OSMR could be blocked by antibody based inhibition, strategy that has had a major impact on breast cancer.
A novel interaction of AURKA with MAPK pathway in breast cancer cells as a potential therapeutic target

Shipra Gandhi¹, Malgorzata Gil¹, Thaer Khoury¹, Kazuaki Takabe¹, Igor Puzanov¹, Irwin Gelman¹, Antonio D'Assoro² and Mateusz Opyrchal¹. ¹Roswell Park Comprehensive Cancer Center, Buffalo, NY and ²Mayo Clinic, Rochester, MN.

Background: Aurora A (AURKA) is a mitotic kinase responsible for centrosome segregation and mitotic spindle formation. In normal cells, expression of AURKA is highly regulated and is predominantly restricted to G2/M phases of the cell cycle. Unlike healthy cells, cancer cells overexpress AURKA through all phases of the cell cycle resulting in the acquisition of alternate non-mitotic functions. Little is known about cellular functions regulated by AURKA and its interaction with other signaling molecules. Here, we report a novel interaction between AURKA and the mitogen-activated protein kinase (MAPK) pathway at the level of MEK1 in breast cancer cells. This interaction may serve as a novel target as well as demonstrate by an additive cytotoxic effect of AURKA- and MEK1/2-specific inhibitors against estrogen positive (ER⁺) and triple negative breast cancer (TNBC) cells.

Results: We show that treatment of ER⁺ HER2⁻ MCF-7, ER⁻ HER2⁺ SKBR3 and ER⁻ HER2⁻ BT549 cells with AURKA specific inhibitors alisertib, MK8745 and Aurora A Inhibitor I resulted in over 2-fold increase in relative levels of poMEK1/2 and poERK1/2 compared to untreated controls. The activation of the MAPK pathway was rapid with changes seen within 5 min after treatment with AURKA inhibitors and was sustained for at least 48 hours. Treatment with the pan RAF inhibitor TAK-632 did not diminish alisertib-induced poERK and poMEK1/2. Alternatively, treatment with the MEK1/2 specific inhibitor PD0325901 completely abrogated alisertib-induced phosphorylation of MEK1/2 and ERK1/2. In situ proximity ligation and pull down assays demonstrated AURKA and MEK1/2 direct interaction. In vitro kinase assay showed direct phosphorylation of MEK1 by AURKA. Combined treatment of alisertib and PD0325901 in vitro revealed significant additive cytotoxic effect in MCF-7 and BT549 cells when compared to either agent used alone (p< 0.008 and p<0.011; p <0.04 and p<0.028) with early trend toward significance in survival in a BT549 xenograft breast cancer in vivo model.

Conclusions: Our data shows a novel AURKA-MEK1 interaction in breast cancer cells. In depth in vivo analysis is ongoing. The results reveal a promising new strategy for the treatment TNBC patients using a combination of AURKA and MEK1/2 inhibitors.
The effect of UBE2C expression on intrinsic chemosensitivity in breast cancer cell lines

Toshima Z Parris¹, Peter Larsson¹, Jana Biermann¹, Hanna Engqvist¹, Elisabeth Werner-Rönnerman¹, Anikó Kovács², Per Karlsson¹ and Khalil Helou¹. ¹University of Gothenburg, Sahlgrenska Cancer Center, Gothenburg, Sweden and ²Sahlgrenska University Hospital, Gothenburg, Sweden.

Background: The ubiquitin-proteasome pathway plays a crucial role in cancer-related processes by inducing cell cycle arrest through the degradation of mitotic cyclins and other cell cycle regulatory proteins. We recently showed that elevated levels of ubiquitin-conjugating enzyme E2C (UBE2C) were associated with aggressive tumor features and unfavorable clinical outcome in breast carcinoma (BC). UBE2C suppression has been achieved using the FDA-approved proteasome inhibitor bortezomib (VELCADE®) in colorectal carcinoma, but little is known about the efficacy of UBE2C-targeted therapy with proteasome inhibitors in breast cancer.

Methods: Cell viability assays were used to determine the intrinsic chemosensitivity of five BC cell lines (MCF-7, MDA-MB-436, HCC38, HCC1395, and ZR-75-30; stratified by UBE2C expression and ER status) and the MCF-10A epithelial cell line to proteasome inhibitors (n=8), mitosis inhibitors (n=2), and platinum agents (n=3). UBE2C expression analysis was performed using quantitative real-time PCR and Western blot. IC50 values and growth inhibition metrics (GR50 and GRmax) were calculated for each compound to determine drug potency and efficiency after 24 hour treatment. Proteasome activity was assessed using bortezomib-treated cells.

Results: Heterogeneous UBE2C expression levels were found in the different cell lines, with higher UBE2C levels in ER-negative BC cell lines (HCC38, HCC1395, MDA-MB-436) than ER-positive BC (MCF-7 and ZR-75-30) and MCF-10A control cells (ER-negative). Proteasome inhibition levels close to 50% and 100% were seen in all cell lines after 10 nM and 100 - 1000 nM bortezomib, respectively. As expected, bortezomib blocked cell cycle progression by inducing G2/M phase arrest in HCC38 cells. Due to differences in cell growth rates, calculation of the IC50 value was an ineffective method to determine drug potency. In contrast, the normalized growth rate inhibition method with GR50 and GRmax values demonstrated a correlation between sensitivity to proteasome inhibitors in ER-negative BC cell lines and high UBE2C expression levels. However, MDA-MB-436 cells (GR50, range 1.8-286.1 nM; GRmax, range -0.42 - -0.93) were generally less sensitive to proteasome inhibitors than HCC38 cells (GR50, range 8.2-936.8 nM; GRmax, range -0.97 - -0.99) though both cell lines were ER-negative, which was possibly due to the lower expression of UBE2C in MDA-MB-436 cells. Compared with the other tested drugs, no cell line was sensitive to the mitosis inhibitors and platinum agents were most effective in HCC38 cells.

Conclusions: Taken together, these findings suggest an association between UBE2C expression and response to proteasome inhibition, regardless of ER status.
CDC20 is a novel therapeutic target in triple negative breast cancer

Jayesh Sharma¹, Isabella Raicu¹, Jessica Nguyen¹, Nashir Udden¹, Qian Wang¹ and Prasanna Alluri¹. ¹University of Texas Southwestern Medical Center, Dallas, TX.

Background: Approximately 15% of breast cancers lack expression of Estrogen Receptor (ER), Progesterone Receptor (PR) and Human Epidermal Growth Factor Receptor 2 (HER-2), and are referred to as Triple Negative Breast Cancer (TNBC). Clinical outcomes in patients with TNBC continue to be poor due to inherently aggressive biology of the disease and paucity of targeted therapies. In this study, we identified Cell Division Cycle protein 20 (CDC20), a key regulatory protein that mediates sister chromatid separation in mitosis, as a novel therapeutic target in TNBC.

Methods: To uncover new drivers of TNBC, we nominated genes that are significantly overexpressed in patients with TNBC, compared to non-TNBCs. After identifying CDC20 as a top hit in this analysis, we used expression microarrays, RNA-seq analyses and Western blotting to assess CDC20 expression levels in breast cancer patients and cell lines. Kaplan-Meier analyses were performed to study the correlation between CDC20 expression levels and clinical outcomes, including recurrence-free survival, metastasis-free survival and overall survival. shRNA-mediated knockdown of CDC20 in TNBC cell lines was employed to study the role of CDC20 in TNBC proliferation, invasion, migration and xenograft growth in mice.

Results: CDC20 was significantly overexpressed in TNBCs (compared to non-TNBCs) in The Cancer Genome Atlas (TCGA) breast dataset, and in several other independent breast cancer datasets, including Curtis, Stickeler and Kao. CDC20 expression was also significantly higher in TNBC cell lines compared to non-TNBC cell lines. Furthermore, expression levels of CDC20 were highly significantly correlated with clinical outcomes, including recurrence-free survival, metastasis-free survival and overall survival. shRNA-mediated knockdown of CDC20 expression in TNBC cell lines, MDA-MB-231 and MDA-MB-468, resulted in decreased proliferation, invasion and migration. Our preliminary findings suggest that CDC20 knockdown also results in inhibition of cell line-derived xenograft growth in mice.

Conclusion: We identified CDC20 is a novel therapeutic target in TNBC. Our findings support development of pharmacologic strategies to inhibit CDC20 function as a potential targeted therapy against TNBC.
Endogenous expression of ERβ variants contributes towards chemotherapy-resistance in the triple negative breast cancer cell line HCC-1806

Michelle Faria¹, Jan-Ake Gustafsson¹ and Anders Strom¹. ¹University of Houston, Houston, TX.

Triple negative breast cancer (TNBC) still remains a challenge to treat in the clinic due to a lack of good targets for treatment. Although TNBC lacks expression of ERα, the expression of ERβ and its variants are detected quite frequently in this cancer type and can represent an avenue for treatment. We show that the variants of ERβ, namely ERβ1, ERβ2, ERβ4, and ERβ5, contributes to aggressiveness of the TNBC cell line HCC1806 by affecting E-Cadherin expression and chemotherapy sensitivity. We have previously shown that the HCC1806 cell line expresses all the ERβ variants. To investigate their function we used the recently developed dCas9-KRAB system with Guide RNA for both ERβ promoters 0N and 0K, using 3 guide RNA's for each promoter and we found that expression of panERβ decreased from a ct. of 28 to 33 indicating loss of total ERβ. Treatment of HCC1806 cells with chemotherapy in combination with an ERβ agonist, LY500307, is more effective in reducing cancer cell viability. Knockdown of total ERβ in HCC1806 cells using CRISPR-Cas9 technology, decreased the proliferation and increased chemo-sensitivity to docetaxel agent in cells with the 0K promoter knock down, while cells with the 0N promoter knock down were less affected. Furthermore, after ERβ knockdown, the cell morphology of HCC-1806 changed to a more epithelial phenotype and there was increase in the expression of the classical epithelial marker, E-cadherin. N-Cadherin was unchanged in the cells with the 0K promoter knock down, while E-Cadherin was slightly decreased in cells with the 0N promoter knock down. We also found that cells with the 0K promoter knock down migrated less than control cells in a migration assay, while cells with the 0N promoter knock down were less affected. These findings are in agreement with reports showing that the 0K promoter is responsible for expression of the variants ERβ2 and ERβ5, while the 0N promoter expresses more ERβ1. Furthermore, we have earlier shown that ERβ2 and ERβ5 increase aggressiveness of TNBC via several oncogenic signaling pathways.

In conclusion, knockdown of ERβ variants in HCC-1806 indicated that the variants may be responsible for conferring oncogenic properties to TNBC such as EMT, cancer cell proliferation and chemo-resistance. Therefore, treating TNBC patients with combination therapy including ERβ agonists, may prove to be extremely beneficial for securing better treatment responses and future pre-clinical studies should design appropriate experiments to confirm these findings in vivo.
PEA15-AA, an unphosphorylatable mutant of PEA15, as a novel therapeutic gene for triple-negative breast cancer

Jihyun Park¹, Gaurav Chauhan¹, Evan N Cohen², Naoto T Ueno¹, Venkata L Battula², Debu Tripathy¹, James M Reuben² and Chandra Bartholomeusz¹. §Section of Translational Breast Cancer Research, The University of Texas MD Anderson Cancer Center, Houston, TX and ²The University of Texas MD Anderson Cancer Center, Houston, TX.

Background: Triple-negative breast cancer (TNBC) is an aggressive subtype of breast cancer characterized by a high rate of metastatic recurrence and poor prognosis. Molecular mechanism underlying the metastatic behavior of TNBC has not been well elucidated, and newer approaches addressing drivers of metastasis are crucial to improving patient outcomes. PEA15 (Phosphoprotein enriched in astrocytes-15) regulates cell proliferation, apoptosis, and autophagy. In breast cancer, PEA15 expression inhibits invasion by binding to ERK and preventing its nuclear translocation. The biological function of PEA15 is tightly regulated by its phosphorylation at Ser104 and Ser116. However, the effect of PEA15 phosphorylation status on TNBC remains unknown. In this study, we tested the hypothesis that unphosphorylated PEA15 will prevent metastasis in TNBC through inhibition of the epithelial-to-mesenchymal transition (EMT).

Method: We established stable cells overexpressing unphosphorylatable (PEA15-AA) and phospho-mimetic (PEA15-DD) PEA15 mutants in MDA-MB-468 cells. To dissect specific cellular mechanisms regulated by PEA15 phosphorylation, we performed RT-PCR immune and metastasis arrays. In vivo mouse models were used to see effects of PEA15 phosphorylation on tumor growth.

Results: The clonogenic growth of PEA15-AA–expressing cells was significantly reduced by 80% compared with empty vector-transfected cells (PEA15-V). Anchorage-independent growth, an indicator of in vivo tumorigenicity, was inhibited in cells expressing PEA15-AA by 60% compared with PEA15-V. PEA15-AA upregulated the expression of E-cadherin and decreased the expression of mesenchymal markers, suggesting that PEA15-AA reverses EMT. Compared with PEA15-V, migration and invasion of cells expressing PEA15-AA were reduced by 65% and 72%, respectively. In contrast, PEA15-DD promoted migration, invasion, and expression of mesenchymal markers. To determine the in vivo effect of PEA15-AA, we injected stable PEA15 transfectants of MDA-MB-468 cells into the mammary fat pad of NOD/SCID mice. The PEA15-DD–injected group showed greater tumor volumes than PEA15-V and PEA15-AA groups, suggesting that PEA15-AA has antitumor effects both in vitro and in vivo. From the immune and metastasis arrays, we found that expression level of IL-8, which is known to induce EMT, was greatly decreased by PEA15-AA, while IL-8 was highly expressed in PEA15-DD cells. Addition of recombinant IL-8 to the cells expressing PEA15-AA partially rescued mesenchymal characteristics, increasing migration and expression of mesenchymal markers. By contrast, IL-8 knockdown in PEA15-DD–expressing cells decreased the mesenchymal phenotype. These findings indicate that IL-8 may play an important role as a mediator of phosphorylation of PEA-15 in breast cancer cell migration and invasion and suggest that PEA15-AA inhibits the expression of IL-8, thereby reversing EMT.

Conclusion: Taken together, our results show that PEA15 phosphorylation serves as an important regulator, having a dual role as an oncogene or tumor suppressor. Further studies are warranted to evaluate the impact of PEA15 phosphorylation status on metastasis in vivo. These findings support the development of PEA15-AA as a potential therapeutic strategy for TNBC.
New biomarkers for adjuvant bisphosphonate use in triple-negative breast cancer

Jouko A Sandholm¹, Nataliia Petruk², Katri S Selander³ and Johanna M Tuomela². ¹Cell Imaging Core, Turku Centre of Biotechnology, University of Turku and Ábo Akademi University, Turku, Finland; ²University of Turku, Institute of Biomedicine, Turku, Finland and ³University of Oulu, Oulu, Finland.

We first showed that triple-negative breast cancer (TNBC) patients with low Toll-like receptor 9 (TLR9) expression have significantly worse prognosis than patients with high TLR9 expression. TLR9 is an innate immunity DNA receptor which is also expressed in several cancers, including TNBC. Later, we showed that low-TLR9 cells and tumors are more sensitive to amino-bisphosphonates, especially to zoledronate. Bisphosphonates (BP) inhibit osteoclasts and thereby effectively prevent bone fractures in osteoporosis and in cancer-induced bone disease. BPs also have direct anticancer effects. Interestingly, adjuvant BP use is associated with significantly improved progression-free and overall survival, but only among post-menopausal breast cancer patients. The molecular mechanisms behind this observation is unclear.

CD73 is a 70 kDa glycophtatidylinositol-anchored cell protein, which converts adenosine monophosphate to adenosine and organic phosphate. High CD73 expression has been shown to have cancer cell invasion-promoting properties. On the other hand, CD73 is associated with poor prognosis in TNBC. Interestingly, TLR9 and CD73 have been shown to have inverse relationship in T cells and during colonic inflammation. Currently, we study the relationship of CD73 and TLR9 in vitro and in vivo upon BP treatment.

Our preliminary results show that TLR9 and CD73 have an inverse relationship also in TNBC cells. We use both nitrogen-containing (zoledronate and alendronate) and pyrophosphate-like (clodronate) BPs together with doxorubicin to study TNBC cell responses. We have seen that zoledronate and alendronate, but not clodronate, inhibited 4T1 murine triple-negative mammary tumor cell proliferation in a dose-dependent manner. Also, high concentrations of zoledronate and alendronate significantly inhibited 4T1 cell migration. Additionally, CD73 shRNA cells are more sensitive to zoledronate and alendronate, showing morphological changes and disruption in actin organization.

Our results suggest that CD73 expression may affect treatment responses to BPs in TNBC. Further, low-CD73 tumors could benefit more of BP therapy, compared with high-CD73 tumors.
Breast cancer is one of the leading causes of death among women in the United States. Among all the breast cancer subtypes, triple-negative breast cancer (TNBC) is denoted as having the highest rate of mortality due to inefficacious therapy, drug resistance, and high recurrences rate. Despite many therapeutic advances over the past decades, novel therapeutic approaches are required to treat TNBC. Although lysosomes have recently been identified as novel targets in a variety of cancers, not much known about their role in breast cancer especially in TNBC. Due to the altered features of lysosomes in cancerous cells, its functional ability affects cell proliferation, metabolism, adaptation, and autophagy in tumor cells. Thus, the induction of lysosomal membrane permeabilization (LMP) may be used as a novel approach in controlling the aberrant cellular functions in TNBC.

Cannabinoid receptor 2 (CB2) is expressed in breast cancer and its agonist JWH-015 has been shown to inhibit TNBC growth and metastasis. However, not much is known about the mechanisms by which JWH015 inhibit growth and metastasis. To investigate JWH015-mediated therapeutic mechanisms, we examined the lysosome-mediated cell death in TNBC cells. We found that JWH015 induces cell death in TNBC cells through lysosomal disruption mechanism. We also showed that JWH-015 treatment increases releases of lysosomal proteins, cathepsin D/B, and autophagy marker LC3B and that leads to activation of apoptotic cell death signaling in TNBC. These alterations result in the formation of autolysosomes to promote LMP. Our findings elucidate the mechanism by which JWH-015 promotes LMP induced autophagy and regulates TNBC cell proliferation. These studies elucidate novel lysosomal-mediated cell death mechanisms through activation of CB2 receptors in TNBC.
A phenotypic screening and machine learning platform efficiently identifies triple negative breast cancer-selective and readily druggable targets

Prson Gautam¹, Alok Jaiswal¹, Tero Aittokallio¹,², Al-Ali Hassan³ and Krister Wennerberg¹,⁴. ¹Institute for Molecular Medicine Finland (FIMM), HiLIFE, University of Helsinki, Helsinki, Finland; ²University of Turku, Turku, Finland; ³University of Turku3The Miami Project to Cure Paralysis, Peggy and Harold Katz Family Drug Discovery Center, Sylvester Comprehensive Cancer Center, and University of Miami Miller School of Medicine, Miami, FL and ⁴Biotech Research & Innovation Centre (BRIC), University of Copenhagen, Copenhagen, Denmark.

Identifying effective oncogenic targets is challenged by the complexity of genetic alterations in cancer and their poorly understood relation to cell function and survival. This, combined with the fact that the majority of the proteome is predicted to be undruggable, may explain why genomic approaches have had only moderate success in identifying and translating oncogenic drug targets. There is a need for methods that rapidly and accurately identify “pharmacologically effective” targets without the requirement for priori knowledge of complex signaling networks. We developed an approach that uses machine learning to relate results from unbiased phenotypic screening of kinase inhibitors to their biochemical activity data. This process, which we call idTRAX (Identification of Drug Targets and Anti-targets by Cellular and Molecular Cross-referencing), identifies targets that are pharmacologically responsive and readily druggable. Additionally, the identified targets are not typically overcome by the robustness of signaling networks, because only targets that effectively induce a phenotype upon pharmacological engagement are selected. We applied this methodology to triple negative breast cancer, which still lacks targeted therapy. We screened 19 breast cancer cell lines with ~500 small-molecule kinase inhibitors with annotated kinase activity data and identified cell-line specific kinase targets, i.e. kinases whose inhibition causes cell line-specific cytotoxicity or cytostaticity. We were able to identify various unique cell line selective kinase addictions along with well-known driver kinase addictions, for example, dependence on FGFR2 in the MFM-223 cell line and AKT kinases in MFM-223, CAL-148, and others. We also found that triple negative breast cancer cell lines exhibit heterogeneous target patterns, indicating the need of personalized medicine approach to tackle them. We further compared candidate targets identified by idTRAX with those reported from RNAi- and CRISPR-based screens. Strikingly, the correlation between targets identified by the pharmacological approach and those identified by knockdown/knockout-based screens was low [average rank correlation (\(\rho\)) = 0.0273- 0.1074], suggesting that gene-silencing approaches may not be the most efficient at identifying targets for small-molecule drug discovery or repurposing. Our approach provides a platform for rapidly identifying sample-specific drug targets and potentially guiding personalised therapy regimens.
Prediction model for lymphoedema, and effect of Lymphoedema diagnosis on quality of life (QoL) and distant recurrence from breast cancer

Nigel J Bundred, Philip Foden, Katie Riches, Julie Morris, Abigail Evans, Chris Todd, Maria Bramley, Anthony Skene, Arnie Purushotham and Vaughan Keeley.

Introduction

Lymphoedema develops after surgery in 30% patients. In a prospective, multi-centre UK study, we used a validated perometer arm measurement to determine 1) the factors predicting lymphoedema development and 2) the effect of a lymphoedema diagnosis on QoL and survival.

Methods

Participants (n = 1100) undergoing axillary clearance at 9 centres underwent arm volume measurements pre and post-surgery by perometry, and completed FACT-B+4 and Lymphoedema checklist questionnaires. Relative arm volume increase (RAVI) of ≥10% diagnosed lymphoedema. Predictors of lymphoedema development were determined using logistic regression, and changes in QoL were assessed using Generalised Estimating Equation (GEE) analyses.

Results

Median patient age was 56 (range 22 to 90) years; 78% received radiotherapy and 65% chemotherapy. Lymphoedema was detected in 21.4% of women by perometry and 24.4% underwent sleeve application by 24 months.

Initial decreases in QoL scores post-surgery were greater in patients with lymphoedema and took longer to return to baseline values (FACT-B p=0.014, TOI p=0.008, ARM subscale p<0.001).

RAVI at 1 month (p<0.001), BMI in three categories (≤25, >25–≤30 and >30, p=0.05), ER status (p=0.05) and number of positive nodes (p<0.001) were used to develop a novel scoring model (AUROC 0.80) to predict lymphoedema. Out of 826 patients used for the model, 75% of patients had low scores (≤1) at 1 month and 11.6% developed lymphoedema by 24 months, whereas 20% who scored moderate risk (1.5–2) had a 31.3% risk and 5% who scored high risk (2.5–4) and had a 66.7% risk. Using the model scores, 75% of patients could be reassured regarding their lymphoedema risk.

Local recurrence was 1.7%. One hundred and twenty-nine patients had died of breast cancer (n=88) or had distant recurrence (n=41) across the study.

Lymphoedema (RAVI≥10%) by 9 months was an independent predictor of post 9 months distant disease-free cancer survival (Table).

**Conclusions**

Lymphoedema is associated with lasting quality of life deficits and early distant relapse. Women at low risk of lymphoedema (75%) can be reassured using the scoring model. Early Arm measurements at 1 month post-surgery a useful measurement time to determine lymphoedema risk and enable patients to be reassured (75%) or plan for lymphoedema monitoring.
A newly derived combined clinical treatment score and immunohistochemical-4 prognostic tool

Andrew Dodson¹, Ivana Sestak², Jane Bayani³, Mitch Dowsett¹, John Bartlett³ and Jack Cuzick². ¹Ralph Lauren Centre for Breast Cancer Research, The Royal Marsden Hospital, London, United Kingdom; ²Centre for Cancer Prevention, Queen Mary, University of London, London, United Kingdom and ³Ontario Institute of Cancer Research, Ontario, Canada.

AIM
To determine whether a modified Clinical Treatment Score (CTS) based on continuous tumor size and 5 lymph node categories provided more prognostic information in an independent test set than the original CTS with and without the Immunohistochemical-4 (IHC4) algorithm for prediction of residual distant recurrence risk over 10-years.

BACKGROUND
Risk of recurrence information in patients with estrogen receptor-positive (ER+), early breast cancer informs decision-making on chemotherapy use. The CTS and IHC4 algorithms provide such information, particularly when used in combination (IHC4+C). Their derivation in the translational cohort of the Arimidex Tamoxifen Alone or in Combination trial (TransATAC) was described by Cuzick et al in 2011. In the original model tumor size and nodal status were each classified into three categories, causing prognostic information to be lost.

METHODS
We modeled a novel CTSn algorithm on outcome data from patients in the anastrozole and tamoxifen arms in ATAC incorporating tumor size as a continuous variable and sub-dividing nodal status into five categories. IHC4n was re-derived in the TransATAC cohort independent of CTSn. Patients were chemotherapy-naïve. We compared ability to predict risk of residual distant recurrence of the new IHC4n+Cn model with that of the original one when tested in a training cohort and in a validation set of chemotherapy-naïve patients from the Tamoxifen vs. Exemestane Adjuvant Multicentre (TEAM) trial using Cox regression models and the C-index.

RESULTS
The ATAC training set for CTSn comprised 4056 patients, the TransATAC training set for IHC4n comprised 1125 patients; 2591 patients were in the TEAM validation set. Patients in the TEAM set were older (median age in TransATAC: 63.5, TEAM: 68.3 years), had a higher nodal-burden (node-positive in TransATAC: 29.4%, TEAM: 51.8%) and had more Grade 3 tumors (TransATAC: 18.3%, TEAM: 32.2%).

The new IHC4n+Cn was significantly prognostic, and non-significantly more prognostic than the original IHC4+C in both the training and validation cohorts. When assessed using the C-index statistic, IHC4n+Cn had a higher discriminatory ability than the original algorithm (Table 1).

CONCLUSION
By separately remodelling the part of the IHC4+C score based on clinicopathological characteristics using the whole ATAC chemo-naïve cohort, and the part that uses IHC-derived information in chemo-naïve TransATAC patients, we increased the precision of the individual risk estimates produced by both CTSn and IHC4n compared to those given by the original algorithms. The new IHC4n+Cn shows a trend for improved prognostic ability compared to the original IHC4+C. Like its predecessor, it relies on information that is readily available to clinicians and integrates it in an evidence-based way to improve prognostication in ER+ early breast cancer.
Result: Pre-surgical MRI FTV is significantly associated with DRFS (Wald p<0.00001), and more effective at predicting

Background: Patients achieving a pathologic complete response (pCR) following neoadjuvant therapy have significantly improved event-free survival relative to those who do not; and pCR is an FDA-accepted endpoint to support accelerated approval of novel agents/combinations in the neoadjuvant treatment of high risk early stage breast cancer. Previous studies have shown that recurrence risk increased with increasing burden of residual disease (as assessed by the RCB index). As well, these studies suggest that patients with minimum residual disease (RCB-I class) also have favorable outcomes (comparable to those achieving a pCR) within high risk tumor subtypes. In this study, we assess whether integrating RCB with MRI functional tumor volume (FTV), which in itself is prognostic, can improve prediction of distant recurrence free survival (DRFS); and identify a subset of patients with minimal residual disease with comparable DRFS as those who achieved a pCR. Imaging tools can then be used to identify the subset that will do well early and guide the timing of surgical therapy.

Method: We performed a pooled analysis of 596 patients from the I-SPY2 TRIAL with RCB, pre-surgical MRI FTV data and known follow-up (median 2.5 years). We first assessed whether FTV predicts residual disease (pCR or pCR/RCB-I) using ROC analysis. We applied a power transformation to normalize the pre-surgical FTV distribution; and assessed its association with DRFS using a bi-variate Cox proportional hazard model adjusting for HR/HER2 subtype. We also fitted a bivariate Cox model of RCB index adjusting for subtype; and assessed whether adding pre-surgical FTV to this model further improves association with DRFS using a likelihood ratio (LR) test. For the Cox modeling, penalized splines approximation of the transformed FTV and RCB index with 2 degrees of freedom was used to allow for non-linear effects of FTV and RCB on DRFS.

Result: Pre-surgical MRI FTV is significantly associated with DRFS (Wald p<0.00001), and more effective at predicting

Pre-surgical MRI FTV is significantly associated with DRFS (Wald p<0.00001), and more effective at predicting...
pCR/RCB-I than predicting pCR alone (AUC: 0.72 vs. 0.65). Larger pre-surgical FTV remains associated with worse DRFS adjusting for subtype (Wald p <0.00001). The RCB index is also significantly associated with DRFS adjusting for subtype (Wald p<0.00001). Adding FTV to a model containing RCB and subtype further improves association with DRFS (LR p=0.0007). RCB-I patients have excellent DRFS (94% at 3 years compared to 95% in the pCR group). Efforts are underway to identify an optimal threshold for dichotomizing pre-surgical FTV and FTV change measures for use in combination with pCR/RCB-I class to generate integrated RCB (iRCB) groups as a composite predictor of DRFS.

**Conclusion:** Pre-surgical MRI FTV is effective at predicting minimal residual disease (RCB0/I) in the I-SPY 2 TRIAL. Despite the association between FTV and RCB, FTV appears to provide independent added prognostic value (to RCB and subtype), suggesting that integrating MRI volume measures and RCB into a composite predictor may improve DRFS prediction.
Prognostic value of residual cancer burden (RCB), neo-bioscore and neoadjuvant response index (NRI) to evaluate response to neoadjuvant trastuzumab-based therapy in HER2-positive breast cancer (BC)

Tessa G Steenbruggen¹, Maartje van Seijen¹, Liselore M Janssen¹, Mette S van Ramshorst¹, Erik van Werkhoven¹, Esther H Lips¹, Marie-Jeanne TDF Vrancken-Peeters¹, Hugo M Horlings¹, Jelle Wesseling¹ and Gabe S Sonke¹. ¹The Netherlands Cancer Institute, Amsterdam, Noord-Holland, Netherlands.

Intro Pathological complete response (pCR) to neoadjuvant systemic therapy is associated with favorable long-term outcome. As pCR is not an optimal surrogate marker for outcome, other tools were developed to predict long-term outcome more accurately, including the RCB⁴, NRI³, and Neo-Bioscore⁵. We evaluated the prognostic value of these tools in a cohort of patients with HER2+ BC with the aim of selecting a group of patients with residual disease but a similar long-term outcome as patients achieving pCR.

Methods We included all patients with stage II-III HER2+ BC who were treated with trastuzumab-based neoadjuvant therapy and surgery in the Netherlands Cancer Institute between November 2004 and December 2016. Patients were identified from the institutes' tumor registry and data was collected from the patients' records. To assess RCB scores surgical specimens (breast and axilla tissue) of patients without pCR were retrospectively reviewed. NRI and Neo-Bioscore were calculated based on original pathology reports.

Primary endpoint was recurrence-free interval (RFI), defined as time since diagnosis of BC till locoregional or distant recurrence or death from BC, whatever came first. Cox proportional models were used with transformations of RCB, NRI, and Neo-Bioscore. In addition, we evaluated at which cut-off point the NRI could select patients with a similar good prognosis as patients who achieved a pCR, defined by the same lower bound of the 95%CI of the 5-year RFI estimate for the pCR-group.

Results 283 women were included, 149 (53%) with HER2+/ER+ BC. 28% received dual HER2-blockade. Median follow-up was 66 months (range 11-148). 157 patients (55%) achieved a pCR in breast and axilla; predicted 5-year RFI for this group was 91% (95%CI 86-96), HR no-pCR vs pCR 2.19, 95%CI 1.07-4.47. Table 1 shows the predicted 5-year RFI and HR for RCB classes.

The HR of an RFI event increases gradually for lower NRI values compared to NRI of 1 and gets more steep near NRI values of 0. Patients with a NRI of ≥0.80-0.99 have a 5-year RFI estimate of 90% (95%CI 86-96), HR 1.1 (95%CI 0.6-1.9) compared to patients with NRI of 1 (which is pCR). Table 2 shows the predicted 5-year RFI and HR for the Neo-Bioscore.

Conclusions We show that in a HER2+ BC cohort the RCB and NRI are able to identify a subgroup of patients with limited residual disease after neoadjuvant therapy with similar good prognosis as patients with pCR and therefore may not benefit from additional adjuvant therapy.

A clinical calculator to predict disease outcomes in women with hormone receptor-positive advanced stage breast cancer treated with first-line endocrine therapy

Mei-Yin C Polley¹, Maura N Dickler², Stephen Johnston³, Matthew P Goetz¹, Juan de la Haba⁴, Sibylle Loibl⁵, Rita S Mehta⁶, Jonas Bergh⁷, John Roberton⁸, William Barlow⁹, Heshan Liu¹, Kathleen Tenner¹ and Miguel Martín¹⁰. ¹Mayo Clinic, Rochester, MN; ²Eli Lilly, Indianapolis, IN; ³The Royal Marsden NHS Foundation Trust, London, United Kingdom; ⁴GEICAM, Madrid, Spain; ⁵German Breast Group (GBG), Neu-Isenburg, Germany; ⁶University of California, Irvine, Orange, CA; ⁷Karolinska Institute, Stockholm, Sweden; ⁸University of Nottingham, Nottingham, United Kingdom; ⁹Southwest Oncology Group (SWOG), Seattle, WA and ¹⁰Gregorio Marañón University Hospital, Madrid, Spain.

Purpose: Endocrine based therapy is an effective strategy to manage hormone receptor-positive, human epidermal growth factor receptor 2-negative (HR+/HER2-) advanced breast cancer (ABC). However, nearly all patients exhibit/develop either de novo or acquired resistance. While prognostic biomarkers of endocrine responsiveness are well established for the adjuvant treatment in ER+ breast cancer, less is known regarding prognostic and predictive biomarkers of response in the first line ABC setting. We sought to develop a clinical calculator based on clinical criteria for predicting progression-free survival (PFS) and overall survival (OS) of women with HR+/HER2- ABC who will be receiving endocrine monotherapy as first-line treatment for ABC.

Methods: The development of the clinical calculator will be based on data from modern clinical trials in women with HR+/HER2-ABC. The studies to be included in the final analyses are given in Table 1. The control arm data from trials 1-6 will form the training dataset (N = 1,223) and be used to construct the clinical prediction models. Variables considered include age, race, ECOG status, disease measurability, body mass index, disease-free interval, number of metastatic sites, locations of metastatic sites, prior endocrine therapy, and prior chemotherapy. Missing values will be imputed using single imputation with all variables included in the imputation model. For continuous variables, restricted cubic splines will be used to determine if non-linear effects may be more appropriate. The Lasso regression will be used as a variable selection technique to reduce the dimensionality of covariates; initially all pairwise interactions will be included in the model. Following Lasso regression, the multivariable Cox proportional hazards models will be constructed for PFS and OS including only variables retained in Lasso. The final model will be internally validated for discrimination and calibration using 10-fold cross-validation. External validation will be performed using control arm data from EGF 30008 (N = 536).

Results: To date, control arm data from four trials (trials 1-4) have been received. The preliminary results presented here are based on pooled data from C40503 and LEA, for which data elements have been harmonized. Models for predicting PFS and OS have good calibration and are associated with bias-corrected C-indices of 0.61 and 0.65, respectively. These models will be updated using pooled data from trials 1-6.

Conclusions: Our preliminary data demonstrate that clinical calculators based on baseline clinical factors can provide accurate prediction of PFS and OS in patients with HR+/HER2- ABC treated with first-line ET. If validated, these tools may be used for risk stratification in future clinical trials and to identify patients who may require more or less aggressive therapy.

Cumulative copy number imbalances after neoadjuvant chemotherapy residual breast tumor is an independent predictor of relapse

Patricia A Thompson¹, Abenaa Brewster², Spiridon Tsavachidis³, Georgina Armstrong³, Kim-Anh Do², Min-Jin Ha², Carolina Gutierrez², Fraser Symmans² and Melissa Bondy³. ¹Stony Brook School of Medicine, Stony Brook, NY; ²University of Texas MD Anderson Cancer Center, Houston, TX and ³Dan L Duncan Cancer Center, Baylor College of Medicine, Houston, TX.

Background: Identifying breast cancer patients after neoadjuvant chemotherapy (NAC) at greatest risk of recurrence would enhance selection of patients who may benefit from novel adjuvant treatments.

 Patients. 243 stage I-III breast cancer patients who underwent NAC with ≥10% residual tumor cellularity were identified from the MD Anderson Cancer Center and Ben Taub General Hospital, Harris County hospital. Tumor DNA was isolated for DNA copy number using OncoScan CNV FFPE, Affymetrix. Median follow-up was 67.8 months. Continuous residual cancer burden (RCB) scores with CNI data were available for 152 cases. To test if CNIs covering large regions were associated with recurrence after adjusting for prognostic variables and study site, data were summed to a chromosome-arm level. Eleven chromosome arms with false discovery rate <0.05 for breast cancer recurrence were identified. A stepwise multivariable model including age at diagnosis, tumor subtype, histologic grade, pre- and post-treatment stage, study site, and the 11 chromosomal arms were used to fit a parsimonious multivariate model for recurrence. Minimizing the Akaike Information Criterion yielded a final model with post-stage and a 5-arm CNI (5A-CNI) indicator including 2q, 3q, 4q, 10p, and 18p. Tumors were classified on 5A-CNI as 0 [no CNI], 1 [1-2] and 2 [≥2].

Results. The study population included 76 non-Hispanic White, 89 Hispanic, and 68 African American patients with a mean age of 49.1 years. 105 patients were classified as 5A-CNI-0, 97 as 5A-CNI-1 and 41 as 5A-CNI-2. A higher 5A-CNI score was associated with tumor grade, ER-negative tumors (p<0.002) and tumor subtype (p=0.014). For 5A-CNI scores of 0, 1 and 2, recurrence rates of 14%, 34% and 58.5% were observed, respectively. In the final multivariable model adjusted for post-stage, RCB and study site, when compared to 5A-CNI-0, the hazard of recurrence was elevated for 5A-CNI-1 (HR= 2.27 [95% CI, 1.01-5.1]) and 5A-CNI-2 tumors (HR=7.43 [95% CI, 2.85-19.39]). Further, while the sample size is limiting, of 10 patients who were RCB3 and 5A-CNI-2, 9 relapsed (90%) during follow-up compared to only 6 of 43 (14%) of RCB3 patients with 5A-CNI-0 (p<10⁻⁶). For patients with RCB1 or 2, relapse did not differ by 5A-CNI score. Neither race nor ethnicity were found to be independently associated with recurrence or tumor subtype. However, African American, followed by Hispanic patients, were more likely than non-Hispanic White patients to be classified as 5A-CNI-2 (p=0.013).

Conclusion. The 5A-CNI score in post NAC tumor identifies a patient population with very poor prognosis independent of current clinical prognostic factors including RCB. Validation of these findings may lead to a post NAC genomic test that identifies patients who would benefit from additional treatment. Further investigation of the nature of the association between the 5A-CNI score and race/ethnicity, which appears independent of tumor subtype, is warranted.
Development of a machine learning-based classifier for Oncotype DX® category prediction in a population of lymph node positive breast carcinoma patients

Francisco Beca¹, Soo-Ryum Yang¹, Joshua G Gruber¹, Keegan Barry-Holson¹, Robert West¹, Hannah Y Wen² and Kimberly H Allison¹. ¹Stanford University School of Medicine, Stanford, CA and ²Memorial Sloan Kettering Cancer Center, New York City, NY.

INTRODUCTION: Oncotype DX® (ODX) Assay is a valuable prognostic and predictive tool in ER+, Her2- invasive breast cancer (IBC). Initially tested and validated in lymph node (LN) negative patients, the indications of this test have been expanded to include patients with limited LN-positive disease. Several prediction systems have been developed to predict the ODX Recurrence Score (RS) with substantial performance in predicting a high vs low RS score but with low performance when predicting the 3 classes that compose the standard ODX. Additionally, many of these prediction systems have not been developed and/or tested for a population of LN+ patients.

OBJECTIVES: The primary objective of this study was to evaluate the performance of several previously published ODX RS predictive systems in a population of LN+ patients. Furthermore, we developed a machine-learning based classification system to accurately predict the ODX 3 category RS for this specific population.

METHODS: We conducted a retrospective search of Stanford's pathology database for all patients with LN+ IBC diagnosed between January 2013 and December 2017 with an ODX RS available. A total of 119 patients were identified for inclusion in this cohort. Our multivariate pathologic feature-based discriminatory model aimed to classify each case as belonging to the low, intermediate or high ODX RS category. We performed model validation by the 10-fold cross validation (10F-CV) method. The model's performance was assessed by comparing simple accuracy, balanced accuracy, F1 score (harmonic average of the precision and recall) and several concordance classification metrics.

RESULTS: Of the evaluated methods, Magee equations performed well in this population of LN+ patients with the modified Magee equation 2 displaying the best accuracy (70.9%) which was surprisingly better than originally reported (55.8%, in Klein et al. Mod Path. 2013). After an initial screen of methods and tuning of the best performing model, our model achieved an overall accuracy of 78.1% on 10F-CV with a 79.1 % balanced accuracy and no two-step discordances. This corresponded to an increase of weighted Cohen's kappa of 30% versus the best performing Magee equation in this cohort and an increase of 103% versus the modified Magee 1 equation (which uses the same features as our model except for tumor grade).

DISCUSSION: Classifiers aimed at providing an alternative to Oncotype DX testing are available and perform consistently across datasets. We are currently validating our approach in a population of 1000 LN-negative patients from the MSKCC and the SEER database. Due to the substantial performance of our machine learning-based classifier based on standard reported pathologic features, our model may be considered an alternative to the ODX standard testing or a screening method for ODX testing, especially for cases with where the cost and availability of the ODX test are a concern.
Standardized prediction of Oncotype DX® risk classes by local RT-qPCR

Hans-Anton Lehr¹, Sebastian Aulmann², Alfred Etzrodt¹, Mark Laible³, Kerstin Hartmann³, Claudia Gürtler³, Ralph M Wirtz⁴, Ugur Sahin³ and Zsuzsanna Varga⁵. ¹Institute of Pathology, Medizin Campus Bodensee, Friedrichshafen, Germany; ²OptiPath - MVZ für Pathologie, Frankfurt a.M., Germany; ³BioNTech Diagnostics GmbH, Mainz, Germany; ⁴Stratifyer Molecular Pathology GmbH, Köln, Germany and ⁵Institute of Pathology and Molecular Pathology, University Hospital Zurich, Zürich, Switzerland.

Background: Recent results from the prospective validation of the Oncotype DX® recurrence score (RS) have underlined the clinical validity of the assay for the prediction of chemotherapy benefit in ER+/HER2- early stage breast cancer patients. Due to health economic restrictions, some patients have no easy access to the test. A pre-selection of tumor samples may help identify patients with a high likelihood to be spared chemotherapy. Histology and semi-quantitative IHC are hence used to select samples for Oncotype testing, but these suffer from intra- and inter-observer variability, especially for Ki-67 which is a main factor in most RS prediction algorithms. We have established and validated a tool for the prediction of RS risk classes (TAILORx cutoff RS ≤25) based on highly standardized, reproducible and locally performed RT-qPCR measurements of ERBB2, ESR1, PGR and MKI67 mRNA using the CE-marked IVD MammaTyper®.

Methods: Total RNA was extracted from whole surface 10µm sections from FFPE breast cancer samples with a known RS result and a tumor cell content ≥20%. ERBB2, ESR1, PGR and MKI67 mRNA expression was measured by RT-qPCR on a CFX96 qPCR cycler using the MammaTyper® kit. A prediction model for an RS ≤25 result was established using multivariable logistic regression. Based on this model and the training data two cutoffs for confident prediction of low chemotherapy benefit patients in a clinical setting were established at 95% and 97.5% specificity. The model and the cutoffs were then fixed and validated in a second, separate set of breast cancer samples. ROC analysis was used to characterize predictive power of the continuous values resulting from the prediction model. Positive and negative predictive values for detection of an RS ≤25 result were also determined on the validation samples using the two pre-defined cutoffs.

Results: The sample set for training of the prediction model encompassed 202 samples including 29 samples (14.4%) with an RS >25. In an initial multivariable model with all four markers, PGR and MKI67 were the strongest predictors while the influence of ESR in the model was lower, but still significant. ERBB2 was no significant predictor in this set of ERBB2 negative samples and was therefore excluded from the final model which was based on three markers only. This three marker model achieved an AUC of 0.920 (95% CI: 0.871-0.968) in the training samples. When applying the fixed model from the training dataset to a second separately collected set of 104 samples containing 20 samples (19.2%) with an RS >25, an AUC of 0.883 (95% CI: 0.810-0.955) was documented. When further applying the two predefined cutoffs established in the training set, 45 and 36 of the 104 validation samples (43.3% and 34.6%) had a predicted low chemotherapy benefit result (RS ≤25). Even with the less stringent cutoff, not a single one of the RS >25 cases from the validation cohort was falsely predicted as RS ≤25 sample.

Conclusion: We have established a highly reliable method for prediction of Oncotype DX® low chemotherapy benefit results based on local and cost effective mRNA measurements. This method enables local pathologies to pre-assess routine samples using a highly precise molecular tool and thereby reserve the Oncotype DX® test for cases with ambiguous cancer biology.
Immune recurrence score (IRS) using 7 immunoregulatory protein expression can predict recurrence in stage I-III breast cancer patients

Dae-Won Lee¹, Han Suk Ryu¹,², Kyung-Hun Lee¹,², Min-Sun Jin³, Go-Un Woo¹, Koung Jin Suh⁴, Yaewon Yang⁵, Hee-Jun Kim⁶, Han-Byoel Lee¹,², Tae-Yong Kim¹,², Hyeong-Gon Moon¹,², Wonshik Han¹,², In Ae Park¹,², Dong-Young Noh¹,² and Seock-Ah Im¹,².

¹Seoul National University Hospital, Seoul, Republic of Korea; ²Cancer Research Institute, Seoul National University College of Medicine, Seoul, Republic of Korea; ³Bucheon St. Mary's Hospital, Bucheon, Republic of Korea; ⁴Seoul National University Bundang Hospital, Seongnam, Republic of Korea; ⁵Chungbuk National University College of Medicine, Cheongju, Republic of Korea and ⁶Chung-Ang University College of Medicine, Seoul, Republic of Korea.

Background: Immune cells in the tumor microenvironment play an essential role in tumor progression and regression. However, immunologic characteristics and their prognostic role have not been clearly identified in breast cancer patients. This study aimed to evaluate the immunologic characteristics and their prognostic role in breast cancer patients.

Methods: This study enrolled pathologically proven stage I-III breast cancer patients. We performed immunohistochemical staining in stromal tumor-infiltrating lymphocytes (TILs) using 10 immune markers (PD-1, PD-L1, PD-L2, IDO, TIM3, OX40, OX40L, B7-H2, B7-H3, B7-H4) with known/possible clinical relevance. Expression of PD-1, PD-L1, and PD-L2 was also measured in adjacent tumor tissue. Intensity and proportion of the staining was measured for each immune marker. The intensity of immunohistochemical staining (IS, intensity score) was graded as follows: 0 (negative), 1 (weak), 2 (moderate), 3 (strong). The proportion of staining (PS, proportion score) was graded as follows: 0 (stain under <1%), 1 (1% to 5%), 2 (5% to 10%), 3 (10 to 25%), 4 (25% to 50%), Grade 5 (> 50%). Immune markers were defined as positive with one of the following; IS 1 with PS over 3, IS 2 with PS over 2, IS 3 with PS over 1.

Results: A total of 392 patients, 271 (69.1%) luminal A, 36 (9.2%) luminal B, 32 (8.2%) HER2-positive, and 53 (13.5%) triple negative breast cancers were included. In total, PD-1 was expressed by stromal TILs in 130 (33.2%) patients, PD-L1 in 47 (12.0%), PD-L2 in 109 (27.8%), B7-H2 in 225 (57.4%), B7-H3 in 227 (57.9%), B7-H4 in 106 (27.0%), TIM3 in 111 (28.3%), IDO in 96 (24.5%), OX40 in 137 (34.9%), and OX40L in 165 (42.1%). In addition, PD-L1 was expressed in 15 (3.8%) tumor tissue, PD-L2 in 237 (60.5%), and PD-1 was not expressed in tumor tissue. Each breast cancer subtype showed different immunologic characteristics. Expression of PD-1 (stromal TILs) and PD-L1 (Tumor and stromal TILS) was higher in HER2-positive and triple negative breast cancer. By contrast, expression of TIM-3, OX40, and OX40L by stromal TILs were higher in luminal A and luminal B breast cancer. In the univariate analysis, expression of B7-H3 was associated with worse DFS and expression of OX40 and B7-H4 was associated with favorable DFS. Expression of PD-L1 was associated with worse DFS and expression of OX40 and B7-H4 had a tendency of favorable DFS. We devised an immune recurrence score (IRS) using 7 markers with prognostic value (B7-H2, B7-H3, B7-H4, OX40, OX40L, PD-L1, and PD-L2). Patients were classified as high-risk (31 patients, 7.9%), intermediate-risk (265, 67.6%), or low-risk (96, 24.5%) according to 7 immune marker expression. In the multivariate analysis, IRS low-risk (adjusted HR, 0.14; 95% CI, 0.04 – 0.45; p = 0.001) and intermediate-risk (adjusted HR, 0.32; 95% CI, 0.16 - 0.65; p = 0.002) had significantly lower risk of recurrence compared with high-risk. In the subgroup analysis, the prognostic role of IRS were maintained in both luminal A and non-luminal A patients.

Conclusions: This study identified immunologic characteristics of breast cancer patients using 10 immune markers. In addition, we devised an IRS with 7 immune markers which may predict recurrence in stage I-III breast cancer patients.
Development of an NGS-based multigene assay to predict recurrence risk in hormone receptor-positive, HER2-negative, node-negative breast cancer

Han-Byoel Lee1, Kyung Eun Kim1, Young Wook Ju1, Ji-Gwang Jung1, Han-Suk Ryu1, Sae Byul Lee2, Jong Won Lee2, Hee Jin Lee2, Min-Su Kim2, Sunyoung Kwon3, Jinkyoung Kim4, Chungyeul Kim4, Hyeong-Gon Moon4, Dong-Young Noh1, Sei-Hyun Ahn2, In-Ae Park1, Sun Kim3, Sungroh Yoon3, Aeree Kim4 and Wonshik Han1. 1Seoul National University Hospital, Seoul, Korea; 2Asan Medical Center, Seoul, Korea; 3Seoul National University College of Engineering, Seoul, Korea and 4Korea University Guro Hospital, Seoul, Korea.

Introduction: Multigene assays provide prognostic information in hormone receptor (HR)-positive breast cancer. Compared to reverse transcription polymerase chain reaction (RT-PCR) or microarray used in currently available assays, a next-generation sequencing (NGS)-based RNA-sequencing allows for a more precise expression analysis with a broader coverage in a larger number of genes at lower costs. The purpose of this study was to develop and validate an NGS-based multigene prognostic assay to predict distant recurrence risk in HR-positive, HER2-negative, node-negative breast cancer.

Methods: We selected genes that are well correlated with the 21-gene assay recurrence score (RS) calculated from seven public RNA datasets. Using formalin-fixed, paraffin-embedded (FFPE) tissue from 343 consecutive patients with known RS (range 2-71), RNA-sequencing was performed for the selected genes and expression data was developed. A training dataset of 250 samples was used to develop an algorithm that predicts RS, and an independent dataset of 93 samples was used to verify its predictive ability. We validated the prognostic ability of the developed algorithm using 482 FFPE samples with long-term follow up. 78 of which had developed distant metastasis. All cases with no distant metastasis during follow up had not received adjuvant chemotherapy. Kaplan-Meier survival analysis and Cox proportional hazards model was used for validation.

Results: We developed an algorithm that predicts RS using expression data of 149 genes. A verification set of 93 samples demonstrated an accurate classification of predicted RS ≥25 vs <25 in 92.5% and an R² of 0.875 on regression analysis. Median follow up of 482 samples used for validation of prognostic ability of the algorithm was 110 months. Five-year metastasis-free survival (MFS) according to predicted value cut-offs of 25, 20, and 18, as well as their hazard ratios from Cox proportional hazards model are shown in Table 1.

Table 1. Metastasis-free survival according to prognostic scores derived from the NGS-based multigene assay.

MFS, metastasis-free survival; HR, hazard ratio; CI, confidence interval

The prognostic value is greatest when using the cut-off value of 20, and is consistent for 283 patients with age <50 (5yr MFS 98.4±0.9% vs 79.2±4.2%; HR 5.763; 95% CI 2.869-11.575).

Conclusions: We developed an NGS-based multigene assay that accurately predicts distant recurrence risk in HR-positive, HER2-negative, node-negative breast cancer. The prognostic ability is consistent for younger patients under age 50. This assay may be an alternative to commercially available assays.
Prediction of the Oncotype Dx recurrence score (RS) from clinicopathologic factors

Ioannis A Voutsadakis¹², Stephane Thibodeau² and Melissa Reed³. ¹Sault Area Hospital, Sault Ste Marie, ON, Canada; ²Northern Ontario School of Medicine, Sudbury, ON, Canada and ³Algoma University, Sault Ste Marie, ON, Canada.

Background: The Oncotype Dx assay is currently used as an aid to therapeutic decisions for the adjuvant treatment of women with ER-positive, Her2-negative, lymph node-negative or -micrometastatic breast cancer. The recently reported TAILORx study showed that no or minimal benefit is derived from adjuvant chemotherapy in patients with an Oncotype Dx Recurrence Score (RS) of 25 or less.

Methods: Charts of breast cancer patients that had the Oncotype Dx test in our cancer center in a nine-year period were reviewed. Data on demographic, and cancer-specific characteristics of the included patients were extracted. Predicted disease recurrence from the Oncotype Dx test was recorded and correlated with select clinicopathologic characteristics.

Results: Two hundred and thirty patients with ER-positive, Her2-negative, lymph node-negative or micrometastatic breast cancer were included. Mean age was 65 years-old (SD 9.9). Two hundred and three patients (88.3%) were post-menopausal and one hundred and thirty-three patients (57.8%) were 65 years-old or older. Two hundred and nine patients (90.9%) had lymph node-negative disease. Oncotype Dx recurrence score was low (<11) in sixty-four patients (27.8%), intermediate (11-25) in one hundred and forty patients (60.9%) and high (>25) in twenty-six patients (11.3%). High tumor grade and low progesterone receptor (PR) staining by IHC were the two clinicopathologic factors most associated with a high Oncotype Dx RS (x² test p <0.00001 and Fisher's exact test p <0.0001). A predictive index (PI) was constructed, assigning one point each for grade 3 and PR staining in 20% or less of tumor cells. A PI of 0 was observed in one hundred and thirty-eight patients (60%), a PI of 1 was observed in seventy-one patients (30.9%), and a PI of 2 was observed in twenty-one patients (9.1%). One hundred and thirty-four patients (97.1%) with a PI of 0 had a RS of 25 or less. Patients with a PI of 1 and 2 had a RS of >25 in 12.7% and 61.9% of cases, respectively.

Conclusion: The PI based on tumor grade and PR we propose is a simple predictor of Oncotype Dx RS. 97.1% of patients with a grade 1 or 2 tumor and PR positivity in >20% of tumor cells had a RS of 25 or less. The Oncotype Dx test and its associated cost can therefore be avoided in these patients, especially in low-resource settings.
A prognostic prediction nomogram (PDIDC) for breast Paget's disease with infiltrating ductal carcinoma patients: A SEER cohort analysis

Luyuan Tan¹, Kai Chen¹, Wen G Jiang¹,², Na You², Yan Wang¹, Andrew Sanders³, Gehao Liang¹, Zihao Liu¹, Yun Ling¹, Wenjing Zhong¹, Zhenluan Tian¹ and Chang Gong¹. ¹Guangdong Provincial Key Laboratory of Malignant Tumor Epigenetics and Gene Regulation and Breast Tumor Center, Sun Yat-Sen Memorial Hospital, Sun Yat-Sen University, Guangzhou, Guangdong, China; ²School of Mathematics and Computational Science & Southern China Research Center of Statistical Science, Sun Yat-sen University, Guangzhou, Guangdong, China and ³Cardiff China Medical Research Collaborative, Cardiff University School of Medicine, Cardiff University, Heath Park, Cardiff, United Kingdom, Cardiff, Wales, United Kingdom.

Purpose
The aim of the study was to develop a specific nomogram for prediction of prognosis for breast Paget's disease with infiltrating ductal carcinoma (PD-IDC) patients.

Patients and Methods
Patients data were obtained by the Surveillance, Epidemiology, and End Results (SEER) program (N=2502). Study outcome was Breast Cancer Specific Survival (BCSS). Cox proportional hazards model was applied to identify risk factors and develop predictive model. For internal validation, discrimination was calculated with the concordance index (C-index) using the bootstrap method and calibration assessed.

Results
NPI classification, skin symptom, tumor site and age showed significant association with BCSS(table.1) and were used to build the PDIDC nomogram and to calculate risk score.

Variable finally selected for risk predicted model.

* Continuous variable.

PDIDC nomogram's C-index (0.791, 95%CI 0.783-0.818) showed better discrimination power than NPI classification (0.691, 95%CI, 0.650-0.735, P=0.000) and AJCC staging (0.718, 95%CI, 0.695-0.741, P=0.000). Patients were divided into high-risk (1882/2502, 75.21%) and low-risk (620/2502, 24.78%) subgroups with the optimal cut-off of risk scores (4.28). The total BCSS of low-risk subgroup was 77.8% (95%CI 74.4%-81.4%) vs. 31.1% (95%CI 19.4-49.8) of high-risk group (P=0.000). Bootstrap internal validation demonstrated an average C-index of 0.739 (95% CI, 0.692-0.746). The nomogram calibration was validated to be accurate in predicting 5-year and 10-year survival.

Conclusion
Utilizing NPI classification, skin symptom, tumor site and age, we developed the PDIDC nomogram to predict the 5-year and
10-year BCSS of breast PD-IDC patients.
OncoproMex®: An intelligent decision support system for Mexican breast cancer patients

Alejandra Armengol-Alonso⁶, Fabiola M Villalobos-Castaldi⁶, Paula Cabrera-Galeana⁵, Enrique Bargallo-Rocha⁴, Nancy Reynoso-Noverón⁵, Alejandro Mohar⁵ and Julia P Melo-Morin¹. ¹Instituto Tecnológico Superior de Panúco, Panúco, Veracruz, Mexico; ²Instituto de Ciencias Aplicadas y Tecnología/ Universidad Nacional Autónoma de México, Mexico, City, Mexico; ³Breast Medical Oncology Unit / Instituto Nacional de Cancerología, Mexico, City, Mexico; ⁴Instituto Nacional de Cancerología, Mexico, City, Mexico; ⁵Epidemiology Breast Cancer Unit / Instituto Nacional de Cancerología, Mexico, City, Mexico and ⁶Instituto Nacional de Ciencias Médicas y Nutrición Dr Salvador Zubirán, Mexico, City, Mexico.

Background: Breast cancer in Mexico is the first cause of mortality due to malignant tumors among women. The five-year overall survival among Mexican breast cancer patients (MexBCP) treated at governmental facilities is about 75-80% as a result of an increased access to oncology treatments (WHO 20th model list essential medicines) in the Public Health Insurance called "Seguro Popular". Expert systems are computer programs that are derived from a branch of computer Science research called Artificial Intelligence (AI). We do not have a system based on artificial intelligence for MexBCP prognostic and predictive evaluation. The aim was develop an expert system that generates a model based on data mining techniques, which allowed predict the MexBCP survival.

Patients and Methods:
This study was carried out by the methodology currently used in the processes of Knowledge Discovery from Databases (KDD), supported by the WEKA free distribution tool for the modeling of data mining techniques. The breast cancer data of 4,773 were provided by INCAN cohort of 4300 patients diagnosed from 2006 to 2013 with a median follow-up of 40.5 months and by INCMNSZ cohort of 473 patients from 2011 to May 2018 with a median follow-up of 39 months. The clinical and pathologic variables were: age, TNM stage, hormonal status (pre or perimenopause or postmenopause), ER, PR, HER2, Ki67, nuclear grade. Date of histological diagnosis, date of recurrence or last medical consultation, date of death, specific cancer were used for Survival analysis.

Results: The knowledge base for the expert system was based on the rules generated by the different data mining techniques. The rules used were generated by the Prism classification algorithm, which classify with a 97% percentage of instances correctly and a Kappa statistic of 0.9208. These rules obtained characteristics in each of the attributes, as well as the percentage of certainty of each of those rules. In addition to determining the average life of the group of patients that was classified in each of the generated rules. Finally, the basic elements that formed part of the architecture of the expert system carried out were the knowledge base, the inference engine, the database and the interface with the user. An on-line expert system was created, which allows users to interact and thus allow decision-making based on the results presented.

Conclusion:
As far as we know this is the first expert system that allows calculate prognosis according to clinical-pathological variables. It is of great relevance know the survival of a Mexican patient with breast cancer in the public health system with access to essential treatment. The applications of the system can be multiple in the usual clinical practice, education and in the taking of public policies for breast cancer in Mexico. We are currently working on a predictive model of oncological treatment benefit based also on an expert system.
Factors predicting relapse in early breast cancer patients with a pathological complete response after neoadjuvant therapy – Results of a pooled analysis based on the GBG meta-database

Jens Huober¹, Andreas Schneeweiss², Jens-Uwe Blohmer³, Carsten Denkert⁴, Hans Tesch⁵, Claus A Hanusch⁶, Christoph Salat⁷, Kerstin Rhiem⁸, Mahdi Rezai⁹, Christine Solbach¹⁰, Peter A Fasching¹¹, Christian Jackisch¹², Keyur Mehta¹³, Valentina Nekljudova¹³, Fenja Seither¹³, Gunter von Minckwitz¹³, Sibylle Loibl¹³ and Michael Untch¹⁴.

¹Universitätsfrauenklinik, Brustzentrum, Ulm, Germany; ²Nationales Centrum für Tumorerkrankungen, Heidelberg, Germany; ³Brustzentrum, Charité-Universitätsmedizin, Berlin, Germany; ⁴Institut für Pathologie, Charité-Universitätsmedizin, Berlin, Germany; ⁵Centrum für Hämatologie und Onkologie Bethanien, Frankfurt, Germany; ⁶Klinikum zum Roten Kreuz, München, Germany; ⁷Zentrum für Hämatologie und Onkologie, München, Germany; ⁸Zentrum Familiärer Brust- und Eierstockkrebs, Universitätsklinikum, Köln, Germany; ⁹Medical Center, Luisenkrankenhaus, Düsseldorf, Germany; ¹⁰Universitätsklinikum, Frankfurt, Germany; ¹¹Brustzentrum, Universitätsklinikum, Erlangen, Germany; ¹²Sana Klinikum, Offenbach, Germany; ¹³German Breast Group, Neu-Isenburg, Germany and ¹⁴HELIOS Klinikum, Berlin-Buch, Germany.

Background
Even though patients with a pCR following neoadjuvant chemotherapy have an excellent prognosis still some of these patients will eventually relapse. A better identification of pts with an increased risk of relapse despite a pCR would be helpful to select these patients for additional post-neoadjuvant treatment strategies. Thus, the rationale of this retrospective analysis was to identify factors predicting relapse despite a pCR.

Methods
This pooled retrospective analysis based on the GBG meta-database includes the neoadjuvant trials GeparTrio, GeparQuattro, GeparQuinto, GeparSixto and GeparSepto. In these trials 2188 (27%) of 7933 pts had a pCR according to ypT0/ypTis ypN0 and were included. The primary endpoint was disease-free survival (DFS), secondary endpoints were distant DFS (DDFS) and overall survival (OS). A multivariate Cox proportional hazards model was used to report hazard ratios with 95% confidence interval (CI). The two-sided significance level was set to α=0.05. Endpoints were analysed for all pts and in subgroups defined by intrinsic subtypes. The potential risk factors intrinsic subtype (HER2 negative/hormone receptor (HR) positive, triple negative, HER2 positive/HR positive, HER2 positive/HR negative), histological tumor type (lobular vs other), grade (G1/G2 vs G3), Ki67 (≤ 20% vs higher), initial cT and cN stadium (cT1 vs cT2 vs cT3/4; cN0 vs cN+), age (≤ 40 vs 41-59 vs ≥ 60), BMI (< 25 vs 25-29 vs ≥ 30), planned number of cycles of chemotherapy (< 6 vs > 6), menopausal status (pre- vs postmenopausal) and clinical response after 2-4 cycles (SD vs PR vs CR vs PD) were included as covariates in multivariate Cox regression models as well as study identification.

Results
From 2188 evaluable patients DFS, DDFS and OS events were observed in 290/197/130 pts respectively; the median follow-up over all studies was 59 months. In multivariate analysis including study and all potential risk factors DFS was significantly different with regard to the initial cN status (cN+ vs cN0, hazard ratio (HR) 1.70; 95% CI [1.2, 2.4], p=0.002). Of borderline significance was histological type (lobular vs other), grade (G1/G2 vs G3), Ki67 (≤ 20% vs higher), initial cT and cN stadium (cT1 vs cT2 vs cT3/4; cN0 vs cN+), age (≤ 40 vs 41-59 vs ≥ 60), BMI (< 25 vs 25-29 vs ≥ 30), planned number of cycles of chemotherapy (< 6 vs > 6), menopausal status (pre- vs postmenopausal) and clinical response after 2-4 cycles (SD vs PR vs CR vs PD) were included as covariates in multivariate Cox regression models as well as study identification.

Conclusions
Initial tumor load before start of neoadjuvant chemotherapy (tumor stage and nodal status) and lobular subtype were predictors of long term outcome after a pCR following neoadjuvant chemotherapy. Intrinsic subtype, Ki67, grade and planned number of cycles were not predictive for a relapse.
Interaction of PIK3CA mutation subclasses with response to preoperative treatment with the PI3K inhibitor pictilisib in patients with estrogen receptor-positive breast cancer

Peter Schmid1, Sarah Pinder2, Duncan Wheatley3, Charles Zummit4, E J Macaskill5, Jennifer Hu6, Robert Price7, Nigel Bundred7, Sirwan Hadad7, Alice Shia1, Shah-Jalal Sarker1, Louise Lim7, Kelly Mousa1, Carol O’Brien10, Timothy R Wilson10, Mark R Lackner10, Steven Gendreau10, Patrycja Gazinska11, Darren Korbie12, Matt Trau12, Paul Mainwaring13, Alastair Thompson14 and Arnie Purushotham2, 1Barts Cancer Institute, Queen Mary University of London, London, United Kingdom; 2Guy’s and St Thomas’ NHS Foundation Trust, London, United Kingdom; 3Royal Cornwall Hospitals NHS Trust, Truro, United Kingdom; 4Brighton and Sussex University Hospitals NHS Trust, Brighton, United Kingdom; 5Ninewells Hospital, Dundee, United Kingdom; 6Barts Health NHS Trust, London, United Kingdom; 7King’s College Hospital NHS Foundation Trust, London, United Kingdom; 8Manchester University NHS Foundation Trust, London, United Kingdom; 9Sheffield Teaching Hospitals NHS Foundation Trust, Sheffield, United Kingdom; 10Genentech, San Francisco; 11Breast Cancer Now Research Unit, Cancer Centre at Guy’s Hospital, Faculty of Life Sciences and Medicine, King’s College London, London, United Kingdom; 12Australian Institute for Bioengineering and Nanotechnology, University of Queensland, Brisbane City, Australia; 13Mater Research Centre, Brisbane, Australia and 14The University of Texas MD Anderson Cancer Centre, Houston.

Background: Although preclinical data suggest that combining PI3K inhibitors with endocrine therapy may overcome resistance, results from randomized clinical trials have failed to identify a subgroup of patients that derive a substantial benefit. This preoperative window study assessed whether adding the PI3K inhibitor pictilisib can increase the anti-tumor effects of anastrozole in primary breast cancer and aimed to identify the most appropriate patient population for combination therapy.

Methods: In this randomized, open-label, phase 2 study, 167 postmenopausal women with newly diagnosed, operable, ER-positive, HER2-negative breast cancers were recruited. Participants were randomly allocated (2:1, favoring the combination) to two-weeks of preoperative treatment with anastrozole 1 mg once daily or the combination of anastrozole 1mg with pictilisib 260 mg once daily. The primary endpoint was inhibition of tumor cell proliferation, as measured by change in Ki-67 protein expression between tumor samples taken before and at the end of treatment. Secondary endpoints include induction of apoptosis (Caspase3) and safety. Comprehensive biomarkers analyses included targeted NGS of a comprehensive cancer panel of >400 genes (Ampliseq Comprehensive Cancer panel), copy number variation analyses, and pre- and post-treatment reverse-phase protein arrays (RPPA) and RNA profiling (NanoString nCounter platform).

Results: There was significantly greater geometric mean Ki67 suppression of 82.5% (90% CI, 78.3%-85.8%) for the combination vs 70.7% (61.0%-78.0%) for anastrozole [geometric mean ratio (combination/ anastrozole) 0.60 (0.58-0.85); p=0.01]. Higher baseline Ki67, Luminal B status and/or negative PR status were associated with increased benefit from adding pictilisib. A significant interaction was observed between PIK3CA mutation subtypes [helical domain mutations (HD), kinase domain mutations (KD), wildtype (WT)] and mean Ki67 suppression; the combination/anastrozole geometric mean ratio of Ki67 suppression was 0.48 (0.27-0.84; p=0.02) for patients with HD mutations and 0.63 (0.39–1.0; p=0.05) for patients with PIK3Ca WT, compared to 1.17 (0.57–2.41; p=0.64) for patients with KD mutations. This was largely due to patients with HD mutations showing a particularly poor response to anastrozole alone [mean Ki67 suppression 53.9% (9.5%-76.5%)], that was reversed by the addition of pictilisib [mean Ki-67 suppression 78.1% (71.0%-83.4%)]. On the other hand, patients with KD mutations responded well to anastrozole alone [mean Ki-67 suppression 77.7% (57.0%-88.4%) and showed no benefit from the addition of pictilisib [mean Ki-67 suppression 73.9% (59.8%-83.0%)]. There was no significant difference in induction of apoptosis between treatment groups. Comprehensive pre- and post-treatment biomarkers analyses will be presented.

Conclusions: Adding pictilisib to anastrozole significantly increases the anti-proliferative response to preoperative treatment with anastrozole. A significant interaction was observed between PIK3CA mutation subtypes, with patients with helical domain mutations showing a particularly poor response to anastrozole alone that was reversed by the addition of pictilisib.
Multiple foci of microinvasion is associated with an increased risk of invasive local recurrence and an increased risk of breast cancer mortality in women with ductal carcinoma in situ treated with breast-conserving therapy

Eileen Rakovitch¹,², Rinku Sutradhar², Nafisha Lalani¹, Sumei Gu², Sharon Nofech-Mozes¹, Wedad Hanna¹, Cindy Fong² and Lawrence Paszat¹,². ¹Sunnybrook Health Sciences Centre, University of Toronto, Toronto, ON, Canada and ²Institute for Clinical Evaluative Sciences, Toronto, ON, Canada.

Purpose: Ductal Carcinoma in Situ (DCIS) with microinvasion (MI) (≤ 1mm) includes a spectrum of cases with a single focus of MI and those with multiple foci (2 or more) of MI. The impact of multiple foci of MI on the risks of local recurrence (LR), invasive LR and breast cancer-specific survival (BCSS) is unknown, leading to uncertainty if DCIS with multiple foci of MI requires more aggressive treatment than those with a single focus of MI or pure DCIS. We examined the impact of multiple foci of MI, confirmed by expert pathology review, on the 15-yr risks of LR, invasive LR and breast-cancer specific survival (BCSS) in a population cohort of DCIS (+/-MI) treated with breast-conserving surgery (BCS) +/- radiotherapy (RT).

Methods: The cohort includes all women diagnosed with DCIS +/- MI in Ontario from 1994-2003 treated with BCS+/-RT. Cases with prior malignancy were excluded. Treatment and outcomes were ascertained by deterministic linkage with chart validation. Cause of death was determined from the provincial cancer registry or terminal hospital admission records. Cox proportional hazards model was used to evaluate the impact of multiple foci of MI on the risks of ipsilateral invasive LR and ipsilateral DCIS LR, adjusting for significant co-variates. The 15-yr invasive local recurrence-free survival (LRFS), DCIS LRFS and 15-yr BCSS risks were calculated using the Kaplan-Meier method with differences compared using the log-rank test.

Results: The cohort includes 3529 women; 2988 (85%) with pathology review are included in this analysis. 2,721 had pure DCIS (51% received RT), 267 had DCIS with MI (1 focus, N=156; multiple foci, N=111 (58% had RT)). Median follow-up was 13 years. Median age at diagnosis was 58 years. LR developed in 571 cases (21%) of pure DCIS, 33 cases (21%) with 1 focus of MI and 23 cases (27%) with multiple foci of MI. On multivariable analyses, the presence of multiple foci of MI was associated with an increased risk of invasive LR (HR=1.59, 95%CI: 1.01-2.49, p=0.04) but not DCIS LR (HR=0.89, 95%CI: 0.46, 1.76, p=0.7). Women with multiple foci of MI had higher risks of invasive LR and lower BCSS at 15 years compared to those with pure DCIS. The 15-year invasive LRFS risks for cases with pure DCIS, with 1 focus or multiple foci of MI were 85.7%, 85.6%, 74.7% for cases treated by BCS alone and 87.2%, 89.9% and 77% following BCS+RT without boost; however, women treated with boost RT had substantially higher 15-yr invasive LRFS risks than those who did not receive boost RT. The 15-yr invasive LRFS risks for those with pure DCIS, 1 or multiple foci of MI, were 89.2%, 91.3% and 95% (all p values>.05, limited by low event rate). The 15-yr BCSS risks for cases with 1 focus, multiple foci of MI or pure DCIS were 92.1%, 93.1%, 96.4% (p=.006).

Conclusions: The presence of multiple foci of MI in DCIS is associated with higher 15-year risks of invasive LR and lower breast-cancer specific survival after breast-conserving therapy compared to women with pure DCIS but treatment with whole breast and boost RT can mitigate this risk.
Prediction of distant recurrence by EndoPredict in patients with estrogen receptor-positive, HER2-negative breast cancer who received adjuvant endocrine therapy plus chemotherapy (ET+C) or endocrine therapy alone (ET)

1Centre for Cancer Prevention, Queen Mary University London, London, United Kingdom; 2Hospital General Universitario Gregorio Marañón, GEICAM, Madrid, Spain; 3Klinik St. Anna, Lucerne, Switzerland; 4CIBERONC-ISCIII Fundación Jiménez Díaz, GEICAM, Madrid, Spain; 5Medical University of Vienna, Vienna, Austria; 6The Breast Cancer Now Toby Robins Research Centre, Institute of Cancer Research, London, United Kingdom; 7Austrian Breast and Colorectal Study Group, ABCSG, Vienna, Austria; 8Instituto Valenciano de Oncología, GEICAM, Valencia, Spain and 9Hospital Universitario de Elche, GEICAM, Valencia, Spain.

Background: EndoPredict (EPclin) is a validated prognostic test combining expression of 12 cancer-related genes for breast cancer patients with estrogen receptor (ER) positive, HER2-negative disease who received 5 years of endocrine therapy (Buus et al., 2017; Dubsky et al. 2012) and for women who received chemotherapy (Martin et al., 2014). Here, we determine the EPclin and 10-year distant recurrence free interval (DRFI) rates for patients who received adjuvant endocrine therapy plus chemotherapy (ET+C) or endocrine therapy alone (ET) using data from five large clinical trials.

Methods: A total of 3746 women with ER-positive, HER2-negative disease were included in this analysis. 2630 patients received 5 years of ET alone (ABCSG-6/8, TransATAC) and 1116 patients received ET+C (GEICAM 2003-02/9906). EPclin incorporates tumor size and nodal status and accounts for different EPclin scores between ET+C and ET alone cohorts. The primary objective was to evaluate the 10-year DRFI rates as a continuous function of EPclin separately for patients in ET+C and ET. Secondary objectives included assessing the difference in the prognostic ability of EPclin between ET+C and ET overall (years 0-10) and for specific follow-up periods (years 0-5 and years 5-10). The primary endpoint was DRFI and the secondary endpoint was breast cancer free interval (BCFI). Cox proportional hazard models were used to estimate 10-year DRFI rates and to assess the prognostic information provided by EPclin.

Results: All of the women on ET alone and 49% of those on ET+C were postmenopausal. Women who received ET+C had more node positive disease, more poorly differentiated tumours, and higher EPclin scores than those who received ET alone. Women who received ET+C had significantly smaller increases in 10-year DRFI rates with increasing EPclin score than those receiving ET alone (Table). EPclin was highly prognostic for DRFI in all women who received ET alone (HR=2.79 (2.49-3.13), P<0.0001) as well as in those who received ET+C (HR=2.27 (1.99-2.59), P<0.0001), both in the overall cohort and in postmenopausal women only (ET+C: HR=2.64 (2.07-3.37), P<0.0001). We observed a significant interaction between EPclin and treatment for DRFI at 10 years (Pinteraction=0.022). EPclin was highly prognostic in ET alone and ET+C in years 0-5 and in particular in years 5-10. Similar results were observed when BCFI was the endpoint.

Conclusion: In our results from a non-randomized analysis, we observed significantly smaller increases in 10-year DRFI rates with increasing EPclin scores for women who received ET+C compared to those who received ET alone. Our indirect comparisons suggest that a high EPclin score can predict chemotherapy benefit in women with ER-positive, HER2-negative disease.

10-year DRFI risks (%) (95% CI) according to EPclin score for patients who received ET+C versus ET alone.

Background: The expression of ER, PR and HER2 in breast cancer is determined by routine pathology assessment to indicate systemic treatment. Here, we investigated the ability of a standardized mRNA-based assay to predict ER, PR and HER2 status and treatment response.

Methods: ESR1, PGR and ERBB2 expression was analyzed from the standardized nCounter-based PAM50 assay in 1,544 FFPE breast tumors obtained from 13 independent studies (NeoEribulin, GEICAM 2012-09, TBCRC023/006, LPT109096, EGF117165, PAMELA, PerELISA, GEICAM 2003-11, VENTANA, IBIMA and HCB). All immunohistochemical and in situ hybridization analyses followed ASCO/CAP criteria and were performed in central labs except for NeoEribulin and VENTANA studies. To explore the best cutoff for each gene, we used Monte Carlo cross validation (repeated 1000 times, 2/3 training, 1/3 testing) to achieve the highest kappa values when gene expression was compared to pathology assessment. Receiver operating characteristic analysis and area under the ROC curve (AUC) was used to evaluate the performance of each gene to predict ER, PR and HER2 status. Finally, the association of each gene (using the pre-established cutoffs) with pathological complete response (pCR) was evaluated using univariate logistic regression analyses in 2 neoadjuvant cohorts: 1) A combined HER2+ cohort using 191 tumor samples from PAMELA/PerELISA phase II trials, where patients received neoadjuvant dual HER2 blockade without chemotherapy for 15-18 weeks and 2) a combined cohort of hormone receptor-positive/HER2-negative using 205 tumor samples from IBIMA/HCB consecutive series, where patients received anthracycline/taxane-based chemotherapy.

Results: Concordance between ESR1 and ER was 95.3% (95% confidence interval [95Cl] 94.0-96.4%; AUC=0.98). ER+ and ER- cases were classified as ESR1- and ESR1+ in 5.5% and 4.8% of the cases, respectively. Concordance between PR and PGR was 85.2% (95CI 83.1-87.1%; AUC=0.95), and between ERBB2 and HER2 was 92.8% (95CI 91.4-94.1%; AUC=0.95). HER2+ and HER2- cases were classified ESRB2- and ERBB2+ in 16.7% and 2.9% of the cases, respectively. In the neoadjuvant HER2+ cohort, the pCR rates were 44.6% in ESR1- and 18.8% in ESR1+ (odds ratio [OR] 3.9; 95CI 1.9-8.4; p<0.001), 38.5 in PGR- and 15.8% in PGR+ (OR 3.2; 95CI 1.6-6.7; p=0.001), 2.6% in ERBB2- and 35.3% in ERBB2+ (OR 19.7; 95CI 2.6-149.1; p<0.001). In the neoadjuvant HR+HER2- cohort, the pCR rates were 40% in ESR1- and 5.12% in ESR1+ (OR 11.5; 95CI 2.7-48.5; p<0.001), 15.5% in PGR- and 4.3% in PGR+ (OR 3.8; 95CI 1.3-11.7; p=0.019), 7.36% in ERBB2- and 0% in ERBB2+ (OR NA). Finally, ESR1, PGR and ERBB2 expression as continuous variables were found significantly associated with pCR in both cohorts.

Conclusion: ESR1, PGR and ERBB2 standardized mRNA levels show high concordance with ER, PR and HER2, and might provide a more objective and quantitative prediction of response to chemotherapy and anti-HER2 therapy. The level of concordance between GE and pathology-based assessments is similar to 2 FDA 510(k) cleared pathology-based ER assays (e.g. SP1 versus 6F11 antibody clones), local versus central HER2 testing, and ER or PR status when determined by the
ligand-binding assay versus immunohistochemistry.
Prognostic impact of the 21-gene recurrence score assay among young women with node-negative and node-positive ER+/HER2- breast cancer

Philip D Poorvu1, Shari I Gelber1, Shoshana M Rosenberg1, Kathryn J Ruddy2, Rulla M Tamimi3, Laura C Collins4, Jeffrey Peppercorn5, Lidia Schapira6, Virginia F Borges7, Steven E Come4, Ellen Warner8, Debbie M Jakubowski9, Christy Russell10, Eric P Winer1 and Ann H Partridge1. 1Dana-Farber Cancer Institute, Boston, MA; 2Mayo Clinic, Rochester, MN; 3Brigham and Women's Hospital, Boston, MA; 4Beth Israel Deaconess Medical Center, Boston, MA; 5Massachusetts General Hospital, Boston, MA; 6Stanford University, Palo Alto, CA; 7University of Colorado Cancer Center, Aurora, CO; 8Sunnybrook Health Sciences Centre, Toronto, ON, Canada and 9Genomic Health Inc., Redwood City, CA.

Background: The 21-gene Recurrence Score (RS) assay is prognostic among women with early-stage estrogen receptor (ER) positive and human epidermal growth factor receptor 2 (HER2) negative breast cancer (BC) and is used to select patients for chemotherapy (CT). Young women (age ≤40) have represented a minority in studies evaluating gene expression assays, including TAILORx, and additional data in young women are needed.

Methods: In the Young Women's Breast Cancer Study, a prospective cohort study of women diagnosed with BC at age ≤40 enrolling between 2006-2016 (N=1302), we identified those with stage I-III ER+/HER2- BC. Disease and treatment information were obtained through serial surveys and medical record review. The RS was performed on banked specimens for those not tested clinically. Distant recurrence free interval (DRFI), defined as distant recurrence or BC specific death, by risk group was assessed using Cox regression and Kaplan-Meier survival estimates. Outcomes by receipt of CT were explored in the RS 11-25 group, and due to small number of events, reported descriptively.

Results: Among eligible women (N=577), 189 (33%) had undergone RS testing and 320 (56%) had banked specimens sufficient for testing. Median follow-up was 6 years. Median age at diagnosis was 37, most had N0 BC (300/509, 59%), and the majority had RS 11-25 (306/509, 60%).

</table>

Results were similar using conventional RS groups. Among women with N0 BC and RS 11-25, 44% received CT, with two events in the 86 receiving CT (2.3%) and 6 events in the 109 without CT (5.5%); 5/8 (63%) occurred in those with RS 20-25.

Conclusions: The RS is prognostic among young women with node-negative and node-positive BC, and is a valuable tool for risk stratification. Disease outcomes among young women with N0 disease and RS 11-25, a minority of whom received CT, are very good. Evaluation of the effect of ovarian suppression/CT-induced amenorrhea by RS/treatment strata is ongoing.
Isolated ipsilateral local recurrence of breast cancer: Predictive factors and prognostic impact

**Background**

Tumour features associated with isolated invasive breast cancer ipsilateral local recurrence (ILR) after breast conservative treatment (BCT) and consequences on overall survival (OS) are still debated. The aim of our study was to examine predictive factors of isolated ILR after BCT with in sano resection and whole breast irradiation as well as the impact of such an ILR on overall survival in a large multi-institutional cohort.

**Methods**

Patients were retrospectively identified from a large cohort of 23,375 consecutive patients who underwent BCT for invasive breast cancer in 16 cancer centres. End-points were ILR rate and OS. The impact of ILR on OS was assessed through multivariate analysis by logistic regression and Cox model, adjusted on ERs/Grade status (ERs+/Grade 1, ERs+/Grade 2, ERs+/Grade 3 and ERs-) and then on tumour subtypes.

**Results**

Of 15,570 patients, ILR rate was 3.1%. Cumulative ILR rates differed according to ERs/grade (ERs+/Grade2: HR=1.42, p=0.010; ERs+/Grade3: HR=1.41, p=0.067; ERs-: HR=2.14, p<0.0001), endocrine therapy (HR=2.05, p<0.0001) and age<40-years old (HR=2.28, p=0.005) in multivariate analysis. When multivariate analysis was adjusted on tumour subtype, the latter was the only independent factor. OS-after-ILR was significantly different according to ILR-free intervals (HR=4.96 for ILR-free interval between 2-5-years and HR=9.00 when <2-years, in comparison with ≥5-years)

Impact of free interval time on OS among patients with ILR and among all patients

**Conclusion**
ERs/Grade status, lack of endocrine therapy and tumour subtypes predict isolated ILR risk in patients treated with BCT. Short ILR-free-intervals represent a strong pejorative factor for OS. These results may help selecting initial treatment as well as tailoring ILR systemic chemotherapy.
Nomogram update based on TAILORx clinical trial results - Oncotype DX breast cancer recurrence score can be predicted using clinicopathologic data

Amila Orucevic1, Megan L McNeil2, John L Bell1, Alison P McNabb1 and Robert E Heidel1. 1University of Tennessee Medical Center, Graduate School of Medicine, Knoxville, TN and 2University of Tennessee Health Science Center, College of Medicine, Memphis, TN.

Oncotype DX (ODX) recurrence score (RS) breast cancer (BC) assay provides prognostic and predictive BC recurrence information for hormone(+) /node(-) patients (pts). Pts with low ODXRS (0-10) can safely forego adjuvant chemotherapy (ACH), while ACH is recommended for high ODXRS (≥26). No ACH recommendations were previously available for intermediate (11-25) ODXRS until 6/3/2018, when the TAILORx clinical trial results were presented and e-published. According to the new data, pts with ODXRS 11-25 can now safely forego ACH, although some benefit of ACH was found in pts ≤50 with ODXRS 16-25. These new data now allow us to categorize ODXRS as a binary variable. Since ODX is a costly assay, we previously developed and published a user-friendly nomogram based on clinicopathologic characteristics (CPC) of ODX tested patients captured by the National Cancer Data Base (NCDB) as a surrogate prediction model for the ODX assay. As intermediate score patients were excluded from our previously created nomogram, the objective of this update is to test the predictive value of CPC variables for forecasting the new TAILORx binary ODXRS stratification using the entire NCDB population of ODX tested pts.

Five CPC variables (age, tumor size, grade, progesterone receptor status (PR) and the 4 most frequent BC histologic types) were assessed with logistic regression to predict for a low- or high-risk ODXRS test results using 0-15 or 0-25 and 16-100 or 26-100 for a low- and high-ODXRS, respectively. These ranges were used in the TAILORx trial. A training cohort consisted of 65,754 ODX tested ER+/HER2-/lymph-node-negative pts with 6-50mm tumor size, captured by the NCDB from 2010-2014; 18,585 ODX tested pts in 2015 served as an external validation cohort. The predictive accuracy of the regression model was yielded using a Receiver Operator Characteristic (ROC) analysis. Model fit was analyzed by plotting the predicted probabilities against the actual probabilities.

Grade and PR are the most significant predictors for a low- or high-risk ODXRS, followed by tumor size, histologic tumor type and age for any of the tested cut-off values. The ROC curves showed the best agreement between the nomogram prediction and actual observation for 0-25 (low) and 26-100 (high) ODXRS cut-off value (C-index=0.81). Overall, our model correctly predicted for 99.2% of low-risk and 18.6% of high-risk ODX cases. These cut-off values were used for building the updated nomogram model.

**IDC** = Invasive ductal BC  **ILC** = Invasive lobular BC  **G** = grade

An updated nomogram is now available, created and validated based on the entire population of ODX tested pts (84,339) captured by the NCDB from 2010-2015. The updated nomogram correctly predicts for 99.2% of a low ODXRS with a 0.81 C-index. This revised calculator will continue serving as a surrogate for BC pts older than 50 for which ODX testing is not necessary, affordable or available.
Background:
Currently, patients with breast cancer (BC) with hormone receptor (HR) immunohistochemical expression between 1-9% are eligible to receive endocrine therapy. However, recent data suggest that these tumors express a basal-like molecular phenotype associated with triple negative BC (TNBC) rather than luminal phenotype associated with HR positive BC. Here, we aimed to determine the differences between strong HR positive, low HR positive and negative HR BC, in regard to responsiveness to neoadjuvant chemotherapy (NACT) and disease free survival (DFS) in large cohorts from GBG clinical trials.

Methods:
In this retrospective analysis of data from women with BC treated in the neoadjuvant GeparQuinto (n=2572), GeparSixto (n=588) and GeparSepto (n=1206) clinical trials, we compared patients with three HR phenotypes: low positive (ER and/or PR= 1-9%), strong positive (ER or PR= 10-100%), and negative (ER and PR= <1%), regarding pathological complete response (pCR, ypT0 ypN0) and DFS. A logistic regression model for endpoint pCR was performed on pooled data from all trials. Cox regression was used to model DFS for patients participating in GeparQuinto and GeparSixto trial, including 71 with low HR positive phenotype. The models were adjusted by age, tumor and nodal status, grading, Her2 status, histological type, stromal and tumor infiltrating lymphocytes and clinical trial. The survival model was additionally adjusted by pCR after NACT.

Results:
Patients median age was 49 years, the majority had clinical tumor stage 2 (54.1%), negative nodal status (54.7%), and Her2 negative tumors (72.4%). 85.1% of women had BC classified as no special histological type. The pCR rate across the studies was 26.2%. 145 (3.4%) patients had low HR positive, 2417 (57.3%) strong HR positive and 1658 (39.3%) HR negative tumors. After NACT, 16.3% of patients with strong HR positive BC achieved a pCR, while among those with HR negative and low HR positive tumors, pCR rates were 40.2% and 37.9%, respectively (p<0.001). In the adjusted logistic regression model, there was no statistically significant difference between low HR positive and HR negative tumors (OR: 1.34, 95%-CI: (0.84-2.13), p=0.222). But strong HR positive tumors had a significantly lower chance of achieving a pCR compared to low HR positives (OR 0.48, 95%-CI: 0.30-0.76, p=0.002). Patients with strong HR positive BC had a better DFS than patients with low HR positive tumors (hazard ratio 0.35, 95%-CI: 0.18-0.70, p=0.003). DFS was not significantly different between patients with HR negative and low HR positive tumors (hazard ratio 0.74, 95%-CI: 0.38-1.43, p=0.370).

Conclusions:
Similarly to patients with negative HR tumors, patients with low HR positive tumors have a better responsiveness to NACT and worse survival rates, compared to patients with strongly HR positive BC. We suggest that studies on treatment options for basal-like/TNBC, should also consider including patients with low HR positive tumors.
Tumor infiltrating lymphocytes (TILs) in ER+/HER2- breast cancer

Carmen Criscitiello¹, Andrea Vingiani¹, Patrick Maisonneuve¹, Giulia Viale¹, Angela Esposito¹, Giuseppe Viale¹ and Giuseppe Curigliano¹. 'European Institute of Oncology, Milano, Italy.

Background: The prognostic role of tumor-infiltrating lymphocytes (TILs) in ER+/HER2- breast cancer (BC) is debated. We evaluated the association of TILs and clinico-pathological features with distant disease-free survival (DDFS) in a large series of patients (pts) with ER+/HER2- BC treated at a single Institution.

Methods: This case-cohort study was constructed using data from a previous mono-institutional study (Maisonneuve, BCR 2014). The initial cohort of 9415 pts included all women who underwent breast surgery for early ER+/HER2- BC at IEO. Then, the cohort was restricted to 3986 pts who underwent surgery in the period 1998-2002, and for whom long-term follow-up data was available. A case-cohort was built by randomly selecting approximately 17% of the above cohort (680 pts). 307 additional pts with an event (distant metastasis or death due to BC) were added to this cohort. TILs were assessed for these 987 cases on centralized H&E-stained slides according to recommendations (Salgado, Ann Onc 2015). TILs were considered both as continuous variable, and dichotomized in low (<5%) vs high (≥5%). The main outcome was DDFS and was calculated from the date of surgery to the date of any first event or the date of last contact with the patient. Median follow-up was 7.5 years (0.1-10). Differences between BC subtypes were assessed using the log-rank test. Univariable and multivariable Cox proportional hazards regression with inverse sub-cohort sampling probability weighting were used to evaluate the risk across groups. Analyses were carried out with the SAS software version 9.4 (Cary NC).

Results: Median TILs was 2% (Q1-Q3 1-4%). Higher TILs were positively associated with pN (p=0.003), tumor grade (p<0.0001), peritumoral vascular invasion (PVI) (p=0.003), Ki-67 (p=0.0001), luminal B subtype (p<0.0001), and chemotherapy (p<0.0001), while they were inversely associated with ER expression (p<0.0001) and age (p=0.02). There was no association with type of endocrine therapy. In multivariable regression analysis, only Ki-67 expression retained significant association with TILs. Age and ER showed a trend towards negative association with TILs. In univariate Cox regression, TILs expression (≥5% vs. <5%) was not associated with DDFS (HR 1.08, 95% CI 0.80-1.46, p=0.62). At stratified Cox exploratory analyses, we found an association between high TILs and low risk in very young women (p=0.03) and grade 3 tumors (p=0.047); conversely high TILs were associated with worse outcome in grade 1 tumors (p=0.05). We evaluated TILs by treatment group (chemo vs no chemo). TILs were not associated with DDFS in the group that did not receive chemotherapy. Instead, in the group treated with adjuvant chemotherapy, high TILs were associated with better DDFS (HR 0.52, 95%CI 0.33-0.83, p=0.006), particularly in the group with Ki67≥20% (HR 0.50, 95%CI 0.29-0.86, p=0.01).

Conclusion: High TILs in ER+/HER2- BC are significantly associated with several clinico-pathological features of dismal outcome. In this group, treatment escalation might be worthy. Our findings suggest that this subgroup might be more immunogenic, thus deserving the exploration of immunotherapy approaches. The prognostic value of TILs seems to be different in patients treated with or without chemotherapy.
Development and validation of prognostic gene signatures for basal-like breast cancer and high grade serous ovarian cancer

Hai Hu¹, Yi Zhang¹, Jianfang Liu¹, Praveen-Kumar Raj-Kumar¹, Howard Yang², Maxwell Lee², Albert J Kovatch³ and Craig D Shriver⁴. ¹Chan Soon-Shiong Institute of Molecular Medicine at Windber, Windber, PA; ²Center for Cancer Research, National Cancer Institute, Rockville, MD; ³Clinical Breast Care Project, Murtha Cancer Center Research Program, Uniformed Services University/Walter Reed National Military Medical Center, Bethesda, MD and ⁴Murtha Cancer Center Research Program, Uniformed Services University/Walter Reed National Military Medical Center, Bethesda, MD.

Background: Basal-like breast cancer (BLBC) have poor prognosis. Molecular similarities have been reported between BLBC and high grade serous ovarian cancer (HGSOC). To date, there have been no prognostic biomarkers specifically developed for BLBC or HGSOC that can provide risk stratification and inform treatment selections. In this study, we utilized RNA-seq data available from The Cancer Genome Atlas (TCGA) project to develop molecular signatures for risk stratification in BLBC, and further validated these signatures in HGSOC RNA-seq data from TCGA.

Methods: Raw count of RNA-seq data were downloaded from TCGA for 190 BLBC and 374 HGSOC patients. The datasets were annotated with 56963 Ensembl gene IDs. Excluding 31375 gene IDs with no greater than 10 counts in at least 90% of the samples, totally 25228 unique Ensembl gene IDs were used. Progression-free interval (PFI) is the primary study endpoint. Analyses of differentially expressed genes were performed using 3 bioconductor packages: DESeq2, edgeR and voom/limma. Signatures based on commonly identified genes among the 3 analytic methods were established using weighted linear combination of gene expression levels. Their performance was evaluated in the BLBC and HGSOC datasets using Kaplan-Meier survival analysis with log-rank tests and Cox proportional hazard regressions.

Results: Among 190 TNBC patients, 18 had recurrences within 2 years and 40 showed no recurrences for at least 5 years. These patients were used as recurrent vs. non-recurrent cases for differential expression analysis. 307 and 343 genes were differentially expressed based on adjusted p value threshold 0.05 and 0.01 in DESeq2 and edgeR analysis, respectively. voom/limma identified no genes differentially expressed based on adjusted p values, but 228 genes had unadjusted p values < 0.01 and were used in the following analysis. Taken together, 63, 58 and 21 genes were commonly identified by DESeq2/edgeR, DESeq2/limma and edgeR/limma analysis, respectively. All 3 signatures were able to significantly stratify the TNBC full dataset (n=190) using either 20-, 50- or 80-percentile as the cut-points. When evaluated in HGSOC patients using 80-percentile cut-point, both 63- and 58-gene signatures were able to significantly stratify patients into different risk groups (HR 2.16, 95% CI: 1.4-3.34, p < 0.001; HR 2.06, 95% CI: 1.36-3.11, p < 0.001). Multivariate Cox regression adjusting for age, grade and stage showed 63- and 58-gene signatures remained to be statistically significant in stratifying HGSOC patients (p = 0.0005 and 0.001, respectively).

Conclusion: Gene signatures were specifically identified to prognosticate BLBC patients based on RNA-seq data from TCGA project. Which were able to classify HGSOC patients into differential risk groups. With further validations, these signatures may provide additional prognostic tools for clinicians to better manage triple-negative breast cancer that mostly overlap with BLBC, and HGSOC patients who are difficult-to-treat currently.

Survival in women with de novo metastatic breast cancer: Comparison of real-world evidence from publicly-funded Canadian province and the United States by insurance status

Elizabeth N Kornaga¹, Adriana RS Matutino¹, Allan AL Pereira², Sunil Verma¹,³ and Sasha Lupichuk¹,³. ¹Tom Baker Cancer Centre, Alberta Health Services, Calgary, Canada; ²Instituto do Câncer do Estado de São Paulo, São Paulo, Brazil and ³University of Calgary, Calgary, Canada.

**Background:** Access to cancer screening, diagnosis and treatment in the United States (US) is affected by insurance status; whereas, access within a publicly-funded health care system is similar across the whole population. The aim of this study was to compare overall survival (OS) of de novo stage IV (metastatic) breast cancer (BC) pts in a Canadian province and in the US according to insurance status.

**Methods:** All female pts 18-64 yrs of age diagnosed with de novo stage IV BC from Jan 1, 2010 through Dec 31, 2014 with available biomarker information were included. Pts diagnosed by death certificate or autopsy and pts ≥ 65 yrs were excluded due to unreliable insurance status classification in the US SEER database. The Alberta cohort (AB) was obtained from the Alberta Health Services CancerControl Breast Data Mart (BDM), a repository of information on all pts diagnosed with their first BC diagnosis from Jan 1, 2004 onwards in the province of Alberta, Canada. The U.S. cohort was obtained from the US Surveillance, Epidemiology, and End Results (SEER) program cancer database. A total of 9,604 pts from the SEER database and 294 pts from the BDM were analyzed. OS was evaluated over a 2 yr period and median and 2 yr OS were estimated. Unadjusted associations were compared using the log-rank test, and hazard ratios (HR) were estimated using the Cox proportional hazards model with US insured set as reference group.

**Results:** Comparison of AB and US cohorts showed no differences based on age group (18-49 vs 50-64), yr of diagnosis or receipt of primary surgery. The AB cohort had a higher incidence of hormone receptor positive (HR+), similar frequency of HER2+, and a lower incidence of triple negative (TN) BC relative to the US cohort: HR+ 60.5% vs 56.4%; HER2+ 30.6% vs 28.8%; and TN 8.8% vs 14.8%, respectively [p=0.017]. The distribution of HR+, HER2+ and TN BC was consistent between the SEER insured, Medicaid and uninsured groups. AB cohort estimated 2 yr OS was 70.1%, similar to the insured group of 66.0% and significantly better than the Medicaid or uninsured pts [53.2% and 50.9%; p<0.0001]. Subgroup analysis based on biomarker status, surgery and age group showed similar results.

Adjusting for these variables, AB OS remained similar to the insured group [HR=0.92 (0.74-1.15) p=0.474] with worse OS noted in the Medicaid and uninsured populations [HR=1.44 (1.32-1.56) and HR=1.53 (1.33-1.77) p<0.001, respectively].

**Conclusion:** OS in women with de novo stage IV BC in AB was similar to US insured. AB and US insured experienced superior OS compared with US Medicaid and uninsured.
Dissecting the effect of hormone receptor (HR) status expression in patients (pts) with HER2-positive (HER2+) early breast cancer (EBC): Exploratory analysis from the ALTTO (BIG 2-06) trial

Institut Jules Bordet and Université Libre de Bruxelles (U.L.B.), Brussels, Belgium; Frontier Science, Kingussie, United Kingdom; Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA; European Institute of Oncology (IEO) and University of Milan, Milan, Italy; Mayo Clinic, Phoenix, AZ; Peking Union Medical College Hospital, Beijing, China; Breast International Group (BIG), Brussels, Belgium; National Cancer Institute, Bethesda, MD; Novartis Pharma AG, Basel, Switzerland; Mayo Clinic, Jacksonville, FL; Sana Klinikum Offenbach, Offenbach, Germany; Johns Hopkins School of Medicine, Baltimore, MD; Institut Gustave Roussy, Villejuif, France; Hospital de Santa Maria and Instituto de Medicina Molecular, Lisbon, Portugal; Hospital Clinic of Barcelona, Barcelona, Spain and Peter MacCallum Cancer Centre, Melbourne, Australia.

Background

We investigated the clinical outcomes and behavior of HER2+ EBC according to centrally tested HR status in pts treated with modern chemotherapy (CT) and trastuzumab (T)-based regimens.

Patients and methods

ALTTO is an international phase 3 trial in HER2+ EBC pts randomized to 4 adjuvant anti-HER2 treatment arms: T alone, lapatinib (L) alone, their sequence (T→L) or their combination (T+L). Pts in the L alone arm were excluded from the present analysis. HER2 and HR status were centrally tested for all patients. HER2 status was defined based on the 2007 ASCO/CAP guidelines. HR-positive (HR+) was defined as ≥1% tumor cells with expression of estrogen (ER) and/or progesterone receptors. We investigated the prognosis of pts with HR+ or negative (HR-) HER2+ EBC, the risk of developing early (years 0-5) and late (years 6-8) recurrences, the factors impacting this risk, and the patterns of relapse according to HR status.

Univariate and multivariate Cox proportional hazard models were used to compare hazard rates within the HR subgroups; a conditional landmark analysis was conducted to investigate late recurrences. For the hazard ratios for HR status, an interaction between log(time) and HR status was included as proportional hazard assumption was not satisfied.

Results

This analysis included 6,271 HER2+ pts of whom 3,601 (57%) had HR+ and 2,670 (43%) HR- EBC. Median follow-up was 6.93 years (range 6.81-6.96).

5-year disease-free survival (DFS) was 86% (85-87) in HR+ and 83% (82-85) in HR- pts; 8-year DFS was 80% (78-81) in HR+ and 79% (77-81) in HR- pts. The mean annual hazards of recurrence in years 0-5 were 3% in HR+ and 4% in HR- pts, while in years 6-8 they were 3% in HR+ and 2% in HR- pts. The hazard ratios for HR status (ref=HR-) were 0.60 (0.51-0.72) overall, 0.74 (0.65-0.85) for years 0-5 and 1.61 (1.17-2.24) for years 6-8.

In HR+ pts, risk factors for recurrence overall were age ≥65 (p=0.01), tumor size pT3-4 (p<0.001), nodal status pN1-3 (p<0.001), tumor grade 2 or 3 (p<0.001), anthracycline-only CT (p<0.001), no use of aromatase inhibitors (p<0.001), and ER<10% (p=0.01). Main risk factors for recurrence in both years 0-5 and years 6-8 were BMI (obesity; p=0.002). In HR- pts, risk factors for recurrence overall were BMI (obesity or underweight; p=0.01), pT3-4 (p<0.001), pN1-3 (p<0.001) and anthracycline-only CT (p<0.001). No significant risk factors for recurrence in years 0-5 were identified. Main risk factor for recurrence in years 6-8 was BMI (obesity; p=0.002).

HR+ pts had lower incidence of visceral disease (58.8% vs. 69.6%; p=0.005) and lung metastasis (18.5% vs. 27.8%; p=0.006); bone was the most common site of first recurrence (30%).

Conclusions

This large analysis of centrally tested HR+ and HR- HER2+ EBC provides strong evidence on the existence of two different diseases within the HER2+ population based on HR expression. These up-to-date estimates of pts outcomes after modern CT and T-based regimens may be used as “historical control” for the design of future de-escalation or escalation trials separately in HR+ and HR- HER2+ EBC pts.
Metabolic syndrome and early-stage breast cancer outcome: Results from a prospective observational study

Giuseppe Buono\textsuperscript{1}, Anna Crispo\textsuperscript{2}, Mario Giuliano\textsuperscript{1,3}, Carmen G Rea\textsuperscript{1}, Valeria Forestieri\textsuperscript{1}, Rossella Lauria\textsuperscript{1}, Pietro De Placido\textsuperscript{1}, Michelino De Laurentiis\textsuperscript{4}, Carmen Pacilio\textsuperscript{4}, Maria Grimaldi\textsuperscript{2}, Flavia Nocerino\textsuperscript{2}, Maurizio Montella\textsuperscript{2}, Sabino De Placido\textsuperscript{1} and Grazia Arpino\textsuperscript{1}. 1University of Naples Federico II, Naples, Italy; 2Unit of Epidemiology, National Cancer Institute, G. Pascale Foundation, Naples, Italy; 3Lester and Sue Smith Breast Center, Baylor College of Medicine, Houston, TX and 4Breast Unit, National Cancer Institute, G. Pascale Foundation, Naples, Italy.

Background: Previous studies suggested a link between obesity, insulin-resistance and breast cancer outcome. The aim of the present prospective observational study was to investigate the role of metabolic syndrome (MetS) and its components on early breast cancer (EBC) patients’ outcome.

Methods: MetS was defined by the presence of 3 to 5 of the following components: waist circumference (WC) > 88 cm, blood pressure \(\geq 130/\geq 85\) mmHg, serum levels of triglycerides (TG) \(\geq 150\) mg/dL, high-density lipoprotein (HDL) < 50 mg/dL and fasting glucose (FG) \(\geq 110\) mg/dL (National Cholesterol Education Program Expert Panel on Detection, Evaluation, And Treatment of High Blood Cholesterol In Adults - NCEP-ATPIII criteria). Overall, 955 EBC patients were prospectively enrolled between January 2009 and December 2013 at University Hospital Federico II and National Cancer Institute G.Pascale, Naples, Italy. Clinical and tumor characteristics were collected for all the patients. A total of 494 patients (51.7\%) had complete data on all the components of MetS at first diagnosis and thus were included in the current analysis. Study population was divided into 2 main groups: (1) patients with less than 3 components (No MetS); (2) patients with 3-5 components (MetS). Categorical variables were analyzed by the chi-square test and survival data by the log-rank test and Cox proportional hazards regression model.

Results: Overall 366 (74.1\%) and 128 (25.9\%) women were categorized as No MetS and MetS, respectively. MetS patients were more likely to be older and postmenopausal compared to No MetS patients. In detail, 46\% vs 38\% were older than 55 yrs (\(p<0.0001\)) and 87\% vs 54\% were postmenopausal (\(p<0.0001\)) in MetS vs No MetS groups, respectively. No statistically significant differences in tumor stage, type of adjuvant therapy or tumor subtypes defined by immunohistochemistry (IHC) were identified among the two groups. At univariate analysis, stage, tumor subtypes, TG and FG values, number of components of MetS, and presence of MetS were significantly associated to both disease free survival (DFS) and overall survival (OS). Age, BMI, WC, and HDL levels were correlated to OS only. At the multivariate Cox proportional hazards model (adjusted for age, menopausal status, stage, IHC subtypes and adjuvant therapy) MetS patients had numerically higher risk of relapse and significantly higher risk of death compared to No MetS patients [DFS hazard ratio (HR): 1.64 95\% confidence interval (CI): 0.94-2.86, \(p=0.07\) and OS HR: 3.83, 95\% CI 1.7-6.77 \(p=0.001\)]. Additionally, of the 366 No MetS patients included in the analysis, 122 (33.3\%) had 0 and 244 (66.7\%) had “1 to 2” components of MetS. Interestingly, patients with “1 to 2” components of MetS had increased risk of dying compared to patients with 0 components (OS HR: 4.39, 95\% CI:1.26-15.36, \(p=0.02\) ). No significant difference among these two groups was observed in terms of DFS.

Conclusions: MetS is correlated with poor outcome in EBC patients. Among patients without full criteria for MetS diagnosis, the presence of 1 or 2 components of the syndrome may predict for worse survival. Testing for components of MetS in BC patients is recomended to predict outcome and to eventually suggest lifestyle changes, exercise and diet.
Impact of germline BRCA mutation status on survival in women with metastatic triple negative breast cancer

Kelsey Larson¹, Yen Y Wang², Karissa Finke², Anne P O'Dea², Qamar Khan², Lauren Nye², Jaimie Heldstab², Andrew K Godwin², Bruce F Kimler² and Priyanka Sharma². ¹University of Kansas Medical Center, Kansas City, KS and ²University of Kansas Medical Center, Westwood, KS.

Background: 15-20% of patients with triple negative breast cancer (TNBC) harbor deleterious germline (g) BRCA1/2 mutations. Recent data suggests that in metastatic TNBC (mTNBC) gBRCA1/2 mutations are associated with response to PARP inhibitors (PARPi) and platinum chemotherapy. However, diagnosis of mTNBC is associated with short overall survival (OS) with no available biomarkers that can identify mTNBC patients with better prognosis.

Aim: Utilizing data from a prospective registry, the objective of this study was to investigate whether presence of gBRCA1/2 mutation impacts overall survival for patients with mTNBC treated prior to clinical availability of PARPi.

Methods: 643 patients with stage I-IV TNBC were enrolled in an IRB approved multisite prospective registry between 2011 to 2018. Clinical, demographic, and treatment information was collected and patients were followed for recurrence and survival. 100/643 patients had metastatic breast cancer (de novo stage IV disease or metastatic recurrence). OS (from the time of diagnosis of metastatic disease to death from any cause) was estimated according to the Kaplan-Meier method and compared among groups by log-rank test.

Results: For the 100 mTNBC patients, the median age at diagnosis of metastatic disease was 55 years, 17% were African American, 20% had novo stage IV and 80% had relapsed disease. 84% had visceral disease, 12% had bone-only disease, and 4% had lymph node only disease. Metastatic treatment: 87% received chemotherapy, 7% received radiation only without chemotherapy and 6% did not receive any treatment. No patients received treatment with PARP inhibitor. Among de-novo stage IV patients, 35% (7/20) had breast surgery for removal of primary tumor during their course of metastatic treatment. For all 100 patients, 12% (n=12) had gBRCA mutation; 72% (n=72) had no gBRCA mutation; and 16% (n=16) had unknown BRCA mutation status. When compared with non-carriers, gBRCA carriers were younger at time of metastatic diagnosis (median age 49 vs. 57 years, p=0.02). There was no difference in prevalence of visceral disease, de-novo stage IV disease or median lines of metastatic chemotherapy among gBRCA carriers and non-carriers. At a median follow up of 31 months, median OS for all patients is 21 months (95% CI 13-23 months). Median OS is 18 months (95% CI 15-27 months) for non-carriers and has not yet been reached for gBRCA mutation carriers (p=0.023). 3-year estimated OS is 63% in gBRCA carriers compared to 28% in non-carriers (p=0.02). On multivariate Cox regression analysis, gBRCA carrier status was associated with reduced risk of death (HR=0.33; 95%CI [0.23-0.91], p=0.033)

Conclusions: gBRCA mutation associated mTNBC patients have a clinically significant improved OS at 3 years compared to mTNBC patients without BRCA mutations (3-year OS of 63% vs 28%). Further research is needed to understand tumor and host biological reasons for this observation. Outcomes of gBRCA mutation associated mTNBC are likely to be further improved with availability of PARPi. Given that patients with gBRCA mutation are at risk for second breast/ovarian cancers, these findings also underscore need for further research regarding the role of prophylactic surgeries mTNBC with gBRCA mutation.
Tumor inflammation signature (TIS), intrinsic subtypes and chemo-endocrine score (CES) in metastatic triple-negative breast cancer (mTNBC): A SOLTI biomarker program study

Tomas Pascual1,2,3, Cristina Pernaut4, Pablo Tolosa4, Patricia Galvan4, Carmen Bárdena4, María Vidal1,2, Luis Manso4, Barbara Adamo1,2, Marta Dueñas4, Monserrat Muñoz1,2, Nuria Chic1,2, Blanca Gonzalez-Farre1,2,3, Patricia Villagrasa3, Eva Ciruelos4 and Aleix Prat1,2,3. 1Hospital Clinic i Provincial de Barcelona, Barcelona, Spain; 2IDIBAPs, Barcelona, Spain; 3SOLTI Breast Cancer Research Group, Barcelona, Spain and 4Hospital 12 de Octubre, Madrid, Spain.

Background: The TIS is a clinical research gene expression-based assay that enriches for response to anti-PD1 monotherapy in multiple cancer-types (Ayers et al. JCI 2017). However, the expression of the TIS in mTNBC and its relationship with other biological classifications and overall survival (OS) is currently unknown.

Methods: A comprehensive RNA-based characterization of 45 patients with mTNBC treated at 2 SOLTI sites was performed. RNA from metastatic biopsies was analyzed on the nCounter system using the Breast Cancer 360™ panel, which includes 752 breast cancer-related genes, including the TIS and the PAM50 and TNBCtype subtype classifications. The 1st objective was to estimate the proportion of TIS-high tumors (defined as a score above its median expression in the PanCancer TCGA dataset) within PAM50 Basal-like disease. 2nd objectives were 1) to explore TIS distribution across the other molecular subtypes, 2) to evaluate the distribution of the PAM50 and TNBCtype subtype classifications in mTNBC, 3) to explore the association between OS and TIS, subtypes and 38 additional signatures tracking multiple tumor biological processes. OS was defined as the time from the date of metastatic diagnosis to death or last follow-up. Descriptive statistics, log-rank tests and univariate cox models were performed using R code.

Results: Most tumor samples (77.3%) were obtained at first recurrence or diagnosis of metastatic disease. Metastatic biopsies were obtained from 10 different sites, being skin (31.3%), breast (22.2%) and lung (8.9%) the most frequent. PAM50 subtype distribution was as follows: Basal-like (73.3%), Luminal A (13.3%), HER2-enriched (11.1%) and Luminal B (2.2%). Similarly, all the TNBCtype subtypes were identified: Mesenchymal (MSL, 48.8%), Basal-like Immune-activated (31.2%), Luminal Androgen Receptor (LAR, 15.6%) and Basal-like Immune-Suppressed (4.4%). The vast majority of non-Basal-like tumors were identified as LAR or MSL (81.8%). The proportion of TIS-high within Basal-like disease was 73% (95% confidence interval [CI] 59-84%) and similar to the proportion of TIS-high within TNBC from TCGA (70%, CI 61-78%). The proportion of TIS-high was similar across the PAM50 and TNBCtype molecular subtypes. The median OS was 25.3 months (CI 19.2-36.8). TIS, PAM50 and TNBCtype subtypes were not found associated with OS. Among the 41 biological classifications, expression of 6 signatures were found significantly associated with OS: CES (hazard ratio [HR] 0.44; p=0.015), Basal-like score (HR=5.52; p=0.011), FOXA1 (HR=0.83; p=0.014), mast cells (HR=0.77; p=0.017), differentiation score (HR=0.63; p=0.039) and Luminal A score (HR=0.27; p=0.039). Compared to tumors with a CES-low score, tumors with a CES-high score were found enriched for luminal-related genes, including AR.

Conclusions: ~50% of mTNBC tumors are PAM50 Basal-like and are enriched for the TIS. Future studies should determine the ability of this biomarker to predict response to anti-PD1 monotherapy or in combination with chemotherapy. In addition, mTNBC with a high luminal-profile or CES might help identify patients who might benefit from anti-androgen therapies alone or in combination with immunotherapy.
Tumor microenvironment of metastasis (TMEM) score in residual breast carcinoma post-neoadjuvant chemotherapy as an independent prognosticator of distant recurrence

Maja H Oktay1, Timothy D’Alfonso2, Paula Ginter3, Sonali Lanjewar1, David Entenberg1, Jessica M Pastoriza1, Yarong Wang1, Yu Lin1, George S Karagiannnis1, Juan Lin1, Xianjun Ye1, Jesus Anampa1, Xionan Xue1, Thomas E Rohan1, Joseph A Sparano1 and John S Condeelis1. 1Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY; 2Memorial Sloan-Kettering Cancer Center, New York, NY and 3Weill Cornell Medicine, New York, NY.

Background: Tumor microenvironment of metastasis (TMEM) is a microanatomical structure composed by 3 cells in direct contact, including a tumor cell expressing the actin-regulatory protein Mammalian-enabled (Mena), a perivascular Tie2hi/Vegfhi-expressing macrophage, and an endothelial cell. TMEM are intravasation sites that function as doorways for hematogenous tumor cell dissemination and metastases (Harney et al. Cancer Discovery 2015). TMEM may be identified and enumerated by triple immunohistochemistry in mouse and human mammary carcinomas. High TMEM score is associated with increased risk of distant metastasis in early stage breast cancer, and provides complementary prognostic information to IHC4 (Rohan et al. JNCI 2014) and Oncotype DX Recurrence Score in ER+, HER2-negative breast cancer (Sparano et al. NPJ Breast Cancer, 2017). Neoadjuvant chemotherapy (NAC) increases TMEM score in breast carcinoma in animal models and humans, indicating a previously unrecognized mechanism of resistance to cytotoxic therapy (Karagiannis et al. Science Trans Med 2017). Intravasation at TMEM sites may be inhibited using agents that block release of VEGF from TMEM-associated TIE2hi, VEGFhi macrophages (Harney et al. Mol Cancer Ther, 2017). Here we investigated whether TMEM score in post-NAC treated breast carcinoma is prognostic of distant recurrence in localized breast cancer after NAC, and thus provides a foundation for testing agents that block TMEM function in combination with NAC.

Methods: We determined TMEM score in 80 evaluable patients' post-NAC specimens with residual invasive ductal carcinomas of at least 0.5 cm. Approximately 60% of patients had ER+/HER2-negative, 28% had triple negative and 12% had HER2+ disease. Most of the patients received doxorubicin/cyclophosphamide + taxane and an anti-HER2 therapy if applicable. Tissue sections from residual tumors were stained for TMEM using triple immunohistochemistry for Mena-expressing cancer cells, CD31-expressing endothelial cells and CD68-expressing macrophages. The stained slides were scanned, and the images were analyzed by three pathologists, blinded to outcome, who independently determined the tissue areas appropriate for TMEM scoring. TMEM was scored within these areas using an automated algorithm.

Results: TMEM score was significantly higher in patients with distant recurrence (average TMEM=106), compared to patients without distant recurrence (average TMEM=71) (p<0.01, two-sided t-test). Moreover, in a Cox proportional hazards model that included TMEM score (upper tertile vs. lower 2 tertiles), age (>50 yrs. vs. <50), race (black vs non-black), tumor stage (T 1-3), estrogen receptor (ER) status (+ vs -), high TMEM score was associated with a increased risk of distant recurrence (HR=2.2, 95% CI=1.0 to 4.9, p=0.05)

Conclusion: TMEM score may provide independent prognostic information for distant recurrence in patients with residual invasive carcinoma after NAC. These results support the use of agents that block TMEM function in combination with NAC, as planned in the I-SPY2 trial.
Exploratory biomarker analyses of FAIRLANE, a double-blind placebo (PBO)-controlled randomized phase II trial of neoadjuvant ipatasertib (IPAT) + paclitaxel (PAC) for early triple-negative breast cancer (TNBC)

Matthew J Wongchenko1, Mafalda Oliveira2, Cristina Saura2, Paolo Nuciforo3, Isabel Calvo4, Jay Andersen5, José Luis Passos Coelho5, Miguel Gil Gil2, Begona Bermejo6, Debra A Patt6, Eva Ciruelos7, Stina M Singel1, Daniel J Maslyar1, Na Xu, Lorena de la Peña11, José Baselga12, Steven Gendreau1 and Steven J Isakoff13. 1Genentech Inc, South San Francisco, CA; 2Vall d'Hebron Institute of Oncology (VHIO) and SOLTI Breast Cancer Research Group, Barcelona, Spain; 3Vall d'Hebron Institute of Oncology (VHIO), Barcelona, Spain; 4Centro Integral Oncologico Clara Campal (CIOCC), Madrid, Spain; 5Compass Oncology and US Oncology, Portland, OR; 6Hospital Beatriz Angelou, Loures, Portugal; 7Institut Català d'Oncologia, Hospital Duran i Reynals, Barcelona, Spain; 8Hospital Clinico Universitario, Valencia, Spain; 9Texas Oncology Cancer Center, US Oncology, Austin, TX; 10University Hospital 12 de October and SOLTI Breast Cancer Research Group, Madrid, Spain; 11SOLTI Breast Cancer Research Group, Barcelona, Spain; 12Memorial Sloan Kettering Cancer Center, New York, NY and 13Massachusetts General Hospital, Boston, MA.

Background: The oral AKT inhibitor IPAT is being evaluated in cancers with a high prevalence of PI3K/AKT pathway activation. In the PBO-controlled randomized phase II FAIRLANE trial (NCT02301988), adding IPAT to PAC as neoadjuvant therapy for TNBC led to a numerical increase in pathologic complete response (pCR) in unselected patients (17.1% vs 13.3%), with a greater treatment effect in patients with PIK3CA/AKT1/PTEN-altered tumors (17.9% vs 11.8%). The addition of IPAT also led to an increase in complete response (CR) by MRI (27.6% vs 13.3%) that was enhanced in patients with PIK3CA/AKT1/PTEN-altered tumors (39.3% vs 8.8%) [Oliveira, AACR 2018]. We report an exploratory analysis performed to provide better understanding of potential biomarkers for response.

Methods: Pretreatment tumor samples were evaluated for genomic alterations using the FoundationOne® (Foundation Medicine) assay (n=144) and gene expression by RNA-Seq (n=92). Samples were classified into TNBC subtypes based on the method developed by Lehmann and Pietenpol [Lehmann, J Clin Invest 2011]. Tumor-infiltrating lymphocytes (TILs) were quantified using the Salgado method [Salgado, Ann Oncol 2015] (n=135).

Results: Of 62 patients (43%) with PIK3CA/AKT1/PTEN-altered tumors, 21 had an activating mutation in PIK3CA or AKT1 and 47 had an alteration in PTEN (6 [3 in each arm] had both PIK3CA mutation and PTEN alteration). Although only 3 patients with PIK3CA/AKT1-mutant tumors achieved a pCR, there was an increased rate of MRI CR with the addition of IPAT to PAC [Table]. In patients with PTEN alterations, both pCR rate and MRI CR rate were increased with IPAT. In patients treated with PBO + PAC, all 4 pCR patients evaluable by RNA-Seq were of the immunomodulatory (IM) subtype. However, in the IPAT + PAC arm, pCRs were also seen in patients with basal-like 1 (BL-1), mesenchymal (M), and mesenchymal stem-like (MSL) subtypes. Consistent with this observation, in the PBO + PAC arm, samples from patients achieving a pCR had significantly higher levels of stromal TILs than those from patients who did not have a pCR, while no difference was observed in the IPAT + PAC arm.

<table>
<thead>
<tr>
<th>Response, n (%)</th>

</tbody>
</table>

Conclusions: This retrospective exploratory biomarker analysis of the phase II FAIRLANE trial of neoadjuvant IPAT for TNBC provides insight into the potential heterogeneity of response and resistance to taxane therapy. The results also hint that response to PAC alone is dependent on baseline immune infiltration and that this dependency might be relieved with the addition of AKT inhibition.
Prognostic impact of SRC, CDKN1B and JAK2 expression in metastatic breast cancer patients treated with trastuzumab

Panagiota Economopoulou\(^1\), Vassiliki Kotoula\(^1\), Georgia-Angeliki Koliou\(^1\), Kyriaki Papadopoulou\(^1\), Christos Christodoulou\(^1\), George Pentheroudakis\(^1\), Angelos Koutras\(^1\), Dimitris Bafaloukos\(^1\), Pavlos Papakostas\(^1\), Dimitrios Pectasides\(^1\), Athanasios Kotsakis\(^1\), Evangelia Razis\(^1\), Epaminondas Samantas\(^1\), Konstantine T Kalogeras\(^1\), Theofanis Economopoulos\(^1\) and George Fountzilas\(^1\).

\(^1\)Hellenic Cooperative Oncology Group (HeCOG), Athens, Greece.

**Background-aim:** SRC, CDKN1B and JAK2 play a crucial role in the coordination and facilitation of cell-signaling pathways controlling a wide range of cellular functions. In the present study, we investigated the prognostic significance and clinical utility of these biomarkers in metastatic breast cancer (MBC) patients treated with trastuzumab (T). **Methods:** We assessed SRC, CDKN1B and JAK2 mRNA expression with qRT-PCR (Taqman-MGB assays) on 197 paraffin tumors. PIK3CA mutation status was previously assessed. Relapsed (RMBC) and de novo MBC (dnMBC) patients had received T for metastatic disease only. Tumors were centrally re-assessed for HER2 status.

**Results:** Only 133/197 patients (67.5%) were found to be truly HER2(+).

CDKN1B mRNA expression strongly correlated with SRC (rho = 0.71) and JAK2 (rho = 0.54); high CDKN1B was more frequent in RMBC compared to dnMBC (p = 0.001) and in PIK3CA wild-type tumors (p = 0.005). In HER2(+) patients, low CDKN1B conferred higher risk for progression (HR 1.58, 95% CI 1.08-2.32, p = 0.018). In HER2(-) patients, low SRC was associated with longer survival (HR 0.56, 95% CI 0.32-0.99, p = 0.045) and, as a trend, with increased progression-free survival (PFS) (p = 0.067). For PFS, in RMBC, we observed trends for unfavorable low CDKN1B (p = 0.068) and JAK2 (p = 0.086); similarly, in dnMBC for unfavorable low CDKN1B (p = 0.072). Low SRC showed a trend for better survival in RMBC (p = 0.087). Upon multivariable analyses, only PIK3CA mutations strongly predicted for unfavorable PFS in HER2(+) patients (HR 3.37, 95% CI 1.98-5.73, p < 0.001). Low CDKN1B and JAK2 mRNA expression remained unfavorable factors for PFS in dnMBC and RMBC patients (HR 2.36, 95% CI 1.01-5.48, p = 0.046 and HR 1.76, 95% CI 1.01-3.06, p = 0.047, respectively). **Conclusions:** Low CDKN1B and JAK2 mRNA expression were unfavorable prognosticators in a cohort of T-treated MBC patients previously unexposed to this agent, with distinct impact in de novo and RMBC. Our results highlight biological and clinical differences between de novo and RMBC and suggest that CDKN1B and JAK2, if validated, may serve as prognostic factors potentially implicated in T-resistance, which seems to be associated with distinct pathways in the two MBC settings.
Mismatch repair protein loss is a prognostic and predictive biomarker in breast cancers regardless of microsatellite instability

Nicola Fusco¹,², Gianluca Lopez², Chiara Corti¹, Chiara Pesenti¹,², Patrizia Colapietro¹, Giulia Ercoli², Gabriella Gaudioso², Alice Faversani¹, Donatella Gambini², Luca Despini³, Concetta Blundo³, Valentina Vaira¹,², Monica Miozzo¹,², Stefano Ferrero¹,² and Silvano Bosari². ¹University of Milan, Milan, Italy; ²Fondazione IRCCS Ca’ Granda - Ospedale Maggiore Policlinico, Milan, Italy and ³Breast Surgery Unit, Fondazione IRCCS Ca’ Granda - Ospedale Maggiore Policlinico, Milan, Italy.

Despite the approval of pembrolizumab in all tumors showing mismatch-repair (MMR) deficiency and/or microsatellite instability (MSI), there are currently no companion diagnostics for MMR status assessment in breast cancer. Here, we sought to define the diagnostic and prognostic role of MMR and MSI testing in breast cancer patients.

We subjected 444 breast cancers to MMR immunohistochemistry (IHC) and MSI analysis. Cases were classified as MMR-proficient (pMMR), MMR-deficient (dMMR), and MMR-heterogeneous (hMMR) based on the loss of immunoreactivity; MSI was defined by the instability in the five indicators recommended by the National Cancer Institute for endometrial and colorectal cancers. Correlation of MMR status with patients’ survival was assessed using the Kaplan-Meier estimator.

In 75 patients (17%) the loss of MMR proteins was homogeneous, classified as dMMR, while 55 cases (12%) were hMMR. The prevalence of cancers with loss of the MMR proteins was homogeneous across ER+ breast cancers (15-19% for dMMR and 10-18% for hMMR tumors). The level of overlap between IHC and MSI analysis was 9% (p<0.0001). Among ER+/HER2- carcinomas, pMMR and hMMR patients displayed better survival rates (p=0.008). In chemo-treated ER-/HER2- breast cancers, the dMMR status was a marker of good prognosis (p<0.001).

Our study documents the clinical impact of MMR testing in a large series of breast cancers, using the most commonly adopted diagnostic tools and criteria. We show that MMR protein loss is a rather common event in breast cancer and has a remarkable degree of intra-tumor heterogeneity, therefore making the analysis of a small area of the tumor, or a small biopsy, of little clinical value. Our investigation supports the concept that MSI occurs rarely in breast cancer and demonstrate that this condition is restricted to a minority of tumors with MMR protein loss. These data suggest that MMR IHC and MSI analysis should not be considered as interchangeable tests in the diagnostic workup of breast carcinomas. Finally, our observations indicate that the complete loss of at least one of the MMR proteins assessed by IHC is able to identify high-risk ER+/HER2- breast cancers that can potentially benefit from pembrolizumab therapy, whereas first-line chemotherapy shows comparatively good results in dMMR ER-/HER2- breast cancers.
Clinical implication of HER2/neu status in hormone receptor positive pure mucinous breast cancer

Sung-Chan Gwark1, Jong Won Lee1, Sae Byul Lee1, Guiyun Sohn1, Jisun Kim1, Il Yong Chung1, Beom Seok Ko1, Hee Jeong Kim1, Byung Ho Son1 and Sei Hyun Ahn1. 1Asan Medical Center, Seoul, Republic of Korea.

Background: Mucinous carcinoma of the breast is a rare type of breast cancer with favorable outcome compared with other types of breast cancer. The current guideline does not recommend chemotherapy/anti-HER2 therapy for mucinous breast cancer with hormone receptor-positive subtype regardless of HER2/neu status. In this study, we evaluated the survival of pure mucinous breast cancer according to tumor stage and subtype.

Methods: Between 1989 and 2014, in Asan Medical Center, Korea, total 473 pure mucinous carcinomas (stage I-III) undergone curative surgery were reviewed retrospectively. 5yr disease-free and overall survival were analyzed according to size, lymph node metastasis, hormone receptor/HER2 status and given therapy.

Result: Total of 473 patients with pure mucinous breast cancer were analyzed and median follow-up duration was 78.00 months. 439 patients were hormone receptor-positive, 374 were node negative, 55 were HER2/neu positive. Among 374 patients with hormone receptor-positive and node-negative, tumor size was <1cm in 46 patients, 1-2.9cm in 259 patients, ≥3cm in 69 patients. In HR-positive/Node-positive BCs, 90.8%(59/65)were given chemotherapy and 35.3%(6/17) were also given trastuzumab. Sixteen patients given trastuzumab were only included in the analysis to assess the benefit of trastuzumab among HER2 positive BCs. Overall, 5-year disease-free survival (DFS) rate was 94.1% and the 5-year overall survival (OS) rate was 95.9%. Using Cox regression analysis, lymph node metastasis was the only significant prognostic factor for both DFS (HR4.0, 95%CI:1.8-9.0, \(p=0.001\)) and OS (HR3.5, 95%CI:1.3-8.9, \(p=0.008\)). Among HR-positive/node-negative with tumor size ≥3cm, HER2/neu positivity was only significantly associated with 5yr-DFS (71.4% in HER2/neu+ vs. 96.4% in HER2/neu-, HR9.5, 95%CI:1.3-67.5, \(p=0.024\)). This observation was consistently combining both 'HR-positive/node-negative/>3cm' and 'HR-positive/node positive' BCs (N=127) that HER2 positive tumors showed worse survival (HR 3.7, 95%CI:1.2-10.8, \(p=0.015\)). Intriguingly, within this subgroup of HR-positive/node-negative/>3cm' and 'HR-positive/node positive' BCs, among HER2 positive tumors, while 5yr-DFS was 63.7% in patients who didn't receive trastuzumab, 100% were disease free in patients who were given trastuzumab.

Conclusions: Overall, nodal status was the most significant prognostic factor for pure mucinous breast cancer. In hormone receptor-positive, lymph node negative mucinous breast cancer with tumor of ≥3cm, HER2 positive BCs showed worse survival, suggesting a potential role of anti-HER2 strategy in this subgroup.
A combined score of tumour budding and tumour necrosis has prognostic value for cancer specific survival in both ER positive and ER negative primary operable breast cancer

Elizabeth S Morrow¹,², Fadia Gujam¹, Zahra Mohammed³, Donald C McMillan², Paul G Horgan², Antonia K Roseweir¹ and Joanne Edwards¹. ¹Institute of Cancer Sciences, University of Glasgow, Glasgow, United Kingdom; ²Academic Unit of Surgery, University of Glasgow, Glasgow, United Kingdom and ³Omar El-Mukhtar University, Albeida, Libyan Arab Jamahiriya.

Background: As new systemic therapies emerge for the treatment of breast cancer, new prognostic markers are required to help stratify patients into higher and lower risk groups to aid treatment decision making. Features of the tumour microenvironment, such as tumour necrosis, tumour-stroma percentage (TSP), and tumour budding have been shown to have prognostic value in some cancers. However, their role in breast cancer is unclear.

Methods: Patients who underwent surgery for primary operable breast cancer in 2 centres between 1995-2007 and who had paraffin-embedded tissue blocks available were identified. Clinicopathological details and survival data were obtained from patient records. Haematoxylin & Eosin-stained slides were visually assessed within a set visual field for TSP (<50% or >50% tumour stroma), tumour necrosis (<25% or >25% necrosis) and tumour budding (<20 buds or >20 buds). A combined score of tumour necrosis and tumour budding was then created. A score of 0 was assigned to tumours where both components were low, 1 to those where only one component was high, and 2 to those where both were high. Multivariate cox regression analysis was carried out for cancer specific survival (CSS).

Results: A breast cancer cohort of 1301 patients was utilised, from which 1186 H&E slides were scored for necrosis, TSP and tumour budding. Median follow up was 158 months (26-183) and there were 234 breast cancer deaths. In the full cohort, necrosis (p<0.0001), high TSP (p=0.010) and high budding (p<0.0001) were associated with CSS and all 3 were independently prognostic on multivariate analysis (necrosis HR 1.54, 95%CI 1.15-2.07, p=0.004; high TSP HR 1.49, 95%CI 1.12-1.98; p=0.006; high budding HR 1.38, 95%CI 1.02-1.87, p=0.035). In ER positive disease (n=826), necrosis was associated with worse CSS (p<0.0001) and was independently prognostic (HR 1.46, 95%CI 1.03-2.08, p=0.033). In ER negative disease (n=359), necrosis, high TSP and high budding were associated with worse CSS (p=0.001, p=0.002, p<0.0001 respectively) and were independently prognostic (necrosis HR 2.44, 95%CI 1.34-4.43, p=0.003; high TSP HR 1.64, 95%CI 1.06-2.53, p=0.026; high budding HR 2.47, 95%CI 1.56-3.89, p<0.0001). To assess if combining these markers added additional prognostic power a combined budding/necrosis score was established. This was associated with worse CSS in ER positive disease (p<0.0001) and a score of 2 was independently associated with worse CSS compared to a score of 0 (HR 1.96, 95%CI 1.19-3.23, p=0.008). This was potentiated in node-negative patients (HR 5.14, 95%CI 2.18-12.08, p<0.0001). In ER negative disease, an increasing score was associated with worse CSS (p<0.0001) and was independently prognostic (combined score 1 vs. 0: HR 2.37, 95%CI 1.13-5.00, p=0.023; score 2 vs. 0: HR 5.93, 95%CI 2.62-13.40, p<0.0001).

Conclusions: A combined score of tumour necrosis and budding shows promise as a readily-available prognostic tool to aid treatment decision making in primary operable breast cancer, both by stratifying risk in ER negative disease, and by identifying a high-risk group in ER positive, node negative disease.
The average modified Magee score can be helpful in predicting an Oncotype DX recurrence score ≤ 25

Bradley M Turner¹, Mary Ann Sanders², Andrea Breaux², Armen Soukiazian³, Nyrie Soukiazian⁴ and David G Hicks¹. ¹University of Rochester Medical Center, Rochester, NY; ²University of Louisville, Louisville, KY; ³University of Rochester, Rochester, NY and ⁴Drexel University College of Medicine Graduate School of Biomedical and Professional Studies, Philadelphia, PA.

Introduction: The recent TAILORx results suggests that adjuvant endocrine therapy and chemoendocrine therapy had similar efficacy in women with hormone–positive, HER2-negative, axillary node–negative breast cancer who had an Oncotype Dx recurrence score (ODXRS) between 11 and 25. These findings, along with updated results that patients with an ODXRS < 11 have a 9-year recurrence rate of only 3%, suggest that certain populations of patients with an ODXRS ≤ 25 may not benefit from additional systemic chemotherapy. Oncotype Dx is an expensive test (current list price of $4,650.00), and cost has been an impediment to its adoption in many centers throughout the United States, and internationally. The test can be performed only at a commercial specialized laboratory. Based on a modification of the new Magee equations (Klein ME, et al. Mod Pathol. 2013;26(5):658–664) we published an algorithm based on 283 patients with ODXRS's (Turner BM, et al. Mod Pathol. 28(7):921-31) that suggested our algorithm offered a less expensive alternative to Oncotype DX testing. We have validated this algorithm in a multi-institutional study on an additional 619 patients with ODXRS's (in preparation for publication). Our validation data, and our data from the original study, also suggests that the average modified Magee equation can reliably predict patients who will have an ODXRS ≤ 25. Methods: 903 cases with an available ODXRS (2006-2018) were identified from the pathology files at the University of Rochester Medical Center (n = 752) and the University of Louisville (n = 151). Information required to calculate the average modified Magee score, which includes estrogen receptor (ER) and progesterone receptor (PR) status, Her-2 status, Nottingham score, tumor size, and Ki-67 were also extracted from the medical record. 78 patients did not have an available Ki-67, leaving 825 patients for inclusion in this study. Results: 478/488 (98%) patients with an average Modified Magee score ≤ 18 had an ODXRS ≤ 25 (only 2% had an ODXRS > 25 - Table 1). 125/337 (37%) patients with an average Modified Magee score >18 had an ODXRS > 25 (Table 1) . Conclusions: The average Modified Magee Score can be helpful in predicting an ODXRS ≤ 25. Patients with an average Modified Magee score ≤ 18 may not need to be sent out for Oncotype Dx testing. The potential cost savings to the health care system would be enormous.

Introduction: PD-L1 expression as assessed by immunohistochemistry (IHC) is a clinically relevant biomarker in certain malignancies such as lung cancer, since it selects appropriate candidates for PD-1 blockade. Since these agents are under evaluation for breast cancer, discovering and validating predictive biomarkers is of outmost importance. However, the clinical utility of PD-L1 expression in breast cancer is questionable, in light of prior inconclusive reports which have used various IHC antibodies, scoring methods and cut-offs. Moreover, there are only few previous studies on comparing IHC and RNA data at the same cohort, not limited to a single subtype.

Methods: Our cohort is derived from a nested case-control study consisting of 619 patients diagnosed with primary breast cancer between 1997-2005 in Stockholm health care region. Tissue microarrays from epithelial tumor areas have been constructed using duplicate cores from primary tumors and tissue sections were used for IHC with PD-L1 (Ventana; clone SP263) antibody. Positivity was defined as the presence of any single cell with membranous expression of PD-L1. Gene expression profiling was performed using DNA microarrays (GSE48091). Data on clinical and pathological tumor characteristics, survival, loco-regional and systemic treatments, and follow-up have been collected. Correlations between transcript and protein expression levels were estimated using Mann-Whitney test, while survival analyses were conducted using the Kaplan-Meier method. Furthermore, we associated an immune gene module score (IMS) —whose predictive power in neoadjuvant and metastatic settings has been previously demonstrated— with PD-L1 transcript levels by using Spearman's rank correlation coefficient.

Results: IHC data were available for 87.4% (541/619) of the patients. PD-L1 was expressed on tumor cells in 9.6% (52/541) of the patients while it was also expressed by immune cells in 23.1% (125/541) of the patients. Any PD-L1 expression (tumor and/or immune cells) was noted in 24.2% (131/541) of the patients. PD-L1 transcript levels and protein expression on tumor, immune and/or both cell types were statistically significantly associated (p< 2.2e-16). In the whole cohort, patients with higher PD-L1 transcript levels were associated with better breast cancer-specific survival (BCSS) (p=0.0061). In addition, within intrinsic subtypes, high PD-L1 transcript expression was significantly associated with better BCSS only in basal-like (p=0.019) disease. There was no significant correlation between improved BCCS and PD-L1 protein expression by tumor (p=0.13), immune (p=0.12) or both types of cells (p=0.2). PD-L1 transcript levels were also positively associated with the IMS (Spearman's rho = 0.85).

Conclusions: The prognostic value of PD-L IHC expression in breast cancer remains inconclusive. However, RNA expression of PD-L1 may be more informative as a prognostic factor, especially in basal-like disease and merits further validation.
High expression of CYP27A1 in breast cancer is associated with poor tumor pathological features and may differentially predict prognosis depending on menopausal status.

Siker Kimbung, Tor Stålhammar, Maria Inasu, Björn Nodin, Karin Elebro, Helga Tryggvadottir, Karin Jirström, Carten Rose, Christian Ingvar, Helena Jernström and Signe Borgquist. 1Lund University, Lund, Sweden; 2CREATE Health and Department of Immunotechnology, Lund University, Lund, Sweden and 3Aarhus University Hospital, Aarhus, Denmark.

**Background:** Pre-clinical and epidemiological data strongly link high cholesterol with breast cancer progression and poor prognosis. It was recently uncovered that the pathogenicity of cholesterol in breast cancer is directly propagated by 27-hydroxycholesterol (27HC), an oxysterol produced when cholesterol is hydroxylated by cytochrome P450, family 27, subfamily A, polypeptide 1 (CYP27A1) during bile acid synthesis. 27HC promotes breast tumor growth and metastasis via interactions with the estrogen receptor (ER) and liver x receptors respectively. Consequently, pharmaceutical approaches that directly interfere with CYP27A1 activity have been proposed to mitigate the adverse impact of 27HC in breast cancer. However, CYP27A1 expression or deregulation in clinical breast cancer is not well characterised. The aim of this study was to comprehensively describe the impact of tumor-specific expression of CYP27A1 protein on clinical breast cancer pathobiology and prognosis.

**Methods:** CYP27A1 expression in tumor cells was evaluated by immunohistochemistry in two independent population based cohorts including female patients with primary invasive breast cancer diagnosed between 1991 and 2010 (cohort 1) and between 2002 and 2012 (cohort 2). Staining was evaluable in 645 and 813 cases in cohort 1 and cohort 2, respectively. Associations between CYP27A1 expression with tumor pathological factors and survival were assessed by using logistic and Cox regression models respectively. Multivariable models adjusted for age at diagnosis, nodal status, histological grade, tumor size, ER and BMI.

**Results:** CYP27A1 was overexpressed in 21% and 28% in cohort 1 and cohort 2 respectively. High CYP27A1 expression was significantly associated with adverse tumor pathological features including negative hormone receptor (ER and PgR) status and histological grade 3 in both cohorts and with larger tumors (>20 mm) in cohort two only (p<0.05, for all comparisons). In multivariable Cox regression analyses, overexpression of CYP27A1 was neither independently prognostic for recurrence-free survival (cohort 2: HR=1.3, 95% CI= 0.88 – 1.9) nor overall survival (cohort 1: HR=1.3, 95% CI= 0.88 – 1.9 and Cohort 2: HR=1.3, 95% CI= 0.81 – 2.0, respectively). Upon stratification for menopausal status using age at diagnosis (< 50 years vs ≥ 50 years) as surrogate, the relationship between CYP27A1 expression and prognosis remained non-significant for older (postmenopausal) patients. Interestingly, among younger (premenopausal) women, elevated CYP27A1 expression was independently prognostic for shorter time to recurrence or death (HR=3.3, 95% CI= 1.5 – 7.4; cohort 2).

**Conclusions:** Collectively, these results indicate that intratumoral CYP27A1 expression supports the notion that 27HC plays an important pathological role in breast cancer progression but tumor cell-specific CYP27A1 expression is not sufficient to independently predict overall survival in postmenopausal patients. Further sufficiently sized studies are needed to clarify the prognostic significance of CYP27A1 in younger and presumably premenopausal patients and evaluate its role as a treatment predictive factor.
Does a large breast protect against axillary nodal spread in breast carcinoma?

Janine M Rayen¹, Garth H Poole¹ and Ciara Rhodes². ¹Middlemore Hospital, Auckland, New Zealand and ²Auckland University, Auckland, New Zealand.

Introduction
Prognostic scoring systems in breast cancer such as TNM and NPI (Nottingham prognostic index) use maximal diameter for size. Breast cancer is three-dimensional therefore volume and weight are more accurate biological predictors.
Tumour size is an important predictor of axillary node positivity and is used in the Memorial Sloan Kettering Cancer Centre (MSKCC) nomogram.
It has been suggested that positivity rate is related more to increasing tumour size rather than grade.
Nodal spread may be different for tumours occupying a greater or lesser proportion of the breast. An association has previously been identified between a high tumor-to-breast volume ratio and poor prognosis.
The aim of this study was to measure breast cancer volume as a proportion of the mastectomy specimen volume and compare node positivity rates in high and low proportion specimens.

METHODS
Data was retrieved from the CMDHB (Counties Maukau District Health Board) breast clinic database. Size, grade, node positivity (macro, micro, ITC (isolated tumour cells)), LVI (lymphovascular invasion), receptors, quadrant and tumour type were recorded from concerto pathological reports.
The weights of carcinomas from 382 mastectomy specimens were estimated as a proportion of the entire mastectomy weight. Carcinoma volume and weight was estimated using the ellipsoid model \( V = \frac{4}{3} \pi \frac{a}{2} \frac{b}{2} \frac{c}{2} \)
The cohort was then divided at the medians into “low” and “high” tumour proportionality and “large” and “small” tumour.
Logistic regression was applied for node positivity and multivariate analysis was used to standardise by tumour size and grade.

RESULTS
The overall node positivity rate was 194/382 (51%).
In tumours with a low proportionality, 37.6% (72/191) were node positive and in the high proportionality group, 63.8% (122/191) were node positive (p = <0.00001).
Grade 1 tumours were node positive in 16/44 and grade 3 tumours were positive in 84/155 (p = 0.082).
Small volume tumours were positive in 70/191 and large volume tumours were positive in 124/191.
The smallest tumour to breast weight ratio was 0.00001 and the largest was 0.709.

CONCLUSION
Prediction of node positivity preoperatively is essential in all malignant primary breast surgery.
Larger tumour volumes and greater proportion of cancer leads to increased node positivity.
Surgeons should calculate the three-dimensional proportion of the breast that is occupied by cancer, particularly when the patient is on the cusp of sentinel node vs axillary dissections.
Since breast volumes and breast cancer size vary by race, ethnic disparities in risk of lymph node spread may exist.
Relationship between FDG uptake and neutrophil/lymphocyte ratio in patients with breast invasive ductal cancer

Takaaki Fujii¹, Keiko Yanai¹, Shoko Tokuda¹, Yuko Nakazawa¹, Sasagu Kurozumi¹, Sayaka Obayashi¹, Reina Yajima¹ and Tomoko Hirakata¹. ¹Gunma University, Maebashi, Japan.

Background: ¹⁸F-Fluorodeoxyglucose-positron emission tomography (FDG-PET) is used to evaluate the glucose metabolic rates of cancers. Several studies have reported that high FDG uptake is predictive of poor prognosis and aggressive features in patients with breast cancer. FDG uptake is influenced by many factors, including inflammation. In this study, we investigated the relationship between FDG uptake and neutrophil/lymphocyte ratio (NLR), which is an indicator of systemic inflammation. Patients and Methods: We retrospectively investigated the cases of 143 consecutive invasive ductal carcinoma patients who had undergone surgery and FDG-PET preoperatively. PET was evaluated using standardized uptake value max (SUVmax). The median SUVmax was 2.5 (range 0-10.5). Thus, we divided the cases into two groups based on the value of SUVmax; low (<2.5) and high (≥2.5). The relationships between SUVmax and clinicopathological features, including NLR, were investigated. Results: Among the 143 patients, 73 (51.0%) had high SUVmax in the primary tumor. The analysis revealed that large tumor size (p<0.001), high nuclear grade (p<0.001), the presence of lymphovascular invasion (p<0.001), CRP (p=0.046) and high NLR (p<0.001) were significantly associated with high SUVmax in the primary tumor. There were associations between SUVmax and NLR (r=0.323, p<0.001). Among the 70 cases with low SUVmax, there was no recurrent disease, while 6 cases among the 73 cases with high SUVmax had disease recurrence. It is interesting to note that the group with high SUVmax and low NLR had no recurrent disease. Conclusions: To the best of our knowledge, this is the first report to describe the relationship between FDG uptake and NLR in breast cancer. The present study demonstrated that the finding of preoperative high FDG uptake in breast cancer may be reflective of poor prognosis and that high NLR may be predictive of aggressive features among patients with breast cancer. On the other hand, among breast cancer patients with high SUVmax in the primary tumor, it will be useful to identify the subset of patients with low NLR in order to improve prognostic accuracy.
The impact of time interval between diagnosis and surgery in each type and stage of breast cancer

Jae-Myung Kim¹, Hee Jun Choi², Isaac Kim², Jai Min Ryu², Jeong Eon Lee², Seok Won Kim², Seok Jin Nam² and Se Kyung Lee². ¹Gyeongsang National University School of Medicine and Gyeongsang National University Hospital, Jinju, Republic of Korea and ²Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea.

Background: There are many factors that might contribute to the delay of surgery in patients with breast cancer. Previous studies investigate the influence of delay of surgery, but they reported inconsistent results. The purpose of this study was to evaluate the impact of time of surgery on prognosis of breast cancer.

Methods: We performed a retrospective review of the patients with breast cancer, who received surgery between 1992 and 2009, by using data from Korea Breast Cancer Society Registry. Kaplan-Meier survival analysis and Cox regression model were used to evaluate the impact of time to surgery in breast cancer and subgroup analyses were performed for each disease stage and molecular subtype.

Result: A total 14727 patients were included for analysis. Delay of surgery more than 31 days was associated with worse survival for breast cancer [hazard ratio (HR) = 2.16; 95% confidence interval (CI), 1.936-2.408, \( p < 0.001 \)]. Subgroup analyses revealed that over 31 days of surgical delay were significantly associated with worse survival in hormone receptor positive and HER-2 negative \( (p<0.001) \), hormone receptor positive and HER-2 positive \( (p<0.001) \), hormone receptor negative and HER-2 positive \( (p<0.001) \), triple negative \( (p<0.001) \) and stage II, III breast cancer patients \( (p<0.001) \).

Conclusion: Surgical delay of more than 31 days were independent risk factors for worse outcome of breast cancer in each molecular subtype and breast cancer group except stage 0 and I. Although preoperative evaluation is required, surgical delay should be shortened to enhance survival of breast cancer, especially in patients with tumor size more than 2cm or presence of lymph node metastasis.
Vitamin D as a prognostic factor in triple negative early breast cancer

Serafin Morales Murillo¹, Ariadna Gasol Cudos¹, Joel Veas Rodriguez¹, Marta Santacana¹, Carles Canosa Morales¹ and Jordi Mele Olivé¹. ¹Hospital Universitari Arnau de Vilanova, Lleida, Spain.

Background: Triple negative breast cancer is a special phenotype where the pathological complete response (pCR) remains the most important factor but only around a 40% of patients achieve this response. We analyze if the vitamin D receptors (VDR) could be a prognostic factor not related with the histological response.

Methods: A series of 160 patients with early or locally advanced triple negative breast cancer that received neoadjuvant chemotherapy were retrospectively reviewed from 2007 to 2017. Clinicopathological and vitamin D receptors analysis were correlated to pCR.

Results: Median age was 53, median tumor size 30mm, 48% had nodal involvement, and median ki67 expression was of 70%. Androgen receptor was expressed in 28% of tumors analyzed, EGFR in 89%, CK5/6 in 63%. VDR (cytoplasmatic and nuclear) expression was determined in 56 patients, finding in 45 (80%) an expression that was considered as high. We achieved a total of 73/160 pCR (45%) with a significant median disease free survival of 178 months (log rank p: 0.0001). In the univariate analysis, the initial tumoral size, initial nodal involvement and expression of VDR was significant; and in the mutivariate model the expression of VDR maintains the level of significance \( HR: 0.138 \text{ IC 95}\% 0.039-0.493 \text{ p:0,002} \).

Conclusions: The expression of VDR in the initial tumor before starting neoadjuvant chemotherapy is a strong predictor of recurrence independently of histological response with a median disease free survival of 149 months in patients with high expression versus 62 month. Furthermore, in patients without histological response, progression-free median survival is 86 months for patients with high expression versus 35 months.
Predictive and prognostic value of stromal tumor-infiltrating lymphocytes before and after neoadjuvant therapy in triple negative and HER2-positive breast cancer

Tomohiro Ochi¹, Bianchini Giampaolo², Michiko Murai¹, Fumi Nozaki¹, Daiki Kobayashi¹, Takayuki Iwamoto³, Naoki Niikura⁴, Kouyu Suzuki¹, Hideko Yamauchi¹ and Naoki Hayashi¹. ¹St. Luke’s International Hospital, Tokyo, Japan; ²San Raffaele Scientific Institute, Milan, Italy; ³Okayama University Hospital, Okayama, Japan and ⁴Tokai University School of Medicine, Isehara, Japan.

Background: Lymphocyte predominant breast cancer subgroup, defined as ≥ 50% stromal tumor-infiltrating lymphocytes (sTILs), is associated with high pathological complete response (pCR) rate after neoadjuvant therapy (NAT) and favorable outcome. In a cohort of triple negative (TNBC) and HER2+ breast cancer (BC) patients treated with NAT, we aimed to assess the predictive and prognostic value of pre- and post-NAT sTILs and the information provided by the change in sTILs during NAT.

Materials and methods: Two-hundred and nine consecutive patients (n=80 TNBC; and n=129 HER2+) who received NAT between 2001 and 2009 in our institution were evaluated. Pre-NAT sTILs were assessed on biopsy sample (baseline) and post-NAT sTILs on surgical specimens just for non-pCR patients. sTILs level was categorized as low 0-9%, intermediate 10-49%, and high ≥50%. The change in sTILs during NAT was calculated as the absolute difference between pre- and post-NAT sTILs. We evaluated the association of pre-NAT sTILs and pCR, and the association between pre- and post-NAT sTILs, and their change with relapse-free survival (RFS).

Results: Overall pCR rate was 37.8% (31.3% for TNBC, 41.2% for ER+/HER2+, 42.3% for ER-/HER2+). In each subtype, pre-NAT low sTILs group was significantly associated with lower pCR rate. During the median follow-up period of 98 months, 44 recurrences (21.1%) were observed. For TNBC, low pre-NAT sTILs group was associated with higher recurrence risk compared with int/high sTILs (HR=4.675 [2.013-10.859], p<0.001). For only non-pCR patients, both pre- and post-NAT sTILs were significantly associated with RFS. The risk of recurrence was higher in the group with low pre-NAT sTILs (HR=5.333 [1.731-16.427], p=0.004), and the group of low post-NAT sTILs (HR=4.271 [1.498-12.173], p=0.007). Patients with the change of sTILs increase during NAT were not associated with RFS, compared with decrease or equal group (log-rank p=0.163). In multivariate analysis including both pre- and post-NAT sTILs, only pre-NAT sTILs retained significance (HR=3.844 [1.190-12.421], p=0.024). Low post-NAT sTILs group showed only a borderline significant association with shorter RFS (HR=2.836 [0.951-8.457], p=0.061), but it suggests that both pre- and post-NAT sTILs might provide independent prognostic information. In ER+/HER2+, low pre-NAT sTILs were associated with short RFS (p=0.036), but this association was not significant when only non-pCR patients were considered. In ER-/HER2+, sTILs were not significantly associated with RFS.

Conclusion: In TN and HER2+ BCs, tumors with low pre-NAT sTILs have a low likelihood to achieve a pCR (predictive marker). In TNBC, low pre-NAT sTILs were associated with higher recurrence risk. In non-pCR TNBC patients, both low pre- and post-NAT sTILs were associated with shorter RFS. These results suggest that sTILs information should be taken into account when additional post-surgery treatments are considered in non-pCR patients.
Trends in mortality and prognostic significance of hypercalcemia in breast cancer: A nationwide study

Stuthi P Perimbeti¹, Rishi Shrivastav¹, Kristine Ward² and Michael Styler². ¹Mount Sinai St Luke’s Roosevelt Hospital, New York, NY and ²Drexel University, Philadelphia, PA.

Background
Hypercalcemia (HC) in widespread breast cancers results from various mechanisms including increased bone turnover and secretion of Parathyroid hormone-related peptide (PTH-rP). Among patients affected with breast cancer, the presence of HC has been associated with poor prognosis. Recent advances in treatment of HC with bisphosphonates and RANK-L inhibitors, and widely metastatic breast cancers with systemic chemotherapy and immunotherapy, have caused a paradigm shift in the symptoms and progression free survival among these patients. However, with these recent advances, the trends and changes in prognostic significance of HC have not been investigated. Our study aims to examine the trends in the mortality of HC in Breast Cancer (BC) patients.

Methods
Adult admissions (adm) (>18 years of age) between 1999 and 2014 with a primary diagnosis of BC were extracted from the Nationwide Inpatient Sample using the ICD-9 code 174.9. These were stratified into three categories based on the years of admission to minimize the effect of changes over the time interval studied. Adm were filtered for the presence of HC using the ICD-9 code 275.42. We performed bivariate analysis to determine the in-hospital mortality percentage across various categorical variables. Multivariate analysis using the cox proportional hazard regression was employed to estimate the hazard ratio (HR) of mortality within 30 days of admission during the hospitalization in patients with and without HC after controlling for confounders like age, race, income, insurance status, comorbidities, geographic location etc.

Results
A total of 484,859 (N=98,631, weighted N=484,859) adm with a primary diagnosis of BC were extracted and stratified according to the year of admission into three year groups: Group1: 1999-2004, Group 2: 2005-2009 and Group 3: 2010-2014. The percentage of adm with HC increased from 0.52% in 1999 to 1.32% in 2014. The in-hospital mortality percentage and adjusted Hazard Ratios (HR) of mortality among different year groups based on the presence of HC are shown in the table.

Discussion:
The mortality percentage and hazard ratio of death during hospitalization is significantly higher among the patients with HC when compared to their counterparts. The in-hospital mortality percentage declined over the course of 15 years. While examining the HR, there was a 96% increase in risk of mortality in group 1, 39 % increase in group 2, 22% increase in group 3.
Conclusion
Despite the consistent decrease in mortality over the interval studied, the presence of HC continues to be an independent risk factor of mortality among patients with breast cancer after controlling for potential confounders. Considering the limitations of our study, there is further need to evaluate the prognostic significance of HC in breast cancer.
A novel seven-gene signature predicts prognosis in early-stage triple-negative breast cancer

Yixing Ren¹, Yizhou Jiang¹, Wenjia Zuo¹, Xiaoen Xu¹, Xi Jin¹, Ding Ma¹ and Zhimin Shao¹. ¹Fudan University Shanghai Cancer Center, Shanghai, China.

Purpose:
Chemotherapy remains the only systemic treatment option for patients with triple-negative breast cancer (TNBC). However, due to the heterogeneity of TNBC, not all patients benefit from chemotherapy, especially those with early-stage disease. In order to improve prognostic assessment and reduce unnecessary adjuvant systemic therapy in these patients, we have developed a novel seven-gene signature.

Experimental Design:
With the ComBat method, we integrated the results from 150 transcriptome microarrays samples and 246 RNA-seq samples of early-stage TNBC patients, and identified mRNAs associated with recurrence-free survival (RFS) using Lasso-Cox model. We further analyzed these TNBC samples and compared them with 60 paired normal breast tissues (40 samples from RNA-seq and 20 samples from microarrays) to identify tumor-specific mRNAs. Twenty-one overlapped mRNAs of the RFS-associated mRNAs and the tumor-specific mRNAs are selected as candidate mRNAs. An additional 371 samples of frozen primary tumors were then collected from early-stage TNBC patients (mean follow-up of 45 months) and randomly divided into two sets: a training set (n = 186) and a validation (n = 185) set. Expression level of candidate mRNAs in these samples were measured using RT-qPCR assays, and a seven-gene signature was built through all subset regression in the training set. The prognostic and predictive accuracy of our signature was tested in the validation set and other public databases (GSE5327, GSE2034 and METABRIC).

Results:
Twenty-one candidate mRNAs were identified in early-stage TNBC patients, from which we developed a novel seven-gene signature (recurrence risk score [mRNA signature] = 1.108*TMEM101 - 0.213*KRT5 - 0.315*ACAN - 0.464*LCA5 + 0.446*RPP40 - 0.373*LAGE3 - 0.257*CDKL2). Patients in the training set were classified into high- or low-risk group based on our seven-gene signature and an optimum cut-off score derived from x-tile. The patients in high-risk group were more likely to suffer from recurrence (HR, 2.718; 95% confidence interval [CI], 1.928–3.726, P= 0.001), and a time-dependent receiver operating curve showed that the seven-gene mRNA signature had a better prognostic value than the clinicopathologic risk factors in both training set and validation set. The prognostic and predictive accuracy of the signature was also validated in the METABRIC and two other public GEO databases (GSE5327 and GSE2034). The time-dependent receiver operating curve showed that this signature had an area under the curve (AUC) of 0.742 (95% CI, 0.705-0.773) in METABRIC, 0.716 (95% CI, 0.682-0.739) and 0.723 (95% CI, 0.683-0.756) in GSE5327 and GSE2034 respectively.

Conclusion:
In this study, we developed a novel seven-gene signature which can provide additional prognostic information and may guidance in identifying early-stage TNBC patients eligible for adjuvant therapy or reduction of chemotherapy. To our knowledge, this is the first study investigating the prognostic potential of mRNA signature in early-stage triple-negative breast cancer. Our novel signature may provide an opportunity for de-escalating treatment in early-stage TNBC patients in the future.
The network metanalysis of data from PALOMA 2, MONALEESA 2, MONARCH 3, FALCON, SWOG and FACT trials: Progression free survival (PFS) benefit from first-line endocrine-based therapies in postmenopausal women with HR+ HER2-metastatic breast cancer (MBC) according to different prognostic subgroups

Valentina Rossi1, Diana Giannarelli2, Paola Berchialla3, Filippo Montemurro4, Gianluigi Ferretti2, Cecilia Nistico2, Leonardo Vigna1, Francesco Cognetti2 and Alessandra Fabi2. 1Breast Tumour Unit, S.Camillo-Forlanini Hospital of Rome, Rome, Italy; 2Istituto Regina Elena of Rome, Rome, Italy; 3University of Turin, Turin, Italy and 4Investigative Clinical Oncology (INCO)-Fondazione del Piemonte per l'Oncologia, Candiolo, Turin, Italy.

Background
The three classes of Cycline Dependend Kinase (CDK) 4/6 inhibitors, Palbociclib (P), Ribociclib (R) and Abemaciclib (A), in combination with non-Steroidal Aromatase Inhibitors (nSAIs) showed improvement on Progression Free Survival (PFS) in patients with HR+/HER2- MBC compared to AIs monotherapy. Fulvestrant (F) also showed a PFS benefit over AIs in first-line setting of endocrine naive patients (pts) which was even greater in pts without visceral disease.

The absence of direct comparison between F and CDK 4/6 combination therapies and their less favorable toxicity profile generated great interest in the identification of a specific subgroup of pts based on clinical and pathological factors for decision-making in the use of endocrine monotherapy.

This analysis combines data from six randomized phase III trials investigating the role of endocrine-based therapies in the first-line setting of HR+/HER2- MBC to identify clinical factors in the choice among available drugs.

Methods
A Bayesian network meta-analysis was carried out for PFS; Hazard Ratio (HR) and 95% CI were reported. Potential treatment effect modifying covariates were investigated using sub-group analysis, stratifying by age, ECOG, ethnicity, prior chemotherapy or endocrine therapy exposure, measurable disease at the time of metastasis occurrence, visceral or bone only disease, time from the initial diagnosis of breast cancer to the metastasis onset. Data analysis was performed using R Statistical Software version 3.5.0

Results
In the absence of direct comparison between CDK 4/6 inhibitors + nAIs and F endocrine-based therapies, all these therapeutic options resulted in significant PFS benefit compared to nAIs monotherapy (HR: 0.74; 95% CI 0.67-0.80). However, among the three classes of CDK 4/6 inhibitors and F a significant longer PFS was observed according to some clinical-pathological factors as followed reported: from P + nAIs in “bone only” disease (HR 0.47; CI 0.25-0.86); from A + nAIs in “de novo” subgroup (HR 0.60; CI 0.37-0.97), in “Asian” population (HR 0.37; CI 0.16-0.85) and “non visceral” disease (HR 0.48 CI 0.25-0.89); from R + nAIs in “de novo” subgroup (HR 0.55; CI 0.32-0.95) and in “visceral” disease (HR 0.66 CI 0.45-0.96); from all the three combination strategies (A, P and R) in “prior endocrine” exposure subgroup (HR 0.47 CI 0.25-0.87; HR 0.60 CI 0.45-0.80; HR 0.64 CI 0.41-1.0, respectively). Even though no significant PFS benefit was observed in the remaining subgroups, combined CDK 4/6 strategies appeared more effective than F according to relative HR.

Conclusions
CDK 4/6 inhibitors endocrine-based therapies as first-line treatment for postmenopausal women with HR+/HER2- MBC showed PFS improvement, regardless of prognostic subgroup and additionally advantage was emerged by indirect comparison with F. Further direct comparative studies are needed to explore greater benefits from different therapeutic options.
A significance of SUVmax levels on FDG-PET as a prognostic factor may be mediated by local immune environment of breast cancer

Yukie Fujimoto¹, Tomoko Higuchi¹, Takahiro Watanabe¹, Akira I Hida², Michiko Imamura¹, Kazuhiro Kitajima¹ and Yasuo Miyoshi¹.¹Hyogo College of Medicine, Nishinomiya, Japan and ²Kagoshima University Graduate School of Medical and Dental Sciences, Kagoshima, Japan.

(Background) SUVmax levels (maximum radioactivity concentration per a pixel) on FDG-PET reflect glucose uptake and it is clinically useful as a prognostic factor. It is reported that breast cancer with high levels of SUVmax causes insufficient glucose concentration in stromal tissue, which results in suppressed cytotoxic T-lymphocytes function. These data may indicate that the prognostic significance of SUVmax levels is influenced by local immune environment of breast cancer. The aim of this study is to investigate whether local immune responses of breast cancer affect correlation of SUVmax levels and prognosis.

(Method) The 278 invasive breast cancer patients were recruited who underwent surgery at Hyogo College of Medicine Hospital and whose SUVmax levels in the breast were examined before surgery or neo-adjuvant therapy. The cutoff value of SUVmax levels was set at 3.585. Tumor infiltrate lymphocytes (TILs) were evaluated as a local immune response and the distributions of TILs were divided into three groups, inflamed (intra-tumoral lymphocites, Inf), immune excluded (peri-tumoral lymphocytes, IE) and immune desert (very few lymphocytes, ID). During follow-up period (median 39 months), 21 patients relapsed.

(Results) Relapse free survival (RFS) in the SUVmax-high group was significantly worse than in the SUVmax–low group (p=0.0026). There was no correlation between TILs distribution patterns and RFS. In the IE+ID group (175 patients) SUVmax levels were not correlated with prognosis, but in the Inf group (103 patients) RFS of SUVmax-high was significantly worse than of SUVmax-low (p=0.0051). In the multivariate analysis including nodal status and nuclear grade, SUVmax levels of the Inf group was an independent prognostic factor.

(Discussion and conclusion) SUVmax levels in primary lesions were correlated with prognosis only in the Inf group and were not in the IE+ID group. A significance of SUVmax levels as a prognostic factor may be diverse depending on the local immune environment of breast cancer. A novel therapeutic strategy such as inducing suppression of glucose uptake in cancer cells is suggested for breast cancer with immune inflamed.
Comparing prognostic performance of different lymph node staging systems among patients with breast cancer

Yue Gong¹, Peng Ji¹, Yi-Zhou Jiang¹, Xin Hu¹ and Zhi-Ming Shao¹. ¹Fudan University Shanghai Cancer Center, Shanghai, China.

Background: Metastatic regional lymph nodes (LN) is a strong predictor of worse long-term outcome after resection of breast cancer. This study aimed to compare the prognostic performance of American Joint Committee on Cancer (AJCC) N stage relative to lymph node ratio (LNR), log odds of metastatic lymph nodes (LODDS), number of removed lymph nodes (NRLNs), and number of negative lymph nodes (NNLNs) in breast cancer patients.

Methods: All of the breast cancer patients who underwent surgery between 2004 and 2012 were identified from the Surveillance, Epidemiology, and End Results database. Restricted cubic spline functions were used to characterize the association between continuous variables and the risk of death and determine the optimal cut-off points. The Cox proportional hazards models were constructed, and the relative discriminative abilities of the different LN staging systems were assessed using the Akaike's Information Criterion (AIC) and the Harrell's concordance index (C-index).

Results: A total of 264,096 breast cancer patients were enrolled, and 177,598 (67.2%) had no lymph node metastasis, whereas 86,498 (32.8%) had lymph node metastasis. 187,785 (71.1%) patients had a limited number of LNs harvested (NRLN <10). The median follow-up time was 73 months, and the 8-year overall survival (OS) and breast cancer-specific survival (BCSS) were 82.6% and 90.4%, respectively. LNR, LODDS, NRLNs, and NNLNs were all nonlinearly associated with OS and BCSS. Patients with metastatic LN had an increased risk of OS (hazards ratio: 2.32, 95% confidence interval: 2.27–2.37; P < 0.001) and BCSS (hazards ratio: 4.53, 95% confidence interval: 4.40–4.66; P < 0.001). When LNR was equal to 0 or 1, there was a heterogeneity of outcomes, and LODDS still yielded informative values compared to LNR. Among the entire cohort, LNR modeled as a continuous variable had a somewhat better prognostic performance (AIC: 923231.4 and C-index: 0.722 for OS; AIC: 482962.3 and C-index: 0.817 for BCSS) than any of other LN staging systems. Patients with metastatic LN had an increased risk of OS (hazards ratio: 2.32, 95% confidence interval: 2.27–2.37; P < 0.001) and BCSS (hazards ratio: 4.53, 95% confidence interval: 4.40–4.66; P < 0.001). When LNR was equal to 0 or 1, there was a heterogeneity of outcomes, and LODDS still yielded informative values compared to LNR. Among the entire cohort, LNR modeled as a continuous variable had a somewhat better prognostic performance (AIC: 923231.4 and C-index: 0.722 for OS; AIC: 482962.3 and C-index: 0.817 for BCSS) than any of other LN staging systems. However, a model with AJCC N stage showed the best fit in patients with a limited number of LNs harvested (AIC: 501321.8 and C-index: 0.699 for OS; AIC: 212605.6 and C-index: 0.809 for BCSS). When assessed among patients with metastatic LN, LODDS outperformed other staging systems including AJCC N stage, LNR, NRLNs and NNLNs, whenever assessed using continuous (AIC: 428626.2 and C index: 0.728 for OS; AIC: 296886.8 and C index: 0.770 for BCSS) or categorical (AIC: 429527.5 and C index: 0.722 for OS; AIC: 297796.6 and C index: 0.762 for BCSS) cutoff values.

Conclusions: Although LNR assessed as a continuous variable was the most potent method to stratify patients regardless of LN status, the prognostic superiority of LNR is confounded by a limited LN harvest. LODDS was a better and more powerful predictor of survival when patients were LN positive, especially among those patients with either very low or high LNR.
The prognostic impact of synaptojanin 2 expression in estrogen receptor α-positive breast cancer patients

Sayaka Nishikawa1, Naoto Kondo1, Yumi Wanifuchi-Endo1, Tomoka Hisada1, Yasuaki Uemoto1, Yusuke Katagiri1, Yu Dong1, Hiroyuki Kato1, Satoru Takahashi1 and Tatsuya Toyama1. 1Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan.

Background: Synaptojanin 2 (SYNJ2) was reported to be a druggable mediator of metastasis. It is overexpressed and amplified in breast cancer, particularly estrogen receptor α (ERα)-positive breast cancer. SYNJ2 was also shown to promote cell migration and invasion in breast cancer xenograft cultures and lung metastasis in mice. Here, we investigated SYNJ2 mRNA expression in breast cancer patients during long-term follow-up.

Materials and methods: A total of 434 invasive breast cancer tissues were analyzed for SYNJ2mRNA expression using TaqMan PCR, and the correlation of this expression with patient clinicopathological factors was determined. We also examined the expression of markers associated with tumor-initiating capacity, such as SNAI1, SNAI2, and VIM. Survival curves were analyzed using the Kaplan–Meier method. Cox proportional hazards regression analysis was used for univariate and multivariate analyses of prognostic values.

Results: The median follow-up period was 10.7 years. We found positive correlations between high expression of SYNJ2 mRNA and shorter disease-free survival in breast cancer patients (P=0.049), which was limited to ERα-positive patients (P=0.020) and not seen in ERα-negative patients (P=0.863). High SYNJ2 mRNA levels were positively correlated with high tumor grade, ERα negativity, and node positivity. Multivariate analysis indicated that high SYNJ2 mRNA expression was an independent factor for poor disease-free survival in breast cancer patients.

Conclusion: High SYNJ2 expression was shown to be an independent predictive factor of poor prognosis in ERα-positive breast cancer patients. SYNJ2 could therefore be used as a candidate biomarker and therapeutic target in breast cancer.
Influence of prognostic factors on outcomes among metastatic breast cancer patients treated with CDK4&6 inhibitors in routine clinical practice

Kimberly R Saverno¹, Gebra Cuyun Carter¹, Li Li¹, Linda A Battiato¹, Yu-Jing Huang¹, Emily Nash Smyth¹, Gregory L Price¹, Kristin M Sheffield¹, Shrujal S Baxi², Deborah Kuk² and Andrew D Seidman³. ¹Eli Lilly and Company, Indianapolis, IN; ²Flatiron Health, New York, NY and ³Memorial Sloan Kettering Cancer Center, New York, NY.

Background: Evidence suggests that there are clinical features associated with a less favorable prognosis among patients with HR+/HER2- metastatic breast cancer (MBC) such as metastases to non-bone sites, including liver and lung, and negative progesterone receptor (PgR-) status. The objective of this study was to compare baseline characteristics and outcomes between those with and without these clinical factors among a cohort of HR+/HER2- MBC patients treated with a CDK4&6 inhibitor (CDK4&6i).

Methods: This was a retrospective analysis of the Flatiron Health electronic health records-derived database for US patients diagnosed with MBC between 1/1/2011 and 9/30/2017. The study included a random sample of patients with HR+/HER2- MBC who were treated with a CDK4&6i on or after 6/30/2016. Baseline variables, including demographics, comorbidities, and sites of metastasis, were recorded at start of the first CDK4&6i containing line of therapy in the metastatic setting on or after this date. Dates of real-world progression were abstracted from patient charts. Descriptive statistics and appropriate statistical tests were used to compare baseline characteristics between patients with or without select clinical factors associated with unfavorable outcomes. In patients who received a CDK4&6i-based therapy, Kaplan–Meier methods and univariable Cox proportional hazards models were used to assess real-world progression free survival (rwPFS) by line from start of line to the date of first progression or death within line (unadjusted for treatment and other potential confounders).

Results: 518 patients were included in this study. Median age at metastatic diagnosis was 66y (IQR; 59-73y); 99% female and 11.4% had PgR- status. At baseline, 20.5%, 46.3%% and 65.8% of patients had liver, visceral (defined as liver and/or lung), and non-bone only metastases, respectively. Among a total of 207 patients who received a CDK4&6i as initial therapy in the metastatic setting, 69.1% received it in combination with an aromatase inhibitor, 29.5% received it in combination with fulvestrant, and 1.4% as monotherapy. Within the same group, 58 had disease progression or died during first line (1L); median rwPFS measured from start of 1L was not reached (95% CI: 10.7 months, NA). Univariable analyses revealed the presence of liver metastases was associated with a higher risk of progression or death compared to no liver metastases (HR: 2.04, 95% CI: 1.13 - 3.68). Having non bone-only metastases was associated with a higher risk of progression or death compared to having bone-only metastases (HR: 2.23, 95% CI: 1.20 – 4.15). Univariable analyses did not reveal any statistically significant differences in first-line rwPFS by PgR status or presence of visceral metastases. Results from other lines of therapy are forthcoming.

Conclusion: In a real world data set, and consistent with prior prospective data, presence of liver and non-bone only metastases were associated with a higher risk of progression among patients with HR+/HER2- MBC receiving initial therapy with a CDK4&6i. The heterogeneity of prognoses among this population reinforces the need to consider these clinical features in treatment decisions for optimal patient outcomes.
Predictors of distant metastasis in patients with triple negative breast cancer who failed to achieve a pathological complete response after neoadjuvant chemotherapy

Christopher J Tricarico¹, Prashant Gabani¹, Ashley A Weiner², Laura L Ochoa¹, Maria A Thomas¹ and Imran Zoberi¹. ¹Washington University School of Medicine, St. Louis, MO and ²University of North Carolina, Chapel Hill, NC.

Background
Patients with triple-negative breast cancers (TNBC) are at an increased risk of distant metastasis compared to patients with other subtypes of breast cancer. While TNBCs are aggressive as a group, many are potentially curable, reflecting an underlying heterogeneity. As such, there is an interest in identifying factors that may allow further stratification of patients in relation to the risk of distant metastasis and, ultimately, better tailor treatment plans to individual patients. With the increasing use of neoadjuvant chemotherapy (NAC), past studies have shown that patients who achieve a pathological complete response (pCR) following NAC have a decreased risk of distant metastasis. However, beyond the presence or absence of pCR, other risk factors for distant metastasis have not been well characterized.

Methods
This is a single institution, retrospective study of women with TNBC treated with NAC, surgery, and radiation therapy (RT) between 2000 and 2013. The rate of distant metastasis was estimated and compared between patients who achieved pCR versus those who did not achieve pCR using Kaplan-Meier method. In patients who failed to achieve pCR, patient-specific and treatment-specific factors including age, race, menopause status, family history, smoking history, clinical stage, histology, NAC regimen, whether breast conserving surgery was performed, response to NAC, treatment with adjuvant chemotherapy, and use of RT boost were analyzed using multivariable cox proportional hazards method to evaluate factors associated with distant metastasis.

Results
A total of 153 patients with a median follow up of 48.6 months were included. Of the 153 patients, 108 (70.9%) were identified as not having pCR following NAC. Among those 45 patients that did achieve a pCR, only 1 patient (2.2%) went on to have distant metastasis. In contrast, of the 108 patients that failed to achieve a pCR, 47 (43.5%) went on to have distant metastasis. On univariable analysis, factors associated with distant metastasis in patients that did not achieve a pCR included increasing clinical and pathological T and N stage, positive pathologic lymph node status, multifocality, lymphovascular space invasion (LVSI), extranodal extension, and failure of downstaging after NAC. After controlling for potential confounders in multivariable analysis, higher pathological N stage (HR 2.18, 95% CI 1.12 - 4.22), positive pathologic lymph nodes (HR 2.21, 95% CI 1.02 - 4.80), LVSI (HR 1.87, 95% CI 1.04 - 3.37), and multifocality (HR 2.05, 95% CI 1.05 - 4.03) were found to be independent predictors of distant metastasis.

Conclusions
Approximately 43.5% of patients with TNBC that did not achieve a pCR went on to develop distant metastasis, perhaps reflecting an underlying chemo-resistance of these non-pCR tumors. Here we identify multiple risk factors associated with distant metastasis among patients not achieving a pCR, including positive lymph nodes, LVSI, high pathologic N stage, and multifocality. This data can be used to inform prognoses and treatment decisions in this high-risk cohort of patients and future clinical trials are warranted to lower the risk of distant metastasis in this population.
Reconsidering “at risk” criteria for breast cancer recurrence in hormone positive patients: Risk stratification is still important in patients with an Oncotype Dx recurrence score ≤ 25!

Bradley M Turner¹, Mary Ann G Sanders², Armen Soukiazian³, Nyrie Soukiazian⁴ and David G Hicks¹. ¹University of Rochester Medical Center, Rochester, NY; ²University of Louisville, Louisville, KY; ³University of Rochester, Rochester, NY and ⁴Drexel University College of Medicine Graduate School of Biomedical and Professional Studies, Philadelphia, PA.

Introduction: The recent TAILORx results suggest that additional systemic chemotherapy may not be necessary in certain hormone +, HER2 -, node negative breast cancer patients with an Oncotype Dx recurrence score (ODXRS) ≤ 25. ODX is an expensive test (current list price of $4,650.00), and cost has been an impediment to its adoption in many centers throughout the world. Based on a modification of the new Magee equations (Klein ME, et al. Mod Pathol. 26[5]) we published data based on 283 patients with ODXRS's (Turner BM, et al. Mod Pathol. 28[7]), suggesting that the modified Magee equation (MME) offered a less expensive alternative to ODX testing in certain breast cancer patients. We now have outcome data suggesting that the MME along with progesterone receptor (PR), Ki-67, lymph node (LN) status, and lymphovascular invasion (LVI) status can be helpful in predicting which patients with an ODXRS ≤ 25 are more likely to recur. Methods: 248 patients with information on estrogen receptor (ER), PR, Ki-67, Her-2 status, Nottingham score, tumor size, LN status, LVI status, and an available ODXRS (2008-2018) were identified from the pathology files at the University of Rochester Medical Center. Results: All of the patients that recurred had an average modified Magee score (MMS) ≥ 14 (Table 1). Patients with LN involvement (5/43, 12%) or with LVI (5/27, 19%) had a higher percentage of recurrence than patients without LN involvement (8/197, 4%) or without LVI (8/216, 4%). Patients that recurred had a significantly (p < 0.05) lower PR and higher Ki-67 than patients in the same risk class that did not recur (Table 2). Neither grade nor ER status was significantly different between patients that recurred and did not recur (Table 2). All of the patients that recurred had at least a lowered PR, higher Ki-67, LN involvement, or LVI, and most had some combination of these variables (Table 1). 8 of the 13 patients that recurred in our population (61.5%) had an ODXRS of ≤ 25. Conclusions: Risk stratification is still important in patients with an ODX score ≤ 25. The MMS along with PR, Ki-67, LN, and LVI status can be helpful in predicting patients with a higher risk of recurrence.

Biology, metastases pattern and survival of triple negative breast cancer (TNBC) – A comparison between younger (<40 years) and elderly (>74 years) patients

Anna-Karin Tzikas¹, Szilard Nemes² and Barbro K Linderholm¹. ¹Institution of Clinical Sciences, Sahlgrenska University Hospital, Gothenburg, Sweden and ²Institution of Clinical Sciences, Gothenburg University, Gothenburg, Sweden.

**Background:** TNBC remains a poorly defined and heterogeneous subset of breast cancer with an adverse prognosis that more often affects younger patients. The biology and outcome of TNBC in elderly patients are less studied.

**Aims:** To determine the biology, recurrence rate, metastases pattern and survival from diagnosis of primary BC, as well as from diagnose of recurrences in a population based cohort of primary TNBC with focus on the comparison between younger and elderly patients.

**Material and Methods:** Patients with primary TNBC stage I-IV diagnosed from 2007 through 2015 were identified through the regional cancer registry and detailed information on tumor biology: histological grade, lymphovascular invasion (LVI) and Ki67; stage, type of adjuvant/neoadjuvant treatment, disease-free interval, type of recurrences (involved organs), and survival times were extracted from patients’ charts. The definition of younger (<40 years) and elderly (>74 years) patients was chosen as these patients not participate in mammogram screening programs. For comparisons all factors but Ki67 were run as dichotomous variables.

**Results:** A total of 525 patients median age 60 years (range: 24-94) were identified. Stage at diagnose were: stage I (24.0%); II (44.6%); III (23.8%) and IV (3.4%). Biology parameters are as follows: Histopathological grade I (1.7%); grade II, (18.5%) and grade III (77.8%) respectively. LVI was present in 24.4%; median Ki67 was 70% (range 1-100%) and median follow-up time is 55.9 months (range: 24-94). In the whole cohort, 396 (75.5%) patients received adjuvant/neoadjuvant chemotherapy and 373 (71%) patients are free from recurrences. The median DFI was 14.9 months (range: 2.0-64.7).

The clinical stage at diagnosis did not differ between younger (n=58) and elderly (n=96) patients; stage I (12% vs 11.5%; stage II (63.8% vs 48.7%); stage III (22.4% vs 30.8%); stage IV (1.7% vs 9,0%) (p=0.17). A statistically significant difference was found concerning histopathologic grade (grade III 77.0% vs 53.0%; p=0.006) and Ki67 (median 74.5% versus 62.7%; p=0.003) but not for LVI (p=0.915) with a higher proportion of poorly differentiated high proliferative tumors among younger patients. A larger proportion of younger patients received (neo-)adjuvant chemotherapy compared with elderly (94.8% versus 11.5%; p>0.001).

Pattern of recurrence was similar concerning lung (p=0.38); liver (p=0.1); distant lymph nodes (p=0.35) but breast cancer brain metastases were statistically significantly more frequently registered among younger patients (p=0.009). Shorter survival times were found among elderly patients; RFS (p=0.011); BCSS (p=0.002); OS (p<0.001), as well as survival following diagnose of recurrence (p=0.034).

**Conclusions:** We show that primary TNBC is more aggressive in terms of poor differentiation grade and high proliferation rate with more frequently development of brain metastases in younger compared with elderly patients. The majority of elderly patients still have grade III tumors with a Ki67 > 60% and survival following diagnosis of both primary BC and metastatic BC is short. Our results underline the need for novel treatment options suitable also for an elderly patient population.

Use of breast cancer index to analyze tumor proliferation and endocrine responsiveness in genomic intermediate risk patients

Fengting Yan1, Aashini K Master2, Mason A Israel3, Junmei Liu3, Yi Zhang3, Catherine A Schnabel3 and Vijayakrishna K Gadi1.
1University of Washington/Fred Hutchinson Cancer Research Center, Seattle; 2University of California Los Angeles, Los Angeles and 3Biotheranostics, Inc., San Diego.

Background: Breast Cancer Index (BCI) is a genomic assay that stratifies patients (pts) for cumulative 10-year and late (post–5-year) risk of distant recurrence and predicts the likelihood of extended endocrine therapy (EET) benefit based on the algorithmic analysis of gene expression from two functional gene cassettes: 1) The Molecular Grade Index (MGI), which contains 5 proliferation genes and 2) The HoxB13/IL17BR (H/I) ratio, an endocrine response biomarker. BCI more precisely resolves genomic intermediate risk patients into low- and high-risk groups (Sestak, Clin Cancer Res 2016) and adds significant prognostic data beyond clinical features (ie, clinical treatment score; Sestak, JAMA Oncol 2017) by interrogating different aspects of tumor biology such as proliferation and endocrine response. The objective of this study was to measure tumor proliferation and endocrine responsiveness using MGI and H/I respectively and evaluate their correlation with age in genomic intermediate risk pts.

Methods: This study utilized a subset of cases from the BCI Clinical Database for Correlative Studies, an IRB-approved de-identified database that contains clinicopathologic and molecular variables from clinical cases submitted for BCI testing. Genomic intermediate risk cases were defined as LN-, HER2- (or HER2 status unknown) with 21-gene recurrence scores (RS) of 11 to 25 using cut-points from the TAILORx study. Quantitative scores for MGI and H/I were derived by algorithmic analysis of BCI gene expression. Age groups (<50y and ≥51y) were determined using the date of diagnosis. MGI and H/I were evaluated in two different genomic intermediate risk groups: RS 11-15 and RS 16-25. Pearson correlation coefficients were used to determine the correlation between MGI, BCI, H/I, and genomic intermediate risk scores for patients <50y and ≥51y.

Results: Of the 441 pts with RS and BCI results, 303 (69%) with genomic intermediate risk were analyzed. The median MGI score in pts ≥51y was higher in the RS 16-25 group compared to RS 11-15, but there was no difference in MGI score between the two genomic intermediate RS risk groups for pts ≤50y. In contrast to MGI, median H/I was higher in the RS 16-25 group irrespective of age, with 37% of pts ≤50y and 41% of pts ≥51y having tumors predicted as more likely to benefit from EET using validated cut-points for H/I. There was no significant correlation between tumor proliferation (MGI: r=0.166) or endocrine responsiveness (H/I: r=0.244) with genomic intermediate-risk RS 11-25 group.

Conclusion: These data, which show variations in tumor proliferation and endocrine signaling based on age and genomic intermediate risk group, highlight the importance of measuring different features of tumor biology for risk classification and prediction of therapy response. The absence of correlations between tumor proliferation and genomic intermediate risk and age, and between estrogen signaling and genomic intermediate risk and age, suggests that assays such as BCI that combine distinct aspects of tumor biology for prognosticating risk of recurrence and prediction of benefit from endocrine therapy provide additional value for individualizing the management of patients with early-stage ER+ breast cancer.
Can optoacoustic imaging combined with ultrasound non-invasively offer prognosis for breast cancer molecular subtypes?

Gisela LG Menezes¹, Ritse M Mann², Carla Meeuwis³, Bob Bisschops⁴, Jeroen Veltman⁵, Philip T Lavin⁶, Marc J van de Vijver⁷ and Ruud M Pijnappel⁸. ¹UTHSCSA, San Antonio; ²Radboud University Medical Center, Nijmegen, Netherlands; ³Rijnstate Hospital, Arnhem, Netherlands; ⁴Albert Schweitzer Hospital, Dordrecht, Netherlands; ⁵ZGT, Almelo, Netherlands; ⁶Boston Biostatistics Research Foundation, Framingham; ⁷Netherlands Cancer Institute, Amsterdam, Netherlands and ⁸University Medical Center Utrecht, Utrecht, Netherlands.

**Aim:** To investigate the role of optoacoustic imaging combined with gray-scale ultrasound (OA/US) to better differentiate between breast cancer molecular subtypes.

**Materials and Methods:**
This prospective 5-center study was performed in the Netherlands between March 2015 and February 2016. Only masses considered suspicious at conventional diagnostic breast ultrasound (US) were included. The study was approved by the institutional ethical boards of the participating hospitals and written informed consent was obtained from all patients. Dedicated breast radiologists evaluated the included masses using OA/US and scored the internal and external OA/US features accordingly. Spearman Correlation was used to analyze the relationship between OA/US features and mitotic figures. The same statistical method was also used to evaluate the correlation between OA/US features and percentages of ER, PR and Ki67. Wilcoxon-Mann-Whitney tests were used to analyze the relationship between OA/US features and molecular subtypes of breast cancer (Luminal A, Luminal B, Triple Negative and HER2-enriched breast cancers).

**Results:** Overall, 209 patients with 215 breast lesions were included in this study. Sixty-seven masses were considered malignant and the 59 masses classified as invasive breast cancers were included in the final mitotic figures, ER, PR, Ki-67 and molecular subtype analyses. Significant correlations were found between OA/US Total Internal Features and ER (p = 0.0333) and Ki-67 (p = 0.0092) percentages. Regarding molecular subtypes, Internal Vessels (p = 0.0257), Total Internal Features (p = 0.0196) and combined Total Internal and External Features (p = 0.0289) helped to differentiate between Luminal A and Luminal B cancers. Internal Vessels (p = 0.0030), Internal Blush (p = 0.0044), Total Internal Hemoglobin (p = 0.0053), Total Internal Features (p = 0.0010), Total Internal divided by Total External Features (p=0.0255) and combined Total Internal and External Features (p = 0.0108) helped to differentiate between Luminal A and Triple Negative breast cancers. Total Internal Features showed a borderline result (p = 0.0551) regarding the differentiation between Triple Negative and HER2-enriched subtypes.

**Conclusions:** The use of OA/US features to non-invasively differentiate between breast cancer molecular subtypes may help to establish an earlier prognosis and treatment planning, potentially decreasing costs and facilitating larger scale diagnosis. Future research with larger sample sizes may confirm these preliminary results.
Tumor infiltrating lymphocytes in triple negative breast cancer: Our experience at an Argentine breast unit

Carola Allemand1, Maria F Calvo1, Ana C Valerio1, Maria C Riggi1, Francisco Corrao1, Roberto Orti1, Alejandra Wernicke1, Liliana Zamora1, Maria C Paez1 and Claudio Lorusso1. 1Hospital Italiano de Buenos Aires, Buenos Aires, Argentina.

Introduction
The assessment of Tumor Infiltrating lymphocytes (TILs) in primary breast cancer (BC) has been well established as a clinically relevant immunologic biomarker. The available evidence suggests that the extent of the lymphocytic infiltrate has prognostic and predictive significance, especially in triple negative and Her2 positive breast cancers. The presence of TILs has been associated to better response to adjuvant and neoadjuvant treatment as well as better overall long-term prognosis. The goal of this study was to establish the prognostic implications of the presence of TILs in triple negative breast cancer (TNBC) in our patient population.

Materials and Methods
We retrospectively analyzed data collected from all patients who underwent treatment for triple negative breast cancer (TNBC) at the Hospital Italiano at Buenos Aires between January 2007 and December 2016. The presence of TILs was defined as the proportion of mononuclear cells (lymphocytes and plasma cells) in the stromal compartment and within the tumor surface area. The TILs were evaluated on hematoxylin and eosin (H&E) stained tumor sections, measuring 4-5 µm in thickness. Hotspots were not considered. Absence of TILs was defined as less than 10% of mononuclear cells in the stromal compartment. We stratified patients into two groups according to whether the presence of TILs was greater or less than 50%.

Results
A total of 2350 patients underwent treatment for breast cancer (BC) at the Hospital Italiano de Buenos Aires over this period. Among these, 169 (7.19%) were TNBC. The mean patient age was 59.4 years. Seventy percent of patients were postmenopausal. Breast conserving therapy (BCT) was feasible in 61% of patients. The rate of axillary metastasis was 43.7%. Thirty-three patients (19.5%) presented TILs greater than 50%. Mean follow up was 55 months (1-133 months). Patients were stratified according to percentage of TILs. Among the group with TILs greater than 50%, 73 patients (53%) remain disease-free. On the contrary, patients with TILs greater than 50%, 25 (75%) remain without disease, which resulted in a statistically significant difference in survival.

Events in TNBC

<table>
<thead>
<tr>
<th>TILs</th>
<th>Disease Free (%)</th>
<th>Distant Disease (%)</th>
<th>Death (Breast Cancer) (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>TILs &lt;50</td>
<td>73</td>
<td>4</td>
<td>50</td>
</tr>
<tr>
<td>TILs &gt;50</td>
<td>25</td>
<td>2</td>
<td>4</td>
</tr>
</tbody>
</table>

Upon statistical analysis (cox proportional hazard risk model), patients with TILs above 50% had a hazards ratio (HR) of 0.47 for events ($p = 0.046$; CI95% 0.23 – 0.98). The Odds Ratio (OR) for death associated with high TILs was 0.24 (CI95% 0.08 – 0.72). After adjusting for tumor size and axillary status, the difference continues to be statistically significant: OR 0.26 ($p = 0.01$; IC 95% 0.08 – 0.81).

Conclusions
In our experience, patients presenting TILs showed significantly less events during follow up. The presence of TILs in this subgroup appears to behave as an independent prognostic factor in our patient population, which reproduces the data currently published.
Malic enzyme 1 is a potential metastasis-related biomarker of breast cancer

Chang Liu1,2, Zhonghua Tao1,2 and Xichun Hu1,2. 1Fudan University Shanghai Cancer Center, Shanghai, China and 2Shanghai Medical College, Fudan University, Shanghai, China.

Background: Malic enzyme 1 (ME1) catalyzes malate to pyruvate and thus promotes glycolysis, playing a part in the Warburg effect. Recently, several researches have revealed its crucial role in cancer metastasis. KM-plotter, an online analysis tool, showed high ME1 mRNA level was related to poorer RFS and OS. Herein, we explore the prognostic effect of ME1 on invasive breast cancer in Chinese patients and its effect on metastasis in vitro.

Methods: 220 patients with early breast cancer were included in this study. ME1 expression was evaluated semi-quantitatively with tissue microarray-based immunohistochemistry. The relationships between ME1 expression level and clinicopathological features were explored. Survival analyses were carried out by Kaplan-Meier test and COX proportional hazard model. MCF-7 and MDA-MB-468 cell lines were then used for in vitro cell migration and invasion assays.

Results: High expression of ME1 was observed in 51.5% patients. The median follow-up period was 28.9 months (range 0.5-34.0). In correlation analyses, compared with ME1-low cases, ME1-high cases were significantly associated with larger tumor size (P=0.036), positive lymph nodes (P<0.001) and positive lymph-vascular invasion (P=0.003), and tended to be HER2 positive (P=0.094). Survival analysis by Kaplan-Meier test showed high ME1 expression was significantly correlated with poorer recurrence free survival (RFS) (P=0.015). Multivariate analysis identified high ME1 expression as an independent prognostic factor for RFS (P=0.035, HR=5.072 [1.121, 22.942]). Stratified analysis revealed high ME1 expression was related to poorer RFS among cases more than 45 years old (P=0.029, HR=9.833 [1.269, 76.164]) and among those with Ki67 index ≥20% (P=0.038, HR=3.805 [1.074, 13.486]). In vitro, HER2 positive cell line (SKBR3) and TNBC cell lines (MDA-MB-231, MDA-MB-468) showed high expression of ME1, while luminal cell line (MCF-7) showed low expression of ME1. Upregulation of ME1 in MCF-7 cell line remarkably enhanced its ability in migration and invasion, while knockdown of ME1 in MDA-MB-468 cell line had a profound inhibitory effect on migration and invasion.

Conclusions: ME1 enhances migration and invasion of breast cancer cell lines and may be involved in early development of breast cancer metastasis. Thus, ME1 is a promising prognostic indicator and a potential therapeutic target.
Prognostic value of tumor-infiltrating lymphocytes (TILs) and clinical values for prediction of breast cancer recurrence in HER2 positive early breast cancer after surgery in King Chulalongkorn Memorial Hospital

Surampa Prapatsornvichit¹, Taywin Atikankul¹, Virote Sriuranpong¹, Nattaya Poovorawan¹ and Napa Parinyanitikul¹. ¹King Chulalongkorn Memorial Hospital, Bangkok, Thailand.

Background: Tumor-infiltrating lymphocytes (TILs), one of immunological biomarkers have been investigated in breast cancer and other cancers. High levels of TILs or lymphocyte-predominant breast cancer subgroup (LPBC) were associated with better prognosis in HER2 positive and triple negative breast cancers from various studies. Recently, TILs is also the predictive biomarker for response to neoadjuvant chemotherapy. Clinical utility of TILs has been recommended in routine clinical practice for breast cancer patients. However, limitation of TILs in HER2 positive women in Thai ethnicity was reported. So, the aim of this study was to evaluate TILs in combination with clinical values as the prognostic value for predicting the recurrent breast cancer in Thai population.

Methods: Four hundred and eighty-six patients with early stage HER-2 positive breast cancer who were diagnosed and treated at King Chulalongkorn Memorial Hospital from January 2005 to December 2016 were reviewed retrospectively. Clinico-pathological features, stromal TILs classified as low, intermediate and high, and survival outcomes were analyzed.

Results: The median age was 52 years (26-85). Of the 486 HER2 positive women, 56% had postmenopause, 54.5% had T2 tumor, 47.7% had node negative, 66.8% had stage I-II, 44.6% had lymphovascular invasion, and 47.5% had positive hormonal receptor. For the primary treatment, 67.3% underwent modified radical mastectomy, 96.5% received neoadjuvant/adjuvant chemotherapy, 69.7% received adjuvant trastuzumab, 46.7% received adjuvant hormonal therapy. In 92 recurrent patients (18.9%), distant metastasis was identified in 67.4%. In 100 available tissues for evaluating stromal TILs, only 14 (14%) had high stromal TILs (at least 50%) and 46 patients (46%) had recurrent disease. Twenty three of 39 (59%)in low stromal TILs group had disease recurrence while only 4 out of 14 (28.6%) in high stromal TILs had recurrent disease. Median percentage of stromal TILs in recurrent and non-recurrent group was 17.5% and 27.5%, respectively. From multivariate analysis, high stromal TILs (HR 0.52 [95%CI 0.32-0.85]; p = 0.01) and trastuzumab used (HR 0.39 [95%CI 0.25-0.61]; p <0.001) were associated with decreased risk of recurrences. After median follow up of 4.1 years, 5-years disease free survival (DFS) and 5-years overall survival (OS) were 80.9%, 86.8%, 69% and 92.6%, 91.5%, 94.5% in overall populations, trastuzumab and non-trastuzumab used group, respectively. Additionally, 5-year DFS and 5-year OS were 34.3%, 60.8%, 75.7% and 86.2%, 82.5%, 83.1% in low, intermediate and high stromal TILs subgroup, respectively.

Conclusion: High stromal TILs and trastuzumab used were statistically significant prognostic values for predicting disease recurrence in HER-2 positive early breast cancer. Stromal TILs together with clinical values established clinical utility in Thai HER2 positive breast cancer women.

Evaluation of stromal tumor-infiltrating lymphocytes (sTIL) and tertiary lymphoid structures (TLS) in early breast cancer patients with triple negative breast cancer (TNBC) included in a prospective study of neoadjuvant chemotherapy (NAC) with Epirubicin and cyclophosphamide (EC) and carboplatin-paclitaxel (PC) (BSMO 2014-01)

**Background:** BSMO 2014-01 is a completed prospective phase 2 study evaluating the efficacy of neoadjuvant EC and PC. One of the secondary endpoints was the correlation of sTIL with response, pCR and survival. We also assessed the relationship between sTIL and TLS in the diagnostic biopsies.

**Methods:** Stromal TIL (sTIL) were evaluated on H&E stained tumor biopsies before the start of the NAC according to the criteria described by Salgado et al(1). Scores were defined as "low" or "high" if lymphocytic infiltration in the stroma around the tumor was ≤ 10% or > 10%. TLS are ectopic lymph node-like structures recently identified in breast cancer. TLS were counted using a dual IHC stain for CD3 (T cells) and CD20 (B cells) and categorized as "little" if the TLS occupied < 10% or "moderate to abundant" if they occupied ≥ 10% of the adjacent tissue. The correlation between sTIL and pathologic parameters was analyzed using the chi-square test; DFS and OS between the groups was estimated by using the log-rank test.

**Results:** So far we could quantify the number of sTIL in 38 out of 63 TNBC pts treated with neoadjuvant EC-PC. Twenty eight pts had a high sTIL score and 10 pts had a low sTIL score. The high-sTIL group (19/28) achieved a numerical higher pathologic complete remission (pCR) rate than the low-sTIL group (5/10) (p=0.3); both groups had a comparable disease free survival of 28.6 mths and 26.7 mths respectively (p=0.7). The overall survival was similar:29 mths and 27.8 mths respectively (p=0.8). Stromal TLS were identified in 10 out 23 samples available for this analysis and we could demonstrate a positive correlation between high levels of sTIL and high levels of moderate to abundant TLS(CD3) in the adjacent tissue in six out of the ten samples in which TLS were present (p=0.1).

**Conclusion:** These preliminary results could not confirm the results published by Denkert et al earlier this year(2). A trend for correlation of the presence of high sTIL with moderate to abundant levels of TLS was found. Analysis on the remaining samples of all patients included in the study and correlation with outcome is ongoing and these completed results will be presented.

Features associated with long-term survival in metastatic breast cancer

Natalie J Klar¹, Margaret Rosenzweig², Brenda Diergaarde³,⁴ and Adam Brufsky¹. ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²University of Pittsburgh School of Nursing, Pittsburgh, PA; ³Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA and ⁴UPMC Hillman Cancer Center, Pittsburgh, PA.

Background: 5-10% of women with metastatic breast cancer (MBC) survive ≥5 years. Predictors of long-term survival are not clearly elucidated. We used data from 122 long-term MBC survivors (≥5-year survival from date of MBC diagnosis) and 191 short-term MBC survivors (≤2-year survival from date from MBC diagnosis) to identify clinico-pathologic and socioeconomic features associated with MBC survival.

Methods: Women initially diagnosed with breast cancer (BC) in or after 1999, and diagnosed with MBC at Magee Women's Cancer Program of UPMC were included (N=313). Data abstracted from medical records included: stage at initial BC diagnosis, body mass index (BMI), Charlson Comorbidity Index (CCI), age, menopausal status at initial BC diagnosis, tumor receptor status at initial BC diagnosis, site of initial metastases, time to recurrence between initial diagnosis and MBC, household income, race, employment status, and partner status. Differences between groups were assessed using t-tests and Chi-square or Fisher's exact tests. Odds ratios (OR) and 95% confidence intervals (CI) were calculated using multivariate logistic regression models.

Results: Long-term survivors were significantly (P<0.05) younger, had more ER positive, PR positive, and Her2 positive disease, lower CCI, more often premenopausal at initial diagnosis, lower rates of visceral metastases, higher household income, and more often partnered than short-term survivors. The association of premenopausal status at initial diagnosis with long-term survival remained significant after adjustment for stage at initial diagnosis, tumor receptor status, and CCI (OR: 1.96, 95% CI 1.02- 3.79). Long-term term survivors were also significantly more often diagnosed with de novo MBC compared to short-term survivors. The association of de novo MBC with long-term survival remained significant after adjustment for age, tumor receptor status, and CCI (OR: 3.0, 95% CI 1.6-5.4). Time to recurrence between initial diagnosis and MBC, BMI, race, and employment status were not associated with survival.

Conclusions: Diagnosis of de novo MBC, ER-, PR- and/or Her2-positive primary tumor, lower rates of visceral metastases, higher household income, younger age, lower CCI, premenopausal status, and having a partner are associated with long-term survival after diagnosis of MBC. This is one of the first studies to show a survival benefit in MBC for patients with de novo MBC, premenopausal status at initial diagnosis, positive partner status, and higher household income.
The role of neutrophil–lymphocyte ratio (NLR), platelet–lymphocyte ratio (PLR) and monocyte–lymphocyte ratio (MLR) in prognosis of breast cancer patients

Joanna Huszno¹, Zofia Kołosza², Jolanta Mrochem Kwaciak², Tomasz Rutkowski¹ and Krzysztof Składowski¹. ¹MSC Memorial Cancer Center and Institute of Oncology, Gliwice, Silesia, Poland and ²MSC Memorial Cancer Center and Institute of Oncology, Gliwice Branch, Gliwice, Silesia, Poland.

Introduction: Breast cancer (BC) is a common malignancy in women. Biomarkers such as neutrophils, lymphocytes, neutrophil–lymphocyte ratio (NLR), platelet–lymphocyte ratio (PLR), monocyte–lymphocyte ratio (MLR) and PLT have been demonstrated to be closely related to poor prognosis in several solid tumors. The objective of this study was to evaluate the blood PLR, NLR and MLR for its prognostic value in patients with breast cancer.

Material and Methods: We retrospectively reviewed 436 breast cancer patients (all women) diagnosed and treated in MSC Memorial Cancer and Institute of Oncology, Gliwice Branch in years 2005-2018. The median age of patients was 52.5 years (range from 25 to 78). We assessed the prognostic value (overall survival) of pretreatment PLR, NLR and MLR based on univariate and multivariate analysis. The cut-off value of NLR was 'elevated' as >2.65, MLR value was 'elevated' as >0.28 and PLR cut-off value was 'elevated' as >190.9.

Results: Median follow-up was 71 months (range, from 3 to 165 months). The 5-year and 10-year OS rates were 88.1% and 80.2%, respectively. The 5-year OS was lower in NLR > 2.65 in comparison to NLR ≤ 2.65 (82.5% vs. 89.6%, p=0.053), especially in subgroup of triple negative breast cancer (TNBC) (70.3% vs. 89.3%, p=0.034) and in patients with estrogen receptor negative status tumors (66.6% vs. 83.6%, p=0.018). Similarly, the 5-year OS was lower in patients with PLR > 190.9 in comparison to PLR ≤ 190.9 (78.7% vs. 89.4%; p=0.020). The worse OS rate was also observed in subgroup with TNBC and PLR > 190.9 (68.2% vs. 88.5%, p=0.032) or in subgroup with ER negative steroid receptor status tumors with 'elevated' PLR (57.7% vs. 83.6%, p=0.002). The 'elevated' value of MLR (>0.28) was not associated with overall survival time in our group of patients (p=0.830), also in TNBC (p=0.219) and ER (-) (p=0.453) subgroups of patients. Multivariate analysis has showed that NLR and PLR were insignificantly negative prognostic factors in all analyzed group. However the analysis in subgroup of patients with ER (-) negative tumors has showed that higher NLR (p=0.013; HR=2.40; 95% CI 1.20-4.80) and higher PLR (p=0.012; HR=2.51; 95% CI 1.23-5.14) were an independent factors for lower OS together with metastatic lymph nodes (p=0.0001). Conclusion: Elevated pre-treatment NLR (>2.65) and PLR (>190.9) are associated with lower OS in breast cancer patients. In ER (-) subgroups of patients elevated NLR and PLR were significant independent prognostic factors. MLR did not affect overall survival.
Elevated levels of serum tumor marker p53 is a prognostic parameter and a monitoring biomarker for patients who had undergone surgical resection in breast cancer

Mie Arai†, Takuya Nagata†, Shinichi Sekine†, Hayato Baba†, Makoto Moriyama†, Isaya Hashimoto† and Tsutomu Fujii†. †University of Toyama, Toyama, Japan.

**Background**
Elevated levels of serum tumor maker p53 antibody is expected as an indicator of early diagnosis and a parameter of recurrence in breast cancer. P53 mutation accounts for 20% to 35% in all breast cancer patients. Preoperative high level of anti-p53 antibody in breast cancer patients tend to associate with worse prognosis. This study investigated the prognostic value of preoperative serum p53 levels, and the significance as a biomarker to evaluate a recurrence after surgical resections in breast cancer.

**Methods**
Preoperative serum p53 concentration levels were measured in total of 259 breast cancer patients, who had undergone either a total mastectomy or a partial mastectomy, through 2010 to 2015 in our facility. Patients with elevated levels of p53 (29 patients) and normal levels of p53 (230 patients) were compared to analyze the association of a marker level with the prognosis and the indication to diagnose recurrence in breast cancer.

**Results**
Elevated serum level of p53 mutation was identified in 29 (11%) patients. The size of tumor, staging, and pathology did not associate with the level of p53. Patients with elevated serum level of p53 correlated to the high score of nuclear grade (NG2 and NG3) and the high percentage of Ki-67 (>14%), which leading to the worse prognosis. Triple negative breast cancer was the major molecular subtype in the group of high level of p53 comparing with the group of low level of p53. Survival analysis using the Kaplan-Meier method were performed to examine DFS and OS of high serum level of p53 patients. Patients with high level of p53 were significantly showed worse DFS than a normal p53 group. Serum level of p53 was also reflected to the recurrence and metastasis of postoperative breast cancer. There were three patients, who had local recurrences and metastasis, in the group of high levels of p53. Their serum levels of p53 were re-elevated as emerging the local recurrence and metastasis once they had gotten the normal serum levels of p53 after surgical resections. It showed that the increasing of the level of p53 was reflected to the recurrence and metastasis of tumors after surgical resections in breast cancer.

**Conclusions**
This study suggests that preoperative serum level of p53 can be an independent prognostic parameter and a monitoring biomarker for breast cancer.
Residual Ki67 index and PRPTD mutational status after neoadjuvant chemotherapy containing platinum salts predicts the survival in triple negative breast cancer

Liang Huang1. 1Fudan University Shanghai Cancer Center/Cancer Institute, Shanghai, China.

Background: Platinum salts have demonstrated sufficient efficacy and safety to consider their use in a neoadjuvant setting for triple negative breast cancer (TNBC). In this study, we focused on the prognostic value of Ki-67 and PRPTD in TNBC patients who received neoadjuvant chemotherapy containing platinum salts.

Patients and Methods: We retrospectively analyzed 145 TNBC cases to compare the activity and tolerability of cisplatin and carboplatin. Two groups received weekly paclitaxel and platinum salts for 4 cycles. Immunohistochemistry assessment of EGFR, Ki67, CK5/6, CK14 was conducted in paraffin-embedded tumor samples after neoadjuvant treatment. Nonsense/missense mutations of PTPRD were also evaluated in these tumor samples determined by using next generation sequencing.

Results: In total, 87% of patients in the cisplatin group and 82% of patients in the carboplatin group experienced a clinical objective response after 4 cycles (P=0.570). Pathological complete response (pCR) occurred similarly in both groups (44% versus 42%, P=0.789).

In survival analysis, there was no difference between two regimens. The pathological variables of univariate Cox analysis were
obtained from EGRF, Ki67 index, CK5/6, CK14, PTPRD mutational status in residual tumor after NAC. Multivariate Cox analysis identified two significant prognostic factors, including Ki67 index and PRPTD mutational status.

Prognostic value of pathological variables in predicting disease free survival using univariate and multivariate Cox model

Abbreviation: EGFR, epidermal growth factor receptor; PTPRD, protein tyrosine phosphatase receptor type delta

The most common grade 3/4 adverse events were neutropenia and leukopenia.

Conclusion: There was no significant difference between the groups in adverse events. Both types of platinum salts and weekly paclitaxel are feasible therapies that achieved high pCR rates and tolerability in TNBC patients. Ki67 index and PRPTD mutational status in residual tumor should be suggested as promising biomarkers to predict the prognosis.
A predictive model for distant metastasis in breast cancer patients using machine learning

Isaac Kim1, Hee Jun Choi1, Jai Min Ryu1, Se Kyung Lee1, Jong Han Yu1, Seok Won Kim1, Seok Jin Nam1, Sung Wook Seo1 and Jeong Eon Lee1. 1Samsung Medical Center, Seoul, Gangnam-Gu, Korea.

Introduction
Tumor metastasis is a major clinical challenge accounting for the vast majority of cancer related deaths. In previous studies, prediction of distant metastasis was based on subtypes, clinical status and sometimes gene expression were used however clinical application was difficult. In this study, we develop the easy to use prediction tool for distant metastasis using clinical characteristics and gene profiles which came from CancerSCAN$^\text{TM}$, Next Generation Sequencing based targeted-sequencing platform designed at Samsung Medical Center(SMC).

Methods
We performed a retrospective chart review of 326 breast cancer patients who underwent surgery and CancerSCAN$^\text{TM}$ between Jan 2001 and Dec 2014 at SMC. Median follow up period was 83 months (Range 1~190). Cancer scan$^\text{TM}$ cover 381 genes but 27 genes and 34 occasions (loss of function, mutation or copy number variation) were selected for analysis through gradient boosting and Wilcoxon Signed rank test. Azure Machine Learning is a cloud service that enables the execution of machine learning processes. This was accomplished using the steps of (1) edit the data, (2) split the data, (3) train the model, (4) score the model, and (5) evaluate the model. We split the modeling data into training and testing sets using a randomized 50–50 split. Two-class Decision Forest method was used. After deploying the Azure ML predictive model as a web service, we used a Representational State Transfer application programming interface to send data and obtained predictions in real-time.

Results
No distant metastasis group and distant metastasis group consisted of 267 and 59 patients, respectively. HR-/HER2+ and 50 years old and over patients were higher in metastasis group ($p$-value = 0.003 and $p$-value = 0.000). Nuclear grade 3 and N2,3 were higher in metastasis group ($p$-value = 0.010 and $p$-value = 0.000, $p$-value = 0.001 respectively). Stage III was also higher in metastasis group ($p$-value = 0.000). Among 59 patients with distant metastasis, multiple sites metastasis was 21 cases (35.6%) and then lung metastasis was 19 cases (32.2%). In the 21 cases of multiple sites metastasis, triple sites was 6 cases (28.6%) and double sites was 15 cases (71.4%). PIK3CA mutation was the most frequent gene variation in all patients (34.5% of no metastasis group and 27.1% of metastasis group) but there was no difference between two groups ($p$-value = 0.278). BRCA loss of function and BRCA2 loss of function were more frequent in metastasis group than no metastasis group ($p$-value = 0.033 and $p$-value = 0.024, respectively) but total counts was too small. We assessed the area under the curve (AUC) of the receiver operating characteristic (ROC) curve for predictive value. The AUC of ROC curve was 1.000 and also accuracy, precision, recall were 1.000. In addition, we conducted internal validation using 83 patients during 2015. When we applied a 0.5 threshold value with our predictive model, true negative was 81 and true positive was 2 among 83 patients. Finally, the accuracy of validation was 1.000.

Conclusion
Our predicted model could represent a useful and easy-to-access tool for the selection of patients with distant metastasis. After additional evaluation with large data and external validation, worldwide use of our model could be expected.
Tumor elasticity and clinicopathologic factors affecting neoadjuvant chemotherapy response in breast cancer patients

Jeong Yeong Park¹, Jung Eun Choi¹, Young Kyung Bae¹ and Soo Jung Lee¹. ¹Yeungnam University College of Medicine, Daegu, Republic of Korea.

Background: Neoadjuvant chemotherapy for breast cancer has been increased. Many studies have reported on clinicopathologic factors to predict neoadjuvant chemotherapy response. Elastography, which is usually used to differentiate benign and malignant tumors, can be performed to evaluate tissue elasticity during conventional ultrasonography. The purpose of this study was to determine the clinicopathologic factors, including tumor elasticity, that affect neoadjuvant chemotherapy response in stage II or III breast cancer patients.

Methods: From April 2014 to March 2017, 95 patients received neoadjuvant chemotherapy for clinical stage IIa-IIIc primary breast cancer. To evaluate tumor elasticity, strain elastography was performed in 74 patients before neoadjuvant chemotherapy. Patients were divided into two groups by the Tsukuba elasticity scoring system (soft group ≤3 vs. hard group ≥4). Histologic type, nuclear grade, tumor infiltrating lymphocytes (TILs), tumor cellularity, characteristics of stroma, and hormone receptor (HR) and human epidermal growth factor receptor 2 (HER2) status were evaluated using core needle biopsy specimens obtained before neoadjuvant chemotherapy. Pathologic complete response (pCR) was defined as the absence of invasive carcinoma in breast (ypT0 and ypTis) and axillary lymph node (ypN0). Residual cancer burden (RCB) was also calculated in 79 cases and the cases were categorized into 2 groups; favorable RCB group (RCB-0 and I) and unfavorable RCB group (RCB-II and III).

Results: The mean age of patients was 46.43±8.62 years (range, 27-71 years) and the mean initial tumor size was 3.63±1.95cm (range, 2.1-12.8cm). Twenty-four patients (32.4%) were categorized into the soft group and 50 patients (67.6%) into the hard group. The mean tumor cellularity on core needle biopsy specimens and characteristics of stroma were not significantly different between the two groups (p=0.35 and p=0.79, respectively). Twenty-two patients achieved pCR (23.2%). The patients with pCR were more likely to have estrogen receptor (ER) or progesterone receptor (PR) negative breast cancer (p=0.04 and p=0.03). The rate of nuclear grade 3 was higher in patients with pCR than those without (p=0.03). Tumor elasticity was not correlated with pCR (p=0.28). Thirty patients (38.0%) achieved favorable RCB and forty-nine patients (62.0%) had unfavorable RCB. Not only the rates of ER negativity (p=0.05), PR negativity (p=0.03), nuclear grade 3 (p=0.01), and high TILs level (≥10%) (p=0.04) but also the mean TILs level (p=0.05) were significantly higher in the favorable RCB group compared with the unfavorable RCB group. No significant difference in tumor elasticity was observed between the two groups (p=0.30). In univariate analyses, nuclear grade 3 (p=0.03), and high TILs level (≥10%) (p=0.04) were significantly correlated with favorable RCB. HR negativity was an independent predictor of favorable RCB in multivariate analysis (odds ratio, 2.93; 95% confidence interval, 1.04-8.28; p=0.04).

Conclusion: Tumor elasticity was not associated with pCR or RCB. HR negativity was an independent predictor for favorable RCB. Nuclear grade and TILs were also potential predictive factors for neoadjuvant chemotherapy response.
Change in therapeutic management after EndoPredict assay in a prospective decision impact study of Mexican premenopausal patients

Cynthia Villarreal-Garza\textsuperscript{1,2}, Zuratzi Deneken-Hernandez\textsuperscript{3}, Antonio Maffuz-Aziz\textsuperscript{3}, Edna A Lopez-Martinez\textsuperscript{1}, Jose F Muñoz-Lozano\textsuperscript{1}, Regina Barragan-Carrillo\textsuperscript{1}, Omar Peña-Curiel\textsuperscript{1}, Brizio Moreno\textsuperscript{1}, Pier Ramos-Elias\textsuperscript{1}, Hector Díaz\textsuperscript{1} and Veronica Bautista-Piña\textsuperscript{3}. \textsuperscript{1}Tecnologico de Monterrey, Breast Cancer Center, Monterrey, Mexico; \textsuperscript{2}Instituto Nacional de Cancerologia, Mexico City, Mexico and \textsuperscript{3}Fundacion de Cancer de Mama (FUCAM), Mexico City, Mexico.

**Background:** Often, therapeutic decision-making in breast cancer (BC) patients is deeply influenced by age, with young women receiving highly aggressive systemic therapy, even when low clinical risk features are present. Currently, genomic signature studies have included a limited number of young patients, thus hindering their use in this population. Furthermore, significant data about their impact on clinical decision-making is lacking. Consequently, the medical community should strive to identify young patients who would not benefit from chemotherapy (CT). The aim of this prospective study was to determine the impact of the EndoPredict assay on adjuvant decision-making by a multidisciplinary team in premenopausal women.

**Patients and method:** A total of 92 premenopausal women with hormone receptor-positive, HER2 negative, T1-T2, and N0-N1 BC have been included. Clinicopathological characteristics were recorded and each case presented in a multidisciplinary tumor board. Consensual therapeutic decisions before and after EndoPredict results were registered. Pearson chi-square was used to analyze differences between groups.

**Results:** Median age at diagnosis was 43.5 years (y), with 68% being $\leq$ 45y. 28% had node-positive disease. Stage at diagnosis was: I (40%), II A (36%), and II B (23%). 11%, 72%, and 10% of tumors were low-, intermediate-, or high-grade, respectively. A total of 39 patients (46%) had a low-risk EPclin result. Notably, 61% of patients in the N0 group had a low-risk result compared to 9% with N1 status ($p$<.001). Additionally, 30% of patients $\leq$ 40y-old had a low-risk EPclin, compared with 53% in older patients ($p$=0.042). Tumor grade was significantly associated with EPclin, with 90% of low-grade tumors being low-risk, while 89% of grade 3 BC had a high-risk result ($p$=.0023). Grade 2 BC was not predictive of EPclin results, with 45% of patients being classified as low risk. No significant association was found between Ki67 or LVI, and EPclin.

Change in CT decision was recorded in 14/85 patients (17%), with the greatest impact in CT reduction (table 1). Furthermore, 22/85 (26%) and 19/85 (22%) had a change in CT and anti-hormonal therapy regimen, respectively. Overall therapeutic compliance with EndoPredict results was 95%: 100% of patients with a high-risk EPclin received CT, while 87% with a low-risk result did not.

**Conclusions:** This is the first study that evaluates the EndoPredict assay effect in decision-making in a premenopausal BC patient cohort. The less overall therapy change observed, compared to previous studies, could be the result of a reliable clinical judgment for identifying high-risk patients, which represent a large proportion in this young group. Overall, the test's greatest impact was aiding the discrimination of patients that would not benefit from CT, thus avoiding unnecessary adverse effects. In conclusion, the EndoPredict test successfully assisted the clinical decision-making process in premenopausal patients, with a high rate of therapeutic compliance and a significant change in overall decision.
Expression of MTH1 correlates with prognostic factor in breast cancer

He Zhang¹, Teng-Hui Liu², Li-Qun Zhang², Jin Li², Ju Cui², Xin-Yuan Tian², Dan-Ni Li² and Jian-Ping Cai¹. ¹Graduate School of Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing, China and ²The MOH Key Laboratory of Geriatrics, Beijing Hospital, National Center of Gerontology, Beijing, China.

**Purpose:** Genetic mutations are widely found in breast cancer tissues. 8-oxo-7,8-dihydroguanine (8-oxoGsn) in RNA and 8-oxo-7,8-dihydro-2’ deoxyguanosine (8-oxodGsn) in DNA are productions of oxidative Stress, which can induce transversion mutations. MTH1, as the most important repairase of nucleic acid oxidation, degrades 8-oxodG and 8-oxoG to monophosphates in nucleotide pools, thus prevents the occurrence of transversion mutations. This study mainly investigate the relationship between MTH1 expression and prognosis in breast cancer.

**Materials and methods:** MTH1 expression of 140 breast cancer tissues were evaluated by immunohistochemical staining of tissue microarrays. The clinical and pathological data of patients were analyzed by SPSS.

**Results:** Breast cancer patients with high expression of MTH1 had an extremely poor overall survival after surgical resection [figure1]. This phenomenon was significantly associated with American Journal of Critical Care (AJCC) stage (p=0.016), lymph node metastasis (p=0.023) and Lymphatic vessel invasion (p=0.009) of breast cancer specimens.

*: Statistically significant. #: Several data points from the 140 cases were not collected.

Cox univariate analysis shows that the MTH1 was one of prognostic factors in patients (p=0.0173).

**Conclusions:** MTH1 plays an important role in breast cancer prognosis. MTH1 will be a powerful prognostic factor and a potential therapeutic target in breast cancer patients.
Effects of young age on prognosis in patients with node-negative tumors 2 cm or smaller breast cancer

Wenjing Zhong\(^1\), Luyuan Tan\(^1\), Na You\(^2\), Yan Wang\(^1\), Gehao Liang\(^1\), Zihao Liu\(^1\), Yun Ling\(^1\), Zhenluan Tian\(^1\) and Chang Gong\(^1\).

\(^1\)Sun Yat-Sen Memorial Hospital, Sun Yat-Sen University, Guangdong, Guangzhou, China and \(^2\)Sun Yat-Sen University, Guangdong, Guangzhou, China.

Background It is still controversial to consider age as a prognostic factor into the treatment strategy of patients with T1N0M0 breast cancer.

Aim The main purpose of this study was to evaluate the effect of age on recurrence risk in patients diagnosed with T1N0M0 breast cancer as well as compare the prognosis of young aged patients (YA, ≤40 years old) to non-young aged patients (non-YA, >40 years old) by using a propensity score matching (PSM) analysis.

Methods 365 patients with T1N0M0 breast cancer diagnosed between 2003 and 2016 who received surgery in Sun Yat-sen Memorial Hospital Breast Cancer Center were included. The recurrence free survival (RFS) and risk factors for recurrence were identified by using Kaplan-Meier method and Cox proportional hazards models. PSM was then used to reduce the confounding effect of known risk factors on prognosis and then to compare 5-year RFS rates in patients between two age groups.

Results After a median follow up of 79 months, 54 patients developed recurrences and 5-year RFS was 87.6%. YA patients had lower RFS estimates (80.6%), compared to patients diagnosed in a later age (89.1% if older than 40-years old; \(P = 0.049\)). YA patients tended to have Her-2 positive, TNBC tumors, higher rate of Ki-67 expression and nuclear grade tumor. At multivariate analysis, Her-2 positive (HR 2.115; 95% CI 1.103-4.055, \(p=0.024\)) and TNBC (HR 2.963; 95% CI 1.485-5.914, \(p=0.002\)) resulted independent prognostic factors of patient with T1N0M0 breast cancer. In the subgroup analysis, we found significant poor RFS for YA patients with Her-2 positive breast cancer compared to the older counterparts \(p=0.006\) and YA patients were associated with significantly higher rates of the locoregional recurrence rather than metastasis \(p=0.004\), especially in first 5 years after diagnosis. After PSM, the baseline level and treatment status including tumor size, grade, HR status, Her-2 status, Ki67 expression breast surgery type and systemic adjuvant treatment (AST) of patients in the two age groups tended to be equal. As result, we found significant difference in the 5-year RFS between two age groups \(p=0.008\).

Conclusion Based on equal treatment condition, young age at presentation conferred a worse prognosis in patients with T1N0M0 breast cancer is independent on other pathological features.
A biologic signature to predict ipsilateral breast event risk at 10 years for early breast cancer

Troy Bremer1, Jess Savala1, Glen Leesman1, Fredrik Wärnberg2, Malin Sund3, Charlotta Wadsten3 and Pat W Whitworth4.
1PreludeDx, Laguna Hills, CA; 2Uppsala University, Uppsala, Sweden; 3Umeå University, Umeå, Sweden and 4Nashville Breast Center, Nashville, TN.

Background
Outcomes for women with early breast cancer have continually improved. A biologic signature to identify those patients that have elevated ipsilateral breast event (IBE) risk after breast conserving surgery (BCS) treated with or without radiation therapy (RT) is needed. More aggressive systemic or surgical options may be warranted for patients with elevated risk while BCS alone may be an option for very low risk patients. We report early results for a biologic signature interrogating critical pathways.

Material and Methods
This study includes patients from Uppsala University Hospital and Västerås Hospital diagnosed with early breast cancer, 20mm or less, treated surgically between 1987 and 2004. Women with lymph node metastases or treated with mastectomy or chemotherapy were excluded. A panel of biomarkers (HER2, PR, Ki67, COX2, p16/INK4A, FOXA1 and SIAH2) were assayed and scored in PreludeDx's CLIA lab by board-certified pathologists. There were 171 eligible patients with biomarker data; 131 received RT and 9 received hormone therapy.

Risk groups were calculated using biomarkers and clinical factors age and size. Absolute 10-year IBE risk was assessed using Kaplan-Meier survival analysis. Hazard ratios (HR) were determined using Cox proportional hazards analysis.

Results
There were 49 IBEs recorded. The biologic signature classified 41% of women into a low risk group. Patients in the elevated risk group had a significantly increased risk of 10-year IBE compared to those in the low risk group (Table 1). The HR for elevated vs. low risk group was 5.0 [2.2-11], p<0.001, in a multivariate analysis of risk group and RT. Patients in the elevated risk group treated with BCS and RT had an 18% apparent risk difference in 10-year IBE. Patients in the low risk group had similar low 10-year risks of IBE, when treated with BCS, with or without RT. The low risk women had somewhat increased prevalence of low grade tumors (58% vs. 41%). Women with low grade and small tumors (up to 10mm) were classified into both risk groups (54% low vs. 38% elevated risk).

Discussion
A biologic risk signature identified early breast cancer patients with low and elevated 10-year IBE risks for women treated with BCS with or without RT and no chemotherapy. Approximately 40% of women were classified into a low risk group with a 0.5% IBE risk per year. Women in the elevated risk group had 3% to 5% IBE risks per year depending on treatment. Treatment for women in this observational study was neither randomized nor strictly rules based. With further prospective validation, the biologic signature identified herein may provide a tool enabling improved management for women diagnosed with early breast cancer.
Prognostic factors of survival in node positive breast cancer patients after neoadjuvant chemotherapy in a large series after 5y follow-up: Can response overcome the poor prognosis of nodal stage?

Sergi Fernandez1, Amparo Garcia1, Andrea Vethencourt2, Silvia Vazquez2, Anna Petit1, Maria Jesus Pla1, Raul Ortega1, Javier Pérez2, Miguel Gil2, Jordi Ponce1, Sonia Pernas2, Ana Lopez1 and Catalina Falo2. 1Hospital Universitari de Bellvitge, Hospitalet, Barcelona, Spain and 2Institut Català d’Oncologia, Hospitalet, Barcelona, Spain.

Background: Status of the axilla is one of the most significant prognostic factors in breast cancer (BC) patients. On the other hand, response to neoadjuvant chemotherapy (NACT) is related to survival. The aim of the present study is to analyze which prognostic factors impact most on Node positive (N+) BC patient survival after NATC.

Material and methods: Retrospective analyses on a series of N+ BC patients treated with NATC based on anthracyclines and taxanes +/- trastuzumab if HER2 positive tumors, between June 2008 and December 2016. Clinical, radiological and pathological outcomes have been evaluated. Residual cancer burden (RCB) and the neoadjuvant response index (INR) have been recorded. Survival was calculated with Kaplan-Meier survival curve since the start of NATC to the first documented disease recurrence (DFS) or death (OS). Hazard ratios (HRs) with 95% CIs were estimated with cox proportional hazards regression analysis and subgroups were compared with a two-sided log-rank test.

Results: A total of 345 N+ BC patients were included. Pathological complete response was achieved in 72 (20.8%) patients. After NACT, 137 (39.6%) become ypN0, 9 (2.6%) ypN1 mic, 113 (32.7%) ypN1, 60 (17.3%) ypN2 and 26 (7.6%) N3. Those independent predictive factor of ypN0 were molecular subtype (TN and Her2+) with OR: 7.7, p<0.001 and clinical response with OR 6.88, p: 0.04. At a mean follow-up of 58 months there have been 73 (21.1%) recurrences: 9 (2.3%) local, 45 (13%) systemic, 15 (4.3%) systemic+ local, 3 (0.9%) axilla, 1 (0.3%) supraclavicular. The estimated 5y OS was 87.8%.

| Adjusted univariate analysis cox regression of clinical and pathological factors of disease free survival |

| Clinical response              | 2.369          | 1.709-3.284    | <0.001|
| Fibrosis tumor bed             | 0.98           | 0.972-0.989    | <0.001|
| Nodal fibrosis>50%             | 1.795          | 0.874-3.686    | 0.111 |
| Pathological tumoral response  | 1.686          | 1.175-2.418    | 0.005 |
| ypN0                           | 3.56           | 1.853-6.838    | <0.001|
| NRI                            | 0.33           | 0.192-0.565    | <0.001|
| RCB                            | 1.274          | 1.106-1.468    | 0.001 |
In the multivariate model those parameters that were independently prognostic were clinical response HR: 5.44 (IC95% 2.275-13.042, p<0.001) and clinical stage HR: 2.364 (IC95% 1.018-5.490, p: 0.045). **Conclusions:** The most significant prognostic factor in our N+ series was response to NATC, followed by clinical stage. Those independently predictive factors of axillary response (ypN0) were molecular subtype (TN and Her2+) and clinical response. In conclusion, in those patients with chemo sensitive tumors, lymphadenectomy could be safely spared with a more selective axillary approach.
Different predictive and prognostic impact of intra-tumor heterogeneity, tumor biology, and microenvironment in triple negative breast cancer

Naoki Hayashi¹, Mariko Nakamura¹, Daiki Kobayashi¹, Koyu Suzuki¹ and Hideko Yamauchi¹. ¹St. Luke's International Hospital, Tokyo, Japan.

Background
Intra-tumor heterogeneity, tumor biology, and microenvironment in triple negative breast cancer (TNBC) has been reported to be predictive and prognostic factors. However, it is not well known how these factors are correlated each other according to response to chemotherapy and their prognosis. The aim of this study was to assess the predictive and prognostic impact of these factors in TNBC.

Method
Biopsy samples before neoadjuvant chemotherapy (NAC) from 59 TNBC patients who underwent surgery after NAC from 2001 to 2007 were retrospectively assessed. For tumor biology, tumors were classified as Hormonal related luminal androgen receptor (LAR) if >10% staining of AR, Basal-like if positive for cytokeratin 5/6 and EGFR, and Others. Claudin 1 and p16 expression levels were assessed for intra-tumor heterogeneity. and stromal tumor-infiltrating lymphocytes (Str-Tils) levels for tumor-microenvironment were also assessed as low for ≤10%, Intermediate for 10-49%, and high for >50%.The predictive and prognostic impact of clinicopathological factors including age, nuclear grade (NG), lymph node status, were also assessed. Overall survival (OS) and disease-free survival (DFS) were estimated using the Kaplan-Meier method and were compared between groups using the log-rank test.

Results
A median overall survival period of the 59 patients was 98 month(6 -172 month).Eighteen (30.5%) were classified in LAR, 16 (27.1%) in Basal-like, and 25 (42.4%) in Others. According to response to NAC, 10 patients (16.9%) achieved pathologic complete response (pCR). These biological classifications were not associated with pCR rate (p=0.135). high-p16 had significantly high pCR rate (p=0.046).However, Str-Tils level was not associated with pCR rate. Patients with lymph node metastasis had significantly low pCR rate (p=0.017).In terms of their prognosis, age<50 had significantly shorter OS and DFS than that of age>50 (OS: p=0.023, DFS: p=0.027). NG3 had a trend of short OS compared to NG 1 or 2 (NG 1 vs 3, OS: p=0.053, and NG 2 vs 3, OS: p=0.073). There were no difference of their prognosis among three tumor biology classifications except Basal-like had significantly shorter OS than that of LAR (LAR vs Basal OS:p=0.041, DFS:p=0.574, LAR vs Others OS:p=0.407, DFS:p=0.866, Basal vs Others OS:p=0.162, DFS:p=0.713).Claudin 1 and p16 expression levels were not associated with OS and DFS. Low-Str-Tils had a trend of shorter OS and DFS than that of intermediate- or high-Str-Tils (low vs int; OS:p=0.085, DFS:p=0.026, low vs high; OS:p=0.062, DFS:p=0.055).In multivariate analysis, age<50 was only independent prognostic factor (p<0.05).

Conclusion
We showed that intra-tumor heterogeneity, tumor biology, and microenvironment had different predictive and prognostic impact in TNBC. These results might suggest the strategy of additional targeting treatment to non-pCR patients.
FOXA1, Nestin, GATA3 and mammaglobin expression in 164 breast cancer metastases – A retrospective immuno-histochemical study of a 10-year period (2004-2014)

Jenny Nyqvist1, Shahin de Lara2, Toshima Z Parris4, Khalil Helou4, Elisabeth Kenne Sarenmalm5, Zakaria Einbeigi3, Per Karlsson3 and Anikó Kovács2. 1Department of Surgery, Lidköping, Sweden; 2Department of Pathology, Gothenburg, Sweden; 3Department of Oncology, Gothenburg, Sweden; 4Sahlgrenska Center of Cancer Research, Gothenburg, Sweden and 5Center of Research and Education, Skaraborgs Hospital, Skövde, Sweden.

Background. Including additional genes in standard immunohistochemical panels might be helpful in determining the prognosis of breast cancer patients. Previous studies have shown that FOXA1 is a significant predictor of good outcome in breast cancer, while Nestin expression was preferentially found in triple-negative breast cancers, revealing a strong association with germline BRCA1-related breast cancer, a basal-like phenotype, stemness characteristics, high proliferation rates, p53 nuclear expression, increased rate of nodal metastases, and reduced survival (1,2,3,4). GATA3 was not only an important luminal marker, but a reliable immunohistochemical marker, which plays a crucial diagnostic role in verification of breast cancer metastases (Figure 1 and Figure 2). In a cohort containing 164 breast cancer metastases, we found GATA3 to be a reliable and sensitive diagnostic marker. We verified that the metastases originate from breast carcinoma with 95% GATA3-positivity, while mammaglobin showed only 51.2% positivity (5). According to the mammaglobin immunohistochemical profile, we evaluated the expression of FOXA1, Nestin and GATA3 in mammaglobin-positive (n=84) and mammaglobin-negative (n=80) samples.

Materials and method. Full-face formalin-fixed paraffin-embedded (FFPE) specimens for 164 breast cancer metastases (from various anatomical sites) diagnosed between 2004 and 2014 were obtained from the Department of Clinical Pathology and Genetics at Sahlgrenska University Hospital (Gothenburg, Sweden). Each FFPE specimen was examined for mammaglobin, ER/PR, CK7, CK20, and HercepTest at the time of diagnosis and retrospectively analyzed for FOXA1, Nestin and GATA3 expression by immunohistochemistry (IHC). The statistical analyses were performed using a .05 P-value cutoff in R/Bioconductor (version 2.15.0) and all P-values are two-sided. The relationship between clinicopathological features and mammaglobin/GATA3 protein expression patterns was evaluated using two-tailed Fisher's exact test. Results. In mammaglobin-positive metastases, FOXA1-positivity was associated with ER+ (83%) and negatively associated with triple-negativity (81%; Figure 3). Moreover, there was no association between Nestin-positivity and the established clinicopathological features in mammaglobin-positive samples (Table 1 and Figure 4). In mammaglobin-negative samples, FOXA1-positivity was associated with GATA3+ (100%), ER+ (77%), HER2+ (36%), and triple-negative status (82% were non-triple negative). In addition, Nestin-positivity was associated with specific metastatic sites (mostly brain, but even gynecological sites and skin), GATA3- (29%), ER- (50%), PR- (79%), and triple-negative status (50% were triple negative) in mammaglobin-negative samples (Table 2).

Conclusion. In the present study, we found that FOXA1 was expressed mostly in ER-positive breast cancer metastases and Nestin expression was associated with breast cancer metastases with a triple-negative immune profile, where the brain was the most frequent metastatic site.
Predicting survival of triple negative breast cancer using artificial neural networks

Mohamed H Osman¹. ¹Faculty of Medicine, Zagazig University, Zagazig, Egypt.

Background:
Breast cancer is a major health problem with 1.7 million estimated new cases and nearly 459,000 deaths every year worldwide. Triple Negative Breast Cancer (TNBC) is a subtype of breast cancer based on immunohistochemistry in which estrogen receptor (ER), progesterone receptor (PR) and human epidermal growth factor receptor 2 (HER2) are negative. Among all the breast cancer subtypes, TNBC is associated with a worse prognosis. TNBC is highly aggressive cancer with unique molecular profile, aggressive nature, distinct metastatic patterns and lack of targeted therapies. Due to these heterogeneous characteristics, predicting TNBC survival is challenging. Reliable predictions can help in achieving more personalized care and better management. Here, we test the ability of artificial neural networks to predict TNBC survival.

Methods:
Female patients with TNBC were identified through the Surveillance, Epidemiology and End Results database (SEER). Clinical data of the patients were extracted including: age, race, ethnicity, tumor site, tumor histology, grade, tumor size, tumor extension, lymph nodes involvement, metastasis at diagnosis, site of metastasis, laterality, cancer sequence number, TNM stage, surgery, radiotherapy, chemotherapy, radiation sequence with surgery, state, county, survival months. Patients’ records were randomly divided into a training set (80%) and a validation set (20%). Artificial neural networks were used to predict patients’ survival.

Results:
A total number of 9,880 patients were identified through SEER from 2010 – 2011 with median age of 57 years and a median survival of 54 months. Patients with negative ER, PR and HER2 were selected. The parameters of artificial neural networks were tuned to achieve better results. For evaluating model performance, the Area under the Receiver Operating Characteristic Curve (AUC), precision, accuracy and sensitivity were calculated. Artificial neural networks yielded AUCs of 87.6% at 6 months, 80.8% at 12 months, 79.8% at 24 months and 77.7% at 24 months. The trained model achieved an average accuracy on the validation dataset of 94.8%, 91.8%, 85.3% and 80.1% at 6, 12, 24 and 36 months, respectively. Sensitivity of prediction of patients with survival months less than 6, 12, 24 and 36 ranged from 41% to 56%. However, sensitivity for patients with survival months less than 6, 12, 24 and 36 ranged from 88% to 96%.

Conclusion:
Artificial neural networks achieved a good performance in predicting survival of patients with TNBC based on clinical data. High performance of prediction is essential especially for cancers with bad prognosis like TNBC because it can help in in making better treatment decisions and planning social and care needs.
The relationship between serum level of copper and ceruloplasmin and pathologic and clinical characteristics in early breast cancer patients

Jing Fan¹, Yi Wan², Ge Zhao¹ and Ting Wang¹. ¹Xijing Hospital, Fourth Military Medical University, Xi’an, Shaanxi, China and ²Fourth Military Medical University, Xi’an, Shaanxi, China.

Purpose: The increase of serum copper and ceruloplasmin has been reported to positively related with the progress of advanced breast cancers. However, the role of them in early breast cancer (EBC) is unknown.

Methods: 209 female patients that been diagnosed as EBC within Xijing Hospital from Oct 2016 to Apr 2017 were included. The level of serum copper and ceruloplasmin were assayed using atomic absorption spectroscopy and immunoturbidimetry assay, respectively. The pathologic and clinical characteristics were analyzed by X test, t test and Pearson correlation analysis. \( p<0.05 \) is significant.

Results: Table 1 show the primary characteristic of patients. After transforming copper and ceruloplasmin into binary variable (elevated and normal), age was both significant \( (p<0.01) \). The different expression level of ER, PR, Ki67 and molecular type, number and percent of metastatic lymph nodes were significant \( (p<0.01) \). After correlation analysis, negative relationship existed between age and copper or ceruloplasmin (coefficient = 0.265 or 0.233, \( p<0.01 \)). And copper was positively related to the level of Ki67(coefficient = 0.169, \( p=0.018 \)). While ceruloplasmin was negatively related to PR (coefficient = -0.273, \( p<0.01 \)) and molecular type (coefficient = -0.217, \( p=0.05 \)).

Conclusions: This is the first study that revealed the abnormal escalation of serum copper and ceruloplasmin in Chinese EBC patients. The levels of both them were significantly higher in patients of young age, high Ki67 index and Luminal type. It is inferred that they might play an important role in early procedure of breast cancer, and it need more data in the future to validate.

Patterns and predictors of early failure in women with triple negative breast cancer

Elizabeth M Nichols, Hua-Ren Cherng, Stephanie R Rice, Muhammad Hamza, Shruti Murali, Katherine Tkaczuk, Emily Bellavance, Sally B Cheston, Neha Amin and Paula Rosenblatt. 1University of Maryland School of Medicine, Baltimore, MD.

Introduction: Triple negative breast cancer accounts for approximately 15% of breast cancer in the United States, but behaves much more aggressively. It occurs more commonly in younger, black female patients and death within two years of diagnosis is much more common in this subset of breast cancer compared to hormone receptor positive patients. We see a high proportion of triple negative breast cancer patients in our urban academic comprehensive cancer center and present an evaluation of our patients who develop failures within 12 months of completion of definitive therapy in an effort to optimize screening strategies and therapy for women with triple negative breast cancer treated at our institution.

Materials/Methods: A retrospective database of 198 women with triple negative breast cancer treated at our institution from 2005-2017 was constructed. Patient characteristics are as follows: 100% female, median age of 54 years, 64% black, 40% married, 93% infiltrating ductal carcinoma, 68% grade 3, 18% with lymphovascular space invasion, 7% BRCA mutated, and 3% HIV positive. Stage breakdown is as follows: Stage I (33%), Stage II (47%), Stage III (16%) and Stage IV (4%). Thirty percent of patients had neoadjuvant chemotherapy. Adjuvant chemotherapy was given in 67% of patients. Ninety-eight percent of patients underwent surgical resection, 55% of whom underwent lumpectomy with 61% having sentinel lymph node biopsy. Adjuvant radiation was received in 56% of patients with a median dose of 60 Gy. Chi-square testing was used to compare variables, while logistic regression with Kaplan-Meier estimate was used to calculate overall survival (OS) and freedom from recurrence (FFR).

Results: With a median follow up of 45 months, 33 (17%) documented failures occurred. 63% of patients in this cohort were AJCC 7th edition stages II or III. In the women who suffered failures, these occurred at a median of 16 months after initiation of therapy, with a median OS of 29 months. Complete records including the date of last radiation therapy (signaling completion of definitive treatment) were available for 25 (76%) of patients. 10/25 failures (40%) occurred within 6 months of completion of radiation therapy while 14/25 (56%) occurred within 12 months of completion of radiation therapy. In women who failed within 6 months of completion of definitive therapy, site of first failure was local in 4 and distant in 6 patients. In the four additional patients who failed between 6 and 12 months following completion of definitive RT, all were considered local or locoregional. Univariate and multivariate analyses were performed which in this small group of women did not show any statistically significant predictors of early failure.

Conclusion: This institutional analysis shows that a large proportion of women with TNBC fail within 12 months of completion of definitive therapy with 57% of failures occurring locoregionally and the remainder occurring distantly. This data suggests that consideration of systemic imaging should occur to better detect these failures and additional study is warranted to determine if predictive factors can be identified for therapy escalation.
A single-center real-world observational study to explore clinical treatments and prognoses of the Chinese patients with breast cancer complicated with brain metastases

Quchang Ouyang¹, Yu Tang¹, Zheyu Hu¹, Can Tian², Ning Xie², Liping Liu¹, Huawu Xiao¹, Jing Li¹, Hui Wu¹, Xiaohong Yang¹ and Celine Yang³. ¹Hunan Cancer Hospital, Changsha, China; ²Hunan Cancer Hospital, Chasha, China and ³Linkdoc (Beijing) Technology Co. Ltd, Beijing, China.

Introduction: The incidence of brain metastasis complicated with breast cancer (BCBM) is approximately 10-15%. Given that the survival status of the BC patients is not optimistic, the choice of clinical treatments should be based on individualized clinical characteristics of the BC patients. Thus understanding of the patient clinical characteristics is critical for patient management and forecasting the prognoses of the patients.

Methods: The trial was designed as a real-world observational study. The BCBM patients who were enrolled in the clinics from 2012 to 2017 were recruited and the study data on the patient demographic, tumor biological characteristics, and clinical treatments were retrospectively collected for evaluating overall survival (OS), and the OS impact factors. The Kaplan-Meier and Log-rank tests were performed to assess patient survivals. The Cox regression analyses were applied to explore the OS impact factors. All the statistical significance was set as \( \alpha = 0.05 \) except as other specified.

Results: A total of 117 female BCBM patients (mean age: 48.28±9.49 years) were enrolled in this study including 32 patients (27.4%) with extracranial metastases and 85 patients (72.6%) without extracranial metastases. Of all the subjects, by classification of the molecular types, 13.3% of the patients were diagnosed with luminal A tumor and 45.8% were observed with luminal B tumor. The patients with HER2 positive accounted for 19.3% of all the subjects and 21.7% of the subjects were triple-negative BC patients. In the clinical treatments, 65.8% of the patients were administered with chemotherapies, 14.5% with target therapies, and 11.1% with radiotherapies.

The median of the OS duration was approximately 38.57 months. The OS rates were decreased along with the observation period: The 18-month OS rate was 73.6% (95% confidential interval, CI 0.558, 0.852) and the 48-month OS rate was 24.9% (95% CI 0.045, 0.537), respectively. In the patients with >3 metastatic brain tumors, the median of the OS duration was 20.27 months and the median of the OS duration was 38.57 months in the patients with ≤3 metastatic brain tumors. The OS durations in the patients with ≤3 metastatic brain tumors were longer than the durations in the patients with >3 metastatic brain tumors from 12 month- to 36 month- observation period. In the patients with Ki-67\( \leq 14\)%, the OS durations were longer than the durations of the patients with Ki-67\( >14\)%. In the 18 month-observation period, the OS duration was longer in the patients with HER2 positive as compared with that of the patients with HER2 negative. In the univariate and multivariate analyses, those patients with chemotherapies were significantly associated with longer OS durations \( (p<0.05) \). The multivariate analyses showed that the menopausal patients were related to shorter OS durations \( (p<0.05) \).

Conclusions: The real-world study offered the clinical evidences on the clinical characteristics of the BCBM patients, patient management, and patient survivals. The patient survivals improved significantly after clinical treatments with BCBM. The tumor biological characteristics and chemotherapies were predictive for the status of patient survivals.
Outcomes among metastatic breast cancer patients with characteristics that confer a less favorable prognosis

Kim Saverno1, Gebra Cuyun Carter1, Robert Dufour2, Gregory Price1, Li Li1, Angelo DeLuca3, Emily Nash Smyth1, Linda Battiato1, Jonathon Gable1, Mark S Walker2, Yu-Jing Huang1, Scott Hannas1 and Lee S Schwartzberg3. 1Eli Lilly and Company, Indianapolis, IN; 2Vector Oncology, Memphis, TN and 3West Cancer Center, Germantown, TN.

Background: Recent advances in the treatment of hormone receptor positive (HR+), human epidermal growth factor receptor 2-negative (HER2-) metastatic breast cancer (MBC) have contributed to increased overall survival (OS). Despite advances, MBC remains incurable and there is a subset of patients with clinical features that are associated with poorer prognosis. This study described the patient characteristics, treatment patterns, and outcomes of a cohort of US patients with HR+, HER2- MBC as a function of various factors associated with poor prognosis, including presence (vs. absence) of liver metastases (LM).

Methods: This retrospective study used US community oncology electronic health record data from the Vector Oncology Data Warehouse. Eligible women who received systemic treatment for MBC, had a diagnosis of MBC in 2008 or later, and had completed at least three Patient Care Monitor (PCM) surveys, (a patient-reported outcomes survey collected as a part of clinical care), were included. OS was measured from the start of the first three regimen-based lines (1L, 2L and 3L) of treatment; patients without evidence of death were censored at the last observed visit. The statistical significance of differences in categorical and continuous variables between LM positive (LM+) and LM negative (LM-) were evaluated with chi-square ($\chi^2$) tests, and t-tests, respectively. Kaplan-Meier and Cox analyses were applied to evaluate differences in OS by LM status and by line of therapy at the start of MBC treatment (unadjusted for treatment).

Results: A total of 378 women, 98.4% residing in the South and 40.5% African-American, were included; 295 (78.0%) were LM- at the time of diagnosis. Following 1L, approximately 82.8% and 60.8% of patients received 2L and 3L, respectively. Patients with a LM+ status had a lower mean age (mean: 57.2, SD: 13.8 vs. 61.2, 13.1; p=0.016) and a higher percentage had a grade 3 tumor (36.1 vs. 24.7%; p=0.039) compared to patients with LM-status. Table 1 shows the OS results for 1L-3L. For all 3 lines, median OS for LM+ was shorter than the LM- median OS. LM+ patients had a poorer prognosis as they were more likely to have an OS event across 1L-3L compared to LM- patients.

Conclusions: Among this community oncology cohort, median OS in 1L was 14 months shorter in LM+ patients compared to LM- patients. It is important to note that the sample size and selection criteria may limit generalizability of these results. Despite progress in treating women with MBC, treatment options are lacking for patients with less favorable prognosis, including those with LM. Other potential indicators of poor prognosis, such as high tumor grade, are being explored.

Subgroups analysis of a multicenter, prospective, randomized, blinded phase 2b trial of trastuzumab + nelipeptimut-S (NeuVax) vs trastuzumab for prevention of recurrence in breast cancer patients

Guy T Clifton¹, Phillip M Kemp Bohan¹, Diane F Hale¹, John W Myers¹, Tommy A Brown¹, Jarrod P Holmes², Timothy J Vreeland³, Jennifer K Litton⁴, Rashmi K Murthy⁵, Elizabeth A Mittendorf⁶ and George E Peoples⁷. ¹Brooke Army Medical Center, Fort Sam Houston, TX; ²St. Joseph Hospital, Santa Rosa, CA; ³MD Anderson Cancer Center, Houston, TX; ⁴Brigham and Women’s Hospital, Boston, MA and ⁵Uniformed Services University of the Health Sciences, Bethesda, MD.

Background: HER2 low-expressing (LE) (IHC 1-2+, FISH non-amplified) breast cancer (BC) patients (pts) have not benefited from HER2-directed therapy despite HER2 antigen availability. Triple negative BC (TNBC), in particular, is immunogenic and in need of additional therapeutic options. We have previously shown the HER2-derived nelipeptimut-S (E75) + GM-CSF (NeuVax) to be synergistic with trastuzumab (Tz) in pre-clinical and pilot clinical studies. In a planned interim analysis of a multi-center, prospective, randomized, single-blinded, placebo-controlled phase 2b trial of Tz + NeuVax vs Tz to reduce recurrence in HER2 LE, node-positive (NP) and/or triple negative BC (TNBC) pts, we previously reported that the NeuVax + Tz was safe without added cardiac toxicity and demonstrated a significant reduction of recurrences in TNBC pts. This analysis examines additional subsets in this trial.

Methods: HER2 LE, NP and/or TNBC pts who were clinically disease-free after standard therapy were randomized to receive Tz+NeuVax (vaccine group; VG) or Tz+GM-CSF (control group; CG). All pts received 1 yr of Tz per label. NeuVax or GM-CSF was given every 3 weeks x 6 starting with the 3rd Tz dose, and then boosted every 6 months x 4. This pre-specified interim analysis was triggered 6 months after last enrollment. The primary endpoint is intention-to-treat 24 month disease-free survival (DFS) evaluated by log rank.

Results: Of 275 pts randomized in the study (VG n=136, CG n=139), 98 had TNBC (VG=53, CG=45). In the interim analysis, estimated disease-free survival (DFS) was assessed with a median follow up of 18.8 months. No significant clinicopathologic differences were seen between treatment groups. In the TNBC group, estimated DFS was higher overall in VG vs CG (91.9% vs 69.9%, p=0.023; hazard ratio [HR] 0.29, 95% confidence interval [CI] 0.09-0.90). On TNBC subgroup analysis, estimated DFS was higher in VG among pts who received neoadjuvant chemotherapy (VG n=35, CG n=31; HR 0.26, CI 0.07-0.93; p=0.03), HER2 IHC 1+ BC (VG n=34, CG n=28; HR 0.20, CI 0.04-0.96; p=0.03), pts who were AJCC 7th edition stage I/II (VG n=37, CG n=27; HR incalculable, no recurrences in the VG, p=0.008), and pts ≥51yr of age (VG n=32 & CG n = 26; HR 0.26 CI 0.07,0.94; p=0.009). HRs did not appreciably vary based on the histologic grade or presence of lymphovascular invasion.

Conclusion: Examining the subgroups from the pre-specified interim analysis demonstrates a highly significant clinical benefit in TNBC pts overall. Within the TNBC cohort, specific benefit was seen in pts who received chemotherapy neoadjuvantly, expressed lower HER2, were earlier stage, and were older in age. These factors may help enrich the TNBC population targeted in a definitive Phase 3 study in TNBC patients with residual disease after neoadjuvant chemotherapy.
Background. Ductal carcinoma in situ (DCIS) is a risk factor for the subsequent development of invasive breast cancer. Features of DCIS that are associated with a high risk of a subsequent event include large size (> 5 cm), high grade, comedo necrosis, palpable mass, hormone receptor negativity, and HER2 positivity. We have previously shown that immune infiltrates are positively associated with these high-risk features, suggesting that manipulating the immune microenvironment in high-risk DCIS, for example via checkpoint blockade, could potentially alter disease progression.

Methods. In this phase 1 pilot study we investigated changes in the immune microenvironment of high risk DCIS after intralesional injection of anti-PD-1 (pembrolizumab). Study participants received 2 intralesional injections of pembrolizumab, 3 weeks apart, with surgery approximately 3 weeks after the 2nd dose. The study started with a dose of 2 mg/injection (1/100 of the standard 200 mg iv dose), then escalated to 4 mg and 8 mg, with 3 patients at each dose. Tissue samples from pre-treatment biopsies and post-treatment surgical resections were stained with two 6-plex immune panels using Opal immunofluorescence reagents (Perkin Elmer) on a fully automated Ventana Discovery platform, imaged with a Vectra 3 system and analyzed with inForm software (Perkin Elmer). An algorithm for tumor/stroma segmentation developed in inForm was used to randomly select 10 high power fields (hpfs) for imaging. Cell phenotype maps were generated for each of these hpfs for each sample. Cell densities were determined per area of stroma, DCIS, or total tissue and averaged across all hpfs for a given case. Spatial analyses were performed to quantitate co-localization of immune cells with DCIS cells.

Results. The intralesional injections were easily administered and well tolerated. No systemic toxicities were observed at any dose. MRI imaging demonstrated no change in the size of lesions after treatment. Multiplex immunofluorescence analyses demonstrated heterogeneous responses ranging from dramatic increases in T cells, in particular CD8+ T cells, in cases which had a T cell infiltrate prior to therapy, to no post-therapy T cell infiltrate in cases with a pre-therapy immune desert. We also observed increases in B cells and macrophages and a decrease in the ratio of FoxP3+ T cells to CD8+ T cells, the latter mainly due to a significant increase in CD8+ cells, as opposed to a decrease in FoxP3+ cells. Spatial analyses indicated that in some cases, despite a marked increase in T cells post therapy, these cells did not co-localize with DCIS cells, indicating a state of immune exclusion.

Conclusions. We have demonstrated the safety and feasibility of intralesional injection of an immune checkpoint inhibitor (pembrolizumab) in high risk DCIS. In some patients we observed a dramatic change in the immune microenvironment, with an increase in T cells, B cells, and macrophages, and a decrease in the FoxP3:CD8 ratio, even at a dose that is 1/100 of the standard intravenous clinical dose. An expansion study is underway in which patients will receive 4 injections of pembrolizumab at 3 week intervals prior to going to surgery to determine if more injections/time will increase response rate.
Updated efficacy of first or second-line pembrolizumab (pembro) plus capecitabine (cape) in metastatic triple negative breast cancer (mTNBC) and correlations with baseline lymphocyte and naïve CD4+ T-cell count

David B Page¹, Joanna Pucilowska¹, Laura Bennetts¹, Isaac Kim¹, Katherine Sanchez¹, Maritza Martel¹, Alison Conlin¹, Nicole Moxon¹, Staci Mellinger¹, Anupama Acheson¹, Kathleen Kemmer², Zahi Mitri², Jacqueline Vuky², Jenny Ahn³, Christina Abaya³, Tierra Manigault³, Reva Basho³, Walter J Urba¹ and Heather L McArthur³. ¹Earle A. Chiles Research Institute, Portland, OR; ²OHSU Knight Cancer Institute, Portland, OR and ³Cedars-Sinai Medical Center, Los Angeles, CA.

Background: In mTNBC, anti-PD-1/L1 monotherapy is most effective when administered early in the course of disease, with recent trials demonstrating overall response rates (ORR) of 23-26% in the first-line setting and 5-6% in later lines. This may reflect iatrogenic lymphopenia from preceding cytotoxic chemotherapy. Furthermore, curative-intent chemotherapy is associated with prolonged suppression of naïve CD4+ cells, a T-cell subset that may play a critical role in the generation of de novo anti-tumor immune responses. We present the final clinical results of a pilot study evaluating the safety and efficacy of combining pembrolizumab plus standard-of-care capecitabine in the first/second-line mTNBC setting. We also explore potential associations between clinical benefit and lymphopenia, preceding chemotherapy, and absolute naïve CD4+ counts.

Methods: In a pilot study, we evaluated the tolerability and preliminary efficacy of concurrent pembro (200mg IV q21 day) plus investigator-selected 1st/2nd line paclitaxel (80mg/m² IV weekly) or oral cape (2,000mg BID, weekly 1 on/1 off). The primary endpoint was tolerability, defined as the proportion of subjects receiving >6 weeks concurrent therapy without dose discontinuation with toxicities reported per CTCAE v4.0. The secondary endpoint was 12-week objective response rate (ORR) by RECIST1.1. Exploratory endpoints included peripheral blood cell enumeration by real-time flow cytometry and routine clinical laboratory. Naïve CD4+ cells were defined as CD45+ CD3+ TCRab+ CD4+ CD45RA+ CCR7+. Here, we report the results of the pilot phase of the cape cohort (NCT02734290).

Results: Twelve of 14 subjects were treated in the first-line setting. All subjects (14/14, 100%) tolerated cape+pembro for >6 weeks, with toxicities consistent with monotherapy cape experience (diarrhea: grade I-II 50%, grade III 7%; hand-foot: grade I-II 71%) that improved with dose-reduction as needed. At 12 weeks, the ORR was 6/14 (42.9%), and the clinical benefit rate (ORR + stable disease) was 8/14 (57.1%). Depressed absolute lymphocyte count at baseline (ALC<1.0/uL: 33% CBR; ALC ≥1.0/uL: 75% CBR) and recent exposure to cytotoxic chemotherapy (<6 months: 33% CBR; >6 months: 75% CBR) were associated with reduced clinical benefit. By flow cytometry, subjects experiencing clinical benefit had higher baseline absolute naïve CD4+ counts (average 283 cells/uL v. 93 cells/uL, p=.069).

Conclusions: This study met the primary endpoint of safety for cape plus pembro in mTNBC, with encouraging clinical activity. These data are supportive of further studies evaluating combination chemotherapy plus anti-PD-1/L1 mTNBC. We observed greater clinical benefit in subjects with non-suppressed ALC, less exposure to recent chemo, and higher baseline naïve CD4+ counts, suggesting that iatrogenic immunosuppression can impair response to immune checkpoint therapy in mTNBC. These findings should be confirmed in ongoing randomized trials of immune checkpoint +/- chemotherapy in mTNBC, and should be considered in the design of future clinical trials.
Identification of a neoantigen targeted by tumor-infiltrating lymphocytes in a patient with Her2+ breast cancer

Hannah Reimann¹, Andrew Nguyen², Hanna Hübner³, Ramona Erber⁴, Judith Bausenwein¹, Edith D Van der Meijden¹, Michael P Lux³, Sebastian Jud⁵, Marieke Griffioen⁶, Claudia Rauh³, John Z Sanborn², Stephen C Benz², Shahrooz Rabizadeh⁵, Matthias W Beckmann³, Andreas Mackensen¹, Matthias Rübner³, Peter A Fasching⁵ and Anita N Kremer¹. ¹University Hospital Erlangen, Friedrich-Alexander-University Erlangen-Nuremberg (FAU), Erlangen, Germany; ²NantOmics, LLC, Santa Cruz, CA; ³University Hospital Erlangen, Comprehensive Cancer Center Erlangen-EMN, Friedrich-Alexander-University Erlangen-Nuremberg (FAU), Erlangen, Germany; ⁴Institute of Pathology, University Hospital Erlangen, Friedrich-Alexander-University Erlangen-Nuremberg (FAU), Erlangen, Germany; ⁵NantOmics, LLC, Culver City, CA and ⁶Leiden University Medical Center, Leiden, The Netherlands.

Background: Recent studies have demonstrated that the number of tumor infiltrating lymphocytes (TILs) positively correlates with outcome and response to chemotherapy in patients with HER2+ and Triple-Negative Breast Cancer (TNBC). Furthermore, first studies of immune-checkpoint inhibitors showed promising results in those patients. However, the targets of those TILs remain unknown. Neoantigens, which arise in the process of tumorigenesis, appear as potential targets. They can elicit high avidity, tumor-specific T-cell responses. Thus, it is the aim of our study to ascertain if these TILs are directed against tumor-specific mutations.

Methods: TILs from breast cancer biopsies taken at the time point of diagnosis were expanded by unspecific stimulation. Additionally, we used the Gentle Macs Dissociator in combination with flow cytometry to investigate the number of TILs in the tumor tissue. Furthermore, we performed whole-genome sequencing of tumor tissue and as reference autologous blood cells to determine tumor-specific mutations. Mutations leading to a non-synonymous amino acid change were analyzed for RNA expression of the encoding gene as well as to determine potential neoantigens. Neoantigens were evaluated for their potential binding to the patient’s specific HLA molecules. Peptides for potential neoantigens were synthesized, loaded onto autologous antigen presenting cells (APCs) and cocultured with TILs. All IFNγ producing T-cells were clonally expanded and retested for peptide specificity to identify neoantigen specific T-cell clones.

Results: Our flow cytometric analysis of the tumor biopsy for more than 300 patients showed higher frequencies of TILs in TNBC as compared to other types of breast cancer or patients without malignancy. Screening for neoantigen specific T-cells in one patient led to identification of three peptide-specific CD4+ T-cell clones isolated from HER2+ breast cancer tissue taken at the time point of diagnosis. All T-cell clones specifically recognized the same tumor-specific mutation and not the wildtype counterpart. Furthermore, we demonstrated that these T-cell clones also recognized the endogenously expressed mutated antigen. This verified the ability of processing and presentation of the respective protein. Interestingly, we could also isolate a T-cell clone recognizing the same neoantigen in the resected tumor tissue after neoadjuvant therapy. Based on CDR3 sequencing we could prove that the four T-cell clones represented individual clones. This confirms the polyclonal nature of the immune response. Moreover, we showed that the same neoepitope was presented in two different HLA restriction molecules of the patient with three of the clones recognizing it in HLA-DPB1*0401 and one in HLA-DPB1*0201. These results further underline the immunogenicity of this neoantigen.

Conclusion: In conclusion, our data demonstrate tumor-specificity of TILs in a patient with HER2+ breast cancer. Furthermore, we show the feasibility to identify individual cancer specific T-cell targets in breast cancer patients. These results may contribute to the development of targeted patient-specific immunotherapies in the future.
LCCC 1525: A phase II study of a priming dose of cyclophosphamide prior to pembrolizumab to treat metastatic triple negative breast cancer (mTNBC)

Carey K Anders¹, Dominic Moore¹, Maria Sambade¹, Luz Cuaboy¹, Amy Garrett¹, Mark Woodcock¹, Karen McKinnon¹, Kristen Owens¹, Dante Bortone¹, Benjamin Calhoun¹, Lisa Carey¹, Claire Dees¹, Trevor Jolly¹, Hyman Muss¹, Katherine Reeder-Hayes¹, Rebecca Kaltman², Rachel Jankowitz³, Vinay Gudena⁴, Oludamilola Olajide⁵, Charles Perou¹, Benjamin Vincent¹ and Jonathan Serody¹. ¹The University of North Carolina at Chapel Hill, Chapel Hill, NC; ²George Washington University Cancer Center, Washington, DC; ³University of Pittsburgh Cancer Center, Pittsburgh, PA; ⁴Cone Health Cancer Center, Greensboro, NC and ⁵Rex Hematology/Oncology Associates (Rex Hospitals), Raleigh, NC.

Background: While immunotherapy holds promise in the treatment of mTNBC, response rates (RR) in unselected patients (pts) are approximately 20%. Strategies to augment response to immunotherapy include depletion of regulatory T cells (Tregs). A single dose of cyclophosphamide (Cy) given prior to checkpoint inhibition achieved this goal in preclinical models of TNBC (Taylor et al., JCI, 2017). Thus, we designed a phase II study to evaluate this strategy in the clinical setting of mTNBC.

Patients/Methods: In cycle 1 (C1), eligible pts with mTNBC received a single dose of Cy 300mg/m2 IV on day 1 (C1D1) followed by pembrolizumab 200mg IV on day 2 (C1D2), then every 3 weeks thereafter. The co-primary objectives were (1) progression free survival (PFS, null 1.9 mos vs. 2.9 mos, 80% power, alpha 0.05) and (2) reduction in Tregs in peripheral blood measured by flow cytometry. Secondary endpoints were response rate (RR), survival (OS), and RNA-based correlative endpoints.

Results: 40 patients were evaluable for efficacy: mean age 54.5 yrs (33 – 82 yrs), 75% white, 22% black, 3% American Indian. All patients had received 1 prior line of chemotherapy in the metastatic setting; 29% received 5 or more prior lines. The most common grade 3 adverse events (AE's), all 5%, were neutropenia, anemia, elevated AST, and fatigue. Immune-related grade 3 AE's, all 3%, included colitis, dry mouth, pneumonitis. Overall RR was 21% (0 CR, 8 PR), 3 pts had stable disease. Median PFS was 1.8 months (mos) (95% CI 1.4–2.5) and OS was 6.3 mos (95% CI 2.8–8.4). There was a non-significant decrease in Tregs from C1D1 to C1D2 (-3.3%, p=0.19); but from C1D2 to C2D1, Tregs increased 21.7% (p=0.005). There was no association between changes in Tregs or number of prior lines of therapy with RR (p>0.09), while immune-related AE's were associated with response (p=0.02). Correlatives studies illustrate B cell immune gene signature expression and B cell receptor repertoire diversity were enriched in responders, while genes/pathways associated with neutrophils, anti-apoptosis, PI3K/AKT and down-regulation of MHC class 1 were associated with non-response.

Conclusions: While pembrolizumab plus Cy was well-tolerated among pts with mTNBC, efficacy was similar to historical control, likely due to minimal effect of Cy on Tregs. Correlative analyses illustrate that study of adaptive immune features, including B cell biology, is a promising strategy for understanding response to PD-1 inhibition in breast cancer. Further strategies to deplete Tregs in a more sustained manner are worthy of future exploration (NCT02768701).
Safety and efficacy of stereotactic body radiotherapy and Pembrolizumab in advanced breast cancer patients with 1 to 5 metastases

Steven P David¹, Peter Savas¹, Paul J Neeson¹, Stephen J Luen¹, Farshad Foroudi², Shankar Siva¹ and Sherene Loi¹. ¹Peter MacCallum Cancer Centre, Melbourne, Victoria, Australia and ²Olivia Newton John Cancer Centre, Melbourne, Victoria, Australia.

Background
Pre-clinical studies have demonstrated that stereotactic body radiotherapy (SBRT) induces immunogenic cell death and tumor antigen release promoting anti-tumor immunity. We hypothesized that the efficacy of SBRT could be improved with the addition of PD-1 blockade in advanced breast cancer (BC) patients with oligometastatic disease.

Methods
Advanced BC patients with 1 – 5 metastatic sites of disease received SBRT at a dose of 20Gy in 1 fraction to at least 1 metastasis followed by pembrolizumab 200mg IV (within 5 days of SBRT), once every 3 weeks for a total of 8 cycles. The primary endpoint was safety of the combination. The secondary endpoints were response using RECIST 1.1 and PERCIST 1.0 using 18F-Flurodeoxyglucose (FDG)- positron emission tomography (PET) scans as well as local progression-free survival and distant progression-free survival (d-PFS). Correlatives included deep sequencing of the T cell receptor (TCR) CDR3 regions of archival metastatic tumor material and in peripheral blood as well as evaluation of systemic markers of immune activation.

Results
15 patients were enrolled between March 2016 and Nov 2017. The number of patients with 1, 2, 4 and 5 metastases treated with SBRT was 9 (60%), 3 (20%), 2 (13%) and 1 (7%), respectively. There were 3 (20%) TNBC, 2 (13%) HER2+ and 10 (67%) ER+/HER2- (Luminal) BC patients. Five (33%) patients experienced Grade 3 or higher Aes. Immune related Aes were reported in 10 (67%) patients, the most common being rash (n=4), thyroid (n=3) and pneumonitis (n=3) with pembrolizumab delayed in 3 (20%) patients and discontinued in 2 (13%) patients. Nine (60%) patients had a complete response or partial response according to RECIST 1.1 criteria and 13 (86%) patients had a complete metabolic response (CMR) or partial metabolic response (PMR) according to PERCIST 1.0 at the 3-month FDG-PET scan. At time of reporting (median follow-up 15 months; range 9-26 months) no deaths or local progression have been observed. Five patients (33%) progressed distantly at 3, 8, 8, 12 and 18 months: 2 of 3 (66%) TNBC, 2 of 10 (20%) Luminal and 1 of 2 (50%) HER2+. Estimated dPFS at 9 months was 80% (95% CI [62% – 100%]). Three patients have reached the 2-year mark without progression (all Luminal). In a patient who remained progression free at 24 months, TCR profiling showed that TCR sequences in a pre-treatment metastatic tumor biopsy were found in peripheral blood and became elevated after combination treatment, along with the emergence of new TCR sequences not seen in the tumor sample. Markers of increased CD8+ and CD4+ T cell activation using flow cytometry of peripheral blood lymphocytes were observed. This data suggests that the treatment induced peripheral expansion of tumor-specific T cells in this responding patient. Further correlatives are pending.

Conclusion
The combination of SBRT and 6 months of pembrolizumab in advanced breast cancer patients with 1-5 metastases showed an acceptable toxicity profile and promising clinical benefit especially in Luminal BC patients. Evidence of peripheral anti-tumor T cell responses was observed in a patient who remains progression free at 24 months. The potential synergy between these treatment modalities requires further study.
Preoperative pembrolizumab (Pembro) with radiation therapy (RT) in patients with operable triple-negative breast cancer (TNBC)

Heather L McArthur1, Reva Basho1, Stephen L Shiao1, Dorothy Park1, Monica Mita1, Alice Chung1, Brittany Arnold2, Cynthia Martin1, Catherine Dang1, Scott Karlan1, Simon Knott1, Armando Giuliano1 and Alice Ho2.

1Cedars-Sinai Medical Center, Los Angeles, CA and 2Massachusetts General Hospital, Boston, MA.

Background: Radiation therapy (RT) induces immune-mediated cell death and could generate a rich supply of tumor antigens if administered in the pre-operative, curative-intent setting. The addition of PD-1 mediated checkpoint blockade to pre-operative RT could thus, generate robust anti-tumor immune responses, induce long-term tumor-specific memory, and ultimately, improve cure rates. This study aims to establish the safety of pre-operative pembrolizumab (pembro)-mediated immune modulation with a RT “boost” equivalent in patients with operable triple negative breast cancer (TNBC) for whom lumpectomy and adjuvant RT are planned (NCT03366844). Serial research biopsies permit interrogation of conventional biomarkers including tumor infiltrating lymphocytes (TILs) and novel immune correlates as potential predictors of response to pembro alone versus pembro with RT.

Methods: Ten women with operable, primary TNBC >2cm for whom breast-conserving therapy is planned are being enrolled in this single-institution pilot study. Study treatment consists of 1 cycle of pre-operative pembro (200 mg IV) alone, followed 3 weeks later by a RT boost (24 Gy/3 fractions) to the primary breast tumor concurrently with pembro (+/- 5 days). Curative-intent, standard-of-care, neoadjuvant chemotherapy (NAC) or breast-conserving surgery is then undertaken within 8 weeks of study enrollment (i.e. within 5 weeks of pembro #2). Adjuvant RT is administered per standard-of-care after surgery, but without a boost dose. Research blood and fresh tumor biopsies are obtained at baseline and after cycles 1 and 2 of pembro. Co-primary endpoints are: 1) safety/tolerability, as defined by the number of patients who do not necessitate a delay in standard-of-care chemotherapy or surgery and 2) change in TIL score. Secondary endpoints include safety/toxicity up to 19 weeks after study enrollment, pCR rates and disease-free survival. Correlative analysis will include single-cell RNA sequencing of the tumor immune infiltrate and multispectral immunohistochemistry.

Results: Seven patients enrolled between 12/19/17 and 7/1/18. As of 7/1/18, 5 patients have completed the experimental pembro/RT phase of the trial and are currently completing standard-of-care NAC; 1 patient is currently being treated in the experimental pembro/RT phase; and 1 patient with a cT2N0 tumor at baseline achieved a pathologic complete response (pCR, ypT0/Tis ypN0) after completing the experimental pembro/RT phase followed by anthracycline- and taxane-based NAC. No grade 3 or 4 toxicities have been observed during pembro/RT in the 6 patients completing the experimental phase to date. Three additional patients will be enrolled.

Conclusions: This is the first trial of curative-intent, pre-operative checkpoint blockade with RT in breast cancer and the strategy appears to be well tolerated to date. At the time of presentation, safety, change in TIL score, and pCR rates for all patients completing the experimental and NAC phases of the study will be reported.
Imprime PGG, a novel innate immune modulator, combined with pembrolizumab in a phase 2 multicenter, open label study in chemotherapy-resistant metastatic triple negative breast cancer (TNBC)

Steven O'Day¹, Virginia Borges², Bartosz Chmielowski³, Rao Ruta⁴, Maysa Abu-Khalaf⁵, Alison Stopeck⁶, Jamie Lowe⁷, Paulette Mattson⁷, Kelly Breuer⁷, Michele Gargano⁷, Nandita Bose⁷, Mark Uhlik⁷, Jeremy Graff⁷, Michael Chisamore⁸, Joanna Cox⁷ and Bruno Osterwalder⁹. ¹John Wayne Cancer Institute, Santa Monica, CA; ²UCHealth University of Colorado, Aurora, CO; ³Ronald Reagan UCLA Medical Center, Los Angeles, CA; ⁴Rush University Medical Center, Chicago, IL; ⁵Sidney Kimmel Cancer Center, Philadelphia, PA; ⁶SUNY Stony Brook Cancer Center, Stony Brook, NY; ⁷Biothera Pharmaceuticals, Inc., Eagan, MN; ⁸Merck & Co., Inc., Kenilworth, NJ and ⁹B.O. Consulting GmbH, Riehen, Switzerland.

**Background:** CPI monotherapy provides substantial clinical benefit to patients (pts) in multiple cancers, yet response rates are limited (~15-30%) and fails to benefit the majority. In these pts there is limited or no ongoing T cell-based immune response. Imprime PGG (Imprime), a novel beta glucan derived from Saccharomyces, may expand the clinical benefit of CPI therapy by stimulating an anti-cancer immune response. Acting as a pathogen-associated molecularpattern (PAMP), Imprime enlists innate immune functions including cytotoxic effector mechanisms, reversal of immunosuppression and cross-talk with the adaptive immune system. Imprime-mediated innate immune activation requires formation of an immune complex with naturally-occurring anti-beta glucan antibodies (ABA); sufficient ABA levels is required for complex formation. Imprime is now being studied in combination with pembrolizumab (KEYTRUDA®, Pembro), a humanized mAb against PD-1 which has been previously studied in TNBC pts.

**Methods:** In this study of patients who previously failed chemotherapy for metastatic TNBC, Imprime is being used in combination with Pembro in a Simon 2 stage design. Asample size of 12 evaluable pts in Stage 1 was planned. Evaluable pts received at least one dose of study treatment (tx), had measurable disease at baseline per RECIST v1.1, had at least one post-baseline scan or discontinued tx as a result of progressive disease, death, or a tx-related adverse event before the first post-baseline scan. Pts received Imprime (4 mg/kg IV days 1, 8, 15 of each 3-week cycle) + Pembro 200 mg on D1 of each cycle. Criteria to advance to Stage 2 were ≤4 grade 3/4 AEs during the first tx cycle (other than infusion reactions) and ≥1 objective response. Study primary endpoints are ORR and safety; secondary endpoints are TTR, CRR, DoR, PFS, and OS. Exploratory endpoints include ORR and PFS per irRECIST. Biopsies and blood samples are being collected to assess tx impact on immune activating events at the tumor site and in the periphery.

**Results:** A review of efficacy and safety data was conducted at the end of Stage 1. Thirteen pts (12 evaluable) were enrolled into Stage 1. Safety review noted 2 grade 3 adverse events that met protocol definition of Stage 1 events (1 pt: cellulitis and 1 pt: pleural infusion; both unrelated to treatment). Two events lead to 2 pts discontinuing treatment (infusion reaction and pancreatitis) and only 1 autoimmune event was observed (pancreatitis). Observed efficacy responses in the evaluable pts included 1 complete response (CR; ongoing) and 2 partial responses (PR; ongoing). Secondary efficacy endpoints have not been assessed. Early translational results support proposed MOA and analysis of Stage 1 translational data is ongoing.

**Conclusion:** The use of Imprime with Pembro was well tolerated and met both safety and efficacy requirements to move forward with Stage 2 of the study. No significant safety concerns were identified in Stage 1. Further investigation is thus warranted and enrollment into Stage 2 is ongoing. Updated data will be presented.
Initial safety and efficacy of a phase I/IIa trial of a modified whole tumor cell targeted immunotherapy in patients with advanced breast cancer

Saveri Bhattacharya¹, Jarrod P Holmes², Carmen Calfa³, Jason Lukas⁴, Elizabeth Tan-Chiu⁵, Guy T Clifton⁶, George E Peoples⁶, Markus Lacher⁷, Charles L Wiseman⁸ and William V Williams⁹. ¹Thomas Jefferson University, Philadelphia, PA; ²Redwood Reg Medcl Grp, Santa Rosa, CA; ³University of Miami, Miami, FL; ⁴The Everett Clinic, Everett, WA; ⁵Florida Cancer Specialists and Research Institute, Parkland, FL; ⁶Cancer Insight, San Antonio, TX and ⁷BriaCell Therapeutics Corporation, Berkeley, CA.

**Background:** SV-BR-1-GM is a GM-CSF transfected breast cancer cell line which expresses HLA class I & II antigens. In a previous clinical trial, a partial response of widely metastatic breast cancer was seen in a patient who matched SV-BR-1-GM at HLA-DRB3*02:02. Here we report the safety and efficacy analysis with immunologic correlates of response in the initial patients in a phase I/IIa trial of SV-BR-1-GM in patients with advanced breast cancer

**Methods:** This phase I/IIa trial enrolled patients with recurrent and/or metastatic breast cancer refractory to standard chemotherapy/targeted-therapy. Patients received low-dose cyclophosphamide 2-3d prior to intradermal injection of SV-BR-1-GM (20x10⁶ cells divided into 4 sites) and interferon-α into the inoculation sites (10,000 IU/site) ~2 & 4 days subsequently. Cycles were 2 weeks x3 then q mo x 3. Adverse events (AE) were evaluated after each inoculation and graded via CTCAE v4.03. Immunologic response was measured by delayed type hypersensitivity (DTH) after each inoculation. Disease response was evaluated radiographically q3 mo and as clinically indicated (clinical trial NCT03066947).

**Results:** To date, twenty-two patients have been enrolled and 17 have been inoculated for a total of 39 SV-BR-1-GM inoculations given. Per inoculation, the maximum related AE was grade 1 in 64%, grade 2 in 7.7%, and grade 3 in 7.7%. There were no related grade >3 or unexpected AE. Efficacy data is available on the first six (Table). Tumor regression was seen in 2 patients. 01-002 presented with liver, bone and 20 classic miliary lung metastases (up to 9mm). This subject previously received 7 chemotherapy regimens. She matched SV-BR-1-GM at Class I & II HLA loci. Imaging at 3 mo showed virtually complete regression of all 20 identifiable lesions in the lungs. This response was maintained at 6 mo but the subject was taken off protocol because of disease progression (liver and bone). 01-005, matching HLA-A*24:02, had notable regression of cutaneous lesions, but progressed in pleural and pericardial effusions, had irreversible cardiac arrest (unlikely related). DTH increased in 01-002 from 4mm (first dose) to 47mm (8th dose). Three of 3 patients evaluated developed antibodies responses (as measured by flow cytometry with SV-BR-1) including 01-002. Interleukin 8 also increased in 01-002.

**Conclusions:** SV-BR-1-GM in this regimen appears to be safe and well-tolerated. In this initial exploratory analysis, SV-BR-1-GM can produce regression of pre-treated metastatic breast cancer correlating with an immunologic response. HLA matching is being evaluated as a predictor of response.

Epigenetic modulation—unlocking the potential of checkpoint inhibition in breast cancer

Evanthia T Roussos Torres¹, Christine Rafie¹, Todd Armstrong¹ and Elizabeth M Jaffee¹. ¹Johns Hopkins University, Baltimore, MD.

Immune checkpoint inhibition (ICI) has revolutionized treatment in cancers that are naturally immunogenic by enabling infiltration of T cells into the tumor microenvironment (TME) and promoting cytotoxic signaling pathways. Tumors possessing complex immunosuppressive TME’s such as breast cancer present unique therapeutic obstacles as response rates to ICI remain low. Such tumors often recruit myeloid-derived suppressor cells (MDSCs) whose functioning prohibits both T cell activation and infiltration. To date, most studies focus on use of ICI in triple negative disease. Our work aims to uncover the efficacy of ICI in both early and advanced HER2 positive (HER2⁺) disease and to advance our understanding of how to improve response rates to these new promising therapies.

We are using a HER-2/neu transgenic mouse model with tumor challenge of syngeneic cell lines to test the efficacy of different combinations of an epigenetic agent, the histone deacetylase inhibitor entinostat (ENT), checkpoint inhibitors anti-PD-1 and anti-CTLA-4, on primary and metastatic disease. We are examining treatment effects on primary tumor growth, metastatic burden, and survival. Characterization of tumor infiltrating lymphocytes and their functional capabilities are being investigated using fluorescence-activated cell sorting, gene expression profiling, and ex vivo suppression assays. Western blots, qPCR and other in vitro assays will be performed on MDSCs to investigate mechanisms behind response.

In the HER2⁺ mouse model of early stage disease, we show that combining ENT, with ICIs significantly improves survival and delays tumor growth. Preliminary data in models of advanced disease, show only ENT + a-PD-1 improves survival and metastatic burden. Conversely, in the metastatic model, ENT + a-CTLA-4 negatively effects survival and metastatic burden. In primary tumors, ENT + ICIs leads to significantly decreased suppression by granulocytic-MDSCs. However, MDSC infiltration and function is not affected in lungs containing macrometastatic disease. Interestingly, we found an increase in activated granzyme-B-producing CD8⁺ T effector cells in mice treated with combination therapy in both primary and metastatic tumors. Finally, gene expression profiling of MDSCs from primary tumors identified significant changes in immune-related pathways, and identified a common downstream regulator –STAT3. Studies are ongoing to evaluate the mechanistic role of STAT3 in the response observed in primary tumors and to determine if STAT3 is involved in response in the metastatic setting.

In summary, addition of ENT to ICIs significantly affects overall survival in early stage models of HER2+ breast cancer however, only addition of a-PD-1 to ENT is beneficial in models of advanced disease. Additionally, the mechanism of action in early stage disease involves altered infiltration and function of MDSCs, allowing for a more robust adaptive immune response. However, a different mechanism of action is likely responsible for the responses seen in advanced stage disease. These novel findings provide a rationale for combination therapy in patients with HER2+ breast cancer and suggest responses to this combination therapy are linked to stage of disease likely due to different mechanisms of action.
Intratumoral tavokinogene telseplasmid and electroporation in pre-treated inoperable locally advanced or recurrent triple-negative breast cancer

Melinda L Telli¹, Kaitlin Zablotsky¹, Mai H Le², David Canton², Erica Browning², Donna Bannavong², Sharron Gargosky² and Irene Wapnir¹. ¹Stanford University School of Medicine, Stanford, CA and ²OncoSec Medical, San Diego, CA.

Introduction: Triple negative breast cancer (TNBC) accounts for approximately 15% of breast cancer diagnoses and is associated with a higher risk of recurrence and more aggressive course in the metastatic setting. Emerging data suggest that some patients with TNBC benefit from immune-based therapies targeting the anti-programmed cell death protein 1 (PD-1)/PD-1 ligand 1 (PD-L1) axis, but success has been limited in poorly immunogenic tumors. Thus, combination therapies that drive an influx of CD8⁺ tumor infiltrating lymphocytes (TILs) and/or upregulate PD-L1 expression are required to increase response rates to these therapeutics. Intratumoral injection of plasmid IL-12 (tavokinogene telseplasmid; tavo) followed by electroporation (IT-tavo-EP) is a gene therapy approach that drives local expression of the proinflammatory cytokine, interleukin-12 (IL-12). Local expression of IL-12 is hypothesized to result in increased TILs and enhanced expression of proinflammatory cytokines, resulting in conversion of poorly-immunogenic/low TIL TNBC tumors into highly inflamed immunologically active lesions while demonstrating a high safety profile.

Methods: OMS-I140 is a phase I, non-randomized, open-label study of IT-tavo-EP in patients with inoperable locally advanced, metastatic and/or treatment-refractory TNBC (NCT02531425). Eligible patients have pre-treated TNBC and at least 2 anatomically distinct cutaneous or subcutaneous lesions accessible for injection and electroporation, with or without other regional or distant metastases. 10 patients are planned for enrollment. IT-tavo-EP is administered on Days 1, 5 and 8 of a single 28-day cycle. Tavo is injected intratumorally (based on tumor volume) at a concentration of 0.5 mg/mL and immediately followed by co-localized electroporation (6 pulses at 1500 V/cm with 1-second intervals). Tumor biopsies are obtained at baseline and post-treatment on day 28 of both treated and untreated lesions to determine if this therapy can promote a pro-inflammatory molecular and histologic signature. Pain scores and adverse events are recorded.

Results: To date, nine patients have completed study therapy. Reported treatment-related adverse events include pain associated with electroporation (grade 1) in 8 patients and fatigue (grade 1) in 1 patient. Median pain score (range 0-10) immediately after treatment was 2 (range 0-10) and 5 minutes post-treatment was 0 (range 0-6). In some patients, treatment-related increases in CD8⁺ TIL density have been observed by intratumoral chromogenic staining. Further immune profiling is being conducted to characterize the tumor microenvironment pre- and post-therapy. A subset of patients with treatment refractory TNBC received anti-PD-1 monotherapy as their immediate next therapy with clinical response observed. Updated data will be presented.

Conclusions: Our data suggest that IT-tavo-EP is a safe and tolerable TIL stimulating therapy in TNBC. Further study of IT-tavo-EP in combination with pembrolizumab in pretreated metastatic TNBC is planned.
Perilymphatic IRX-2 cytokine therapy to enhance tumor infiltrating lymphocytes (TILs) and PD-L1 expression preceding curative-intent therapy in early stage breast cancer (ESBC)

Joanna Pucilowska1, James E Egan2, Neil L Berinstein3, Nicole Moxon1, Shaghayegh Aliabadi-Wahle4, James H Imatani1, Alison Conlin1, Anupama Acheson1, Kristen Massimino1, Martiza Martel1, Mary Campbell1, Yaping Wu1, Zhaoyu Sun1, William Redmond1, Monil Shah2, Walter J Urba1 and David B Page1. 1Earle A. Chiles Research Institute, Portland, OR; 2IRX Therapeutics, New York, NY; 3University of Toronto, Toronto, ON, Canada and 4The Oregon Clinic, Portland, OR.

Background: Cytokines are being explored as a therapeutic strategy to modulate the tumor microenvironment and facilitate immunotherapy benefit in breast cancer. Here, we investigate a locoregional therapeutic approach whereby cytokines (IRX-2) are administered into the subcutaneous peri-areolar tissue (in an anatomic distribution similar to sentinel lymph node mapping) to facilitate immune cell recruitment/activation within the draining lymph nodes and tumor in ESBC. IRX-2 is derived from ex vivo phytohemagglutinin-stimulated lymphocytes and contains multiple cytokines including IL-1β, IL-2, TNF-α, IFN-γ, IL-6, IL-8, and GM-CSF, with stable concentrations from lot to lot. Preclinically, IRX-2 activates T-cells and natural killer (NK) cells, facilitates antigen presentation, and enhances activity of anti-PD-1/L1 in a SCC7 model. In a preceding head/neck squamous cell carcinoma phase I trial, perilymphatic IRX-2 was safe and increased TILs. Here, we report the final clinical results of a phase Ib trial evaluating the feasibility and immunologic activity of IRX-2 in ESBC.

Methods: Beginning 21 days prior to surgical resection, enrolled operable patients with stage I-III ESBC (all subtypes) received the pre-operative IRX-2 regimen consisting of a single low-dose cyclophosphamide (300 mg/m² to facilitate T-regulatory cell depletion), followed by 10 days of subcutaneous peri-areolar IRX-2 injections into the affected breast (1 mL × 2 at tumor axis and at 90°). Endpoints were feasibility (primary endpoint), stromal TIL (sTIL) count (pre-treatment versus post-treatment, blinded average of two pathologist reads using San Antonio H&E sTIL guidelines), PD-L1 expression (Nanostring) and enumeration of peripheral immune cells by flow cytometry.

Results: All patients (n=16/16) completed and tolerated the regimen with no surgical delays or treatment-attributed grade III/IV toxicities. Common adverse events (occurring in >15% subjects) attributed to IRX-2 injections were: injection site reaction (grade 1, n=8/16), bruising (grade 1, n=7/16), and pain (grade 1, n=3/16). Common adverse events attributed to low-dose cyclophosphamide were: fatigue (grade 1, n=5/16) and nausea (grade 1/2, n=3/16). Treatment was associated with an increase in sTIL score (Wilcoxon signed-rank p=.04), with 4/10 sTIL-low tumors (0-10% score) re-categorized to sTIL-moderate (11-50% score). Increases in PD-L1 RNA expression were observed (Wilcoxon signed-rank p=.04) in 12/16 tumors (median 57% increase, range: -53% to 185% increase), as well as increases in Nanostring NK and Th1 cell signatures. In blood, increases in CD4 and CD8 effector T-cell activation (ICOS, HLA-DR, and CD38) and T-reg depletion were observed.

Conclusions: IRX-2 was well tolerated with preliminary evidence of sTIL increase, PD-L1 upregulation, and peripheral lymphocyte activation. Based upon these data and preclinical evaluations demonstrating synergy with checkpoint inhibition, the IRX-2 regimen is being evaluated for clinical efficacy in conjunction with pembrolizumab and neoadjuvant chemotherapy (doxorubicin, cyclophosphamide, paclitaxel) in patients with stage II-III triple negative breast cancer.
A phase I study of adoptive immunotherapy for ROR1+ advanced triple negative breast cancer (TNBC) with defined subsets of autologous T cells expressing a ROR1-specific chimeric antigen receptor (ROR1-CAR)

Jennifer M Specht1,2, Sylvia M Lee1,2, Cameron Turtle1,2, Carolina Berger2, Ashwini Balakrishnan2, Shivani Srivastava2, Valentini Viollet2, Josh Veatch2, Ted Gooley2, Erin Mullane3, Colette N Chaney2, Christoph Rader4, Robert H Pierce2, Raphael Gottardo2, David G Maloney1,2 and Stanley R Riddell1,2. 1University of Washington, Seattle, WA; 2Fred Hutchinson Cancer Research Center, Seattle, WA; 3Seattle Cancer Care Alliance, Seattle, WA and 4Scripps Florida, Jupiter, FL.

BACKGROUND: ROR1 is a type 1 transmembrane tyrosine kinase receptor that plays a critical role in embryonic and fetal development. ROR1 has been described as a possible oncogene and is expressed in numerous malignancies including TNBC and non-small cell lung cancer (NSCLC). We are conducting a first-in-human trial targeting ROR1 with CAR-T cells in patients with advanced TNBC and NSCLC. The cellular construct employed targets the Ig/Fz portion of the extracellular domain of ROR1 and contains 4-1BB/CD3ζ intracellular signaling domain. The manufacturing process utilizes autologous peripheral blood lymphocytes, separated into CD4 and CD8 subsets, which are independently cultured with anti-CD3/anti-CD28 beads and IL-2, then transduced with a lentiviral vector encoding the ROR1 CAR. The CAR-T cell product is formulated in a 1:1 ratio of CD4+ and CD8+ CAR-T cells.

METHODS: This ongoing phase I trial (NCT02706392) is evaluating the safety of administering ROR1 CAR-T cells in escalating doses (3.3x10^5, 1x10^6, 3.3x10^6 and 1x10^7 cells/kg) following lymphodepletion with cyclophosphamide-containing regimens using a continual reassessment method (CRM) for dose escalation. TNBC patients with adequate organ function and performance status, measurable disease, and tumors expressing ROR1 (>20% by IHC) are eligible for enrollment. Persistence of CAR-T cells in blood, cytokine levels, measures of immunogenicity and multi-parametric flow cytometry are being evaluated at multiple time points. Imaging assessments by RECIST 1.1 are performed day 28 - 90, then at 6 and 12 months, and every 6 months as clinically indicated to estimate efficacy.

RESULTS: To date, 4 TNBC patients (age range 38-67) have been enrolled, treated and are evaluable for response. Patients had received prior therapies for metastatic disease (range 3-11). 3 of 4 had visceral metastases. No dose-limiting toxicities, severe neurotoxicity or severe cytokine release syndrome (sCRS) were observed at dose levels 1 and 2. Two patients experienced grade 1 CRS. 2 of 4 patients had evidence of CAR-T cell expansion between days 14 and 20, with peak CD8+ CAR-T up to 232.1 cells/μL. Analysis of surface phenotype revealed upregulation of inhibitory receptors on CAR-T cells at the peak of expansion, confirmed by RNA seq. Post-treatment tumor biopsy in patient with partial response revealed an influx of CD3+ T cells and macrophages suggesting ROR1 CAR-T cell trafficking. Two patients received 2 CAR-T cell infusions. Two patients had confirmed stable disease at 15 weeks and 19 weeks, respectively. One patient has stable disease after 1st CAR-T cell infusion, then confirmed partial response after 2nd CAR-T cell infusion which has persisted for 14 weeks. Results will be updated.

CONCLUSIONS: ROR1+ CAR-T cells can be safely transferred, expand in vivo in patients with TNBC. Current efforts are directed at understanding and overcoming the mechanisms that limit homing, persistence, and/or function at tumor sites. The trial is continuing with dose-escalation. Funding provided by 8RO1 CA114536-11 and Juno Therapeutics.
Immunogenomic pathway and survival analysis in breast cancers based on tumor location and molecular subtypes

Yuanyuan Shen¹, Chi-Ren Shyu¹, Jonathan B Mitchem¹, Fanling Ding² and Ayesha N Shajahan-Haq³. ¹Informatics Institute, University of Missouri, Columbia, MO; ²Hamden Hall Country Day School, Hamden, CT and ³Lombardi Comprehensive Cancer Center, Georgetown University, Washington, DC.

Introduction: Most breast tumors respond poorly to immunotherapy. Triple-negative breast cancer (TNBC) breast tumors are thought to be more immunogenic than other breast cancer subtypes (luminal A/B or HER2+). Increased immune response in TNBC are characterized by high levels of tumor infiltrating T lymphocyte (TIL) composition that would predict excellent response to immune checkpoint blockade. For all breast cancers, tumors appear more commonly in the upper outer quadrant. However, it is not clear whether expression of immune response genes vary with tumor location among the subtypes. Here, we hypothesized that by analyzing differential gene expression associated with immune response pathways among molecular subtypes of breast cancer such as luminal A/B, HER2+ or TNBC, we can identify targetable pathways to improve therapy with breast cancer.

Methods: Using the Cancer Genome Atlas (TCGA) dataset, we have identified 918 breast cancer tumor samples and compared RNAseq gene expression based on molecular subtypes and anatomic locations of biopsies (i.e., right, left, lower inner quadrant, lower outer quadrant, upper inner quadrant or upper outer quadrant). Genes with significantly different expression (p<0.01) were selected for survival analysis. R, Reactome Pathway Browser were used to retrieve and analyze data.

Results: In TNBC, tumors from lower outer quadrant, lower inner quadrant demonstrated significantly higher CD8B mRNA expression compared with luminalA/B and HER2 (p=2.93E-04, 2.73E-04) from same locations. CD8B mRNA was not significantly higher in TNBC tumors of other sites compared with luminalA/B and HER2. However, pathway/genes associated with CTL function remained significantly different between the different sites for TNBC compared with other subtypes. The metastasis suppressor gene, CD82, was significantly higher in TNBC samples from the right side (p=4.83E-05), lower outer quadrant (p=4.33E-05), lower inner quadrant (p=3.32E-03) and upper inner quadrant (p=4.51E-07), but this gene was not significantly expressed in the upper outer region, where tumors are prevalent.

From immune pathway analysis, genes involved in the antigen activates B cell receptor pathway (p<0.05) were associated with overall survival (OS) in right and left sided Luminal A/B and HER2 tumors and right sided TNBC tumors. Finally, genes from pathway involved in immune-regulatory interactions between a lymphoid and a non-lymphoid cells were associated with OS in lower outer quadrant, upper outer quadrant tumors in luminal A/B and HER2 cases and right sided tumors in TNBC (p<0.05).

Conclusion: While previous studies have reported that tumor infiltrating lymphocytes and lymphoid aggregates in tumors are associated with survival, following more complex analysis, we reveal novel genes and immune pathways that demonstrate improved survival prediction in the TCGA dataset for breast cancers. Furthermore, as expected, we confirm that different immune pathways are associated with survival in luminalA/B, HER2 and TNBC tumors. Our findings demonstrate the importance of a patient-centered approach to the treatment of patients with breast cancer.
A phase I study of interferon-gamma (γ) plus weekly paclitaxel, trastuzumab and pertuzumab in patients with HER-2 positive breast cancer

Hyo Sook Han1, Hung Khong1, Ricardo Costa1, Loretta Loftus1, Dawn Goodridge1, Tanisha Henry1, Hatem Soliman1, Roohi Ismail-Khan1, Brooke Fridley1 and Brian Czerniecki1. 1H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL.

Background: IFN-γ, a cytokine that plays diverse roles in innate and adaptive immunity, has been shown to be essential in anti-tumor immune response. In vitro and in vivo studies have shown the synergistic effect of IFN-γ in combination with HER2-targeting monoclonal antibodies with or without taxane chemotherapy. We have conducted a phase 1 clinical trial of systemic IFN-γ in combination with trastuzumab, pertuzumab, and paclitaxel in HER2-positive metastatic breast cancer.

Methods: Two dose levels (DL) of IFN-γ, 50 (DL1) and 75 mcg/m² (DL2), were evaluated. IFN-γ was given as subcutaneous injection three times weekly starting on day 1 of therapy for 12 weeks. Paclitaxel was administered intravenously (IV) weekly at 80mg/m² in combination with trastuzumab IV (8 mg/kg loading dose, then 6 mg/m² q 21 days) and pertuzumab IV (840 mg loading dose, then 420 mg q 21 days). Eligible patients had measurable metastatic HER2-positive breast cancer, were candidates to receive paclitaxel chemotherapy, and had an ECOG PS 0-1. The primary objective of this study was to evaluate the safety and tolerability of the combination therapy during the 12 weeks of treatment and to determine the recommended phase II dose (RP2D). Dose-limiting toxicity (DLT) during cycle one was defined as follows: Non-hematologic or hematologic toxicities that are ≥ grade 3 and probably or definitely related to study therapy which lead to chemotherapy treatment delays > 14 days.

Results: A total of nine patients (3 on DL1 and 6 on DL2) were enrolled between 2/2017 and 11/2017. No DLT was observed. For DL1, no serious adverse events (SAE) or significant adverse events (AE) were observed among 3 patients who completed 12 weeks of treatment. For DL2, two out of 6 patients had SAEs including grade 3 pneumonitis (at week 8; treatment was subsequently discontinued) and grade 3 non-neutropenic fever (at week 6), which were possibly related to study treatment. These toxicities, however, did not meet the protocol definition of DLT. Based on these findings suggesting an improved tolerability of DL1 (50 mcg/m²), DL1 was selected as the RP2D. The most frequently observed grade 1 and 2 AEs that were at least possibly related to IFN-γ were fatigue (45%), nausea (36%), myalgia (36%), and fever (27%) diarrhea (18%). No grade 4 AE was noted. Grade 3 AEs included diarrhea, nausea, pneumonitis, non-neutropenic fever. Three out of 9 patients achieved partial response and 6 patients had stable disease per RECIST criteria.

Conclusion: IFN-γ in combination with trastuzumab, pertuzumab, and paclitaxel was well tolerated in patients with HER2-positive metastatic breast cancer. Updated results will be presented and the phase 2 neoadjuvant trial is ongoing to further assess the efficacy of this approach.
CD8 T cells induced by novel alphaviral vector predict improved progression free survival in advanced HER2+ breast cancer patients

Erika J Crosby¹, William R Gwin², Serena Chang³, Holden T Maecker³, Veronica Lubkov¹, Joshua C Snyder¹, Gloria Broadwater¹, Terry Hyslop¹, Takuya Osada¹, Amy C Hobeika¹, Zachary C Hartman¹, Michael A Morse¹ and H K Lyerly¹. ¹Duke University, Durham, NC; ²University of Washington, Seattle, WA and ³Stanford University, Stanford, CA.

Background: Immune-based therapy for metastatic breast cancer has had limited success. Strategies to augment adaptive immunity include vaccines targeting genomic amplifications like Human Epidermal Growth Factor Type 2 (HER2), an established driver of malignancy. Using a novel alphaviral vector, we constructed a vaccine encoding a portion of HER2 (VRP-HER2).

Methods: In preclinical studies, mice were immunized before or after implantation of hHER2+ tumor cells and HER2-specific immune responses and anti-tumor function were assessed. We then translated this vaccine into a phase I clinical trial in which subjects with advanced HER2-overexpressing breast cancers received VRP-HER2 every 2 weeks for a total of three doses (cohort 1). In cohort 2, subjects received the same dose of VRP-HER2 along with a standard HER2 targeted therapy.

Results: VRP-HER2 induced HER2-specific T cell and antibody responses while controlling tumor growth in murine models. Vaccination with VRP-HER2 was well tolerated in both patient cohorts. PFS was modest, while median OS was 50.2 months in cohort 1 and 32.7 months in cohort 2. In cohort 2, there is one partial response and two patients with continued stable disease. Vaccine induced anti-HER2 antibodies and T cells were identified. Increased perforin expression by memory CD8 T cells post vaccination significantly correlated with improved PFS.

Conclusions: VRP-HER2 led to an increase in perforin expressing HER2-specific memory CD8 T cells in preclinical and clinical studies, and had profound antitumor effects in murine models. The generation of HER2-specific memory CD8 T cells was significantly correlated with increased PFS in patients. Subsequent studies will seek to enhance T cell activity by combination with anti-PD-1/PD-L1 antibodies.
Phase II study of antiangiogenic tyrosine kinase inhibitor apatinib in combination with oral vinorelbine in heavily pretreated HER2-negative advanced breast cancer

Anjie Zhu¹, Peng Yuan¹, Jiayu Wang¹, Ying Fan¹, Yang Luo¹, Rui Kang Cai¹, Pin Zhang¹, Qing Li¹, Fei Ma¹ and Binghe Xu¹.
¹National Cancer Center/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.

**Background:** Metastatic breast cancer remains an incurable disease, and clinical benefit and progression-free survival are the main end points in advanced setting. Targeted therapies have shown promising potentials in HER2-positive breast cancer, but with uncertain effects in HER2-negative breast cancer, especially when the disease is progressing rapidly. The regimen of antiangiogenic therapy in combination with chemotherapy had been studied for years and gained improved efficacy. Apatinib is an oral, highly potent tyrosine kinase inhibitor targeting vascular endothelial growth factor receptor 2. Phase II clinical trials of Apatinib single agent had presented objective response and manageable toxicity in heavily pretreated, metastatic breast cancer. Oral vinorelbine represents a good choice for its toxicity and activity in anthracycline and taxane-pretreated breast cancer patients. This all-oral study aims to investigate the efficacy and safety of the oral vinorelbine-apatinib combination in pre-treated metastatic breast cancer.

**Methods:** This study enrolled patients with HER2-negative advanced breast cancer, pretreated with anthracycline/taxanes, and who failed in the metastatic setting at least one prior chemotherapy or endocrine therapy when hormone receptor is positive. Patients were treated with apatinib 500mg/425mg daily plus oral vinorelbine 60mg/m² day1,8,15 every 3 weeks/cycle. Patients eligible were evaluated by CT or MRI scan at baseline and every 2 cycles (6 weeks) there after until disease progressed. The primary endpoint was PFS. The secondary endpoints were objective response rate, clinical benefit rate, OS, and safety.

**Results:** 40 patients were enrolled with a median age of 55 (30-70) years. First 17 patients started apatinib at the dose of 500mg/day. Considering safety issues, a lower dose of apatinib 425mg/day was subsequently started as the initial dose after these 17 patients recruited. 26(65.0%) patients experienced treatment delay and 20(50.0%) patients experienced dose modification during treatment. Median follow-up time was 10.3 months. Of all 40 patients, median PFS was 5.4 months (95% CI, 3.4m–7.3m). Median OS was not reached. 32 patients were eligible for efficacy analysis. ORR was 15.6% (5/32). CBR was 46.9% (15/32). Patients with triple-negative breast cancer or who received combined therapy as second line treatment gained better ORR and longer median PFS. The most common adverse events of all grades included gastrointestinal reaction (70.0%), myelosuppression (67.5%), hypertension (62.5%), pain (60.0%), malaise (52.5%), anorexia (50.0%), elevated transaminase (47.5%), hand-foot reaction (47.5%), proteinuria (37.5%), and elevated bilirubin (32.5%). Proteinuria, treatment delay, and ECOG performance status were independent predictive factors for PFS.

**Conclusions:** The all-oral therapy of antiangiogenic tyrosine kinase inhibitor apatinib plus vinorelbine presented objective efficacy in advanced HER2-negative breast cancer who failed from first-line therapy, with acceptable and manageable toxicity.
AVASTEM – Stem cells inhibition by bevacizumab in combination with neoadjuvant chemotherapy for locally advanced breast cancers: A prospective proof of concept randomized phase II trial

Renaud Sabatier¹,², Emmanuelle Charafe-Jauffret¹,², Jean-Yves Pierga³, Hervé Curé⁴, Eric Lambaudie¹,², Gilles Houvenaeghel¹,², Christophe Ginestier², Patrick Sfumato⁵, Jean-Marc Extra¹ and Anthony Gonçalves¹,². ¹Institut Paoli-Calmettes, Marseille, France; ²Aix Marseille Univ, CNRS U7258, INSERM U1068, Institut Paoli-Calmettes, CRCM, Marseille, France; ³Institut Curie, Paris, France; ⁴Institut Jean Godinot, Reims, France and ⁵Department of Clinical Research and Innovation, Biostatistics Unit, Marseille, France.

Background. Preclinical works have suggested that conventional cytotoxic chemotherapies may increase the number of cancer stem cells. Angiogenesis inhibition has been described in vitro to have an impact on stem cells proliferation. We developed a proof of concept clinical trial to explore Bevacizumab-chemotherapy activity on breast cancer stem cells for patients treated in the neoadjuvant setting.

Patients and Methods. Breast cancer patients requiring preoperative chemotherapy were included in this open-label, randomized, prospective, multicentre phase II trial. All received FEC-docetaxel combination for a maximum of 8 cycles, and patients randomized in the experimental arm received concomitant Bevacizumab (15 mg/kg Q3W). The primary endpoint was to describe aldehyde dehydrogenase (ALDH1, identified by immunohistochemistry) positive tumour cells rate before treatment and after the 4th cycle. Secondary objectives included safety, pathological complete response (pCR) rate, disease-free survival (DFS), relapse-free survival (RFS), and overall survival (OS).

Results. Seventy-five patients were included from March 2010 to July 2012, including 50 in the experimental arm. More than 80% of patients received all planned chemotherapy cycles. ALDH1 expression could be assessed both before treatment and after the fourth cycle of chemotherapy for 32 patients. The absence of a significant increase (> 5%) in ALDH1+ cells rate after chemotherapy was demonstrated in the Bevacizumab arm (n=19, Median=-0.125, one-sided 95%CI=[-∞-0], p=0.001). Yet, the same was observed in the control arm (n=13, Median=-0.25, one-sided 95%CI=[-∞-0], p=0.006). Grade 3 or 4 adverse events, including haematological, digestive, and cutaneous disorders, were observed for 94% of the patients in the experimental arm and 88% in the control arm. A non-significant increase in pCR was observed in the Bevacizumab arm (OR=2.24, 95CI [0.77-6.54], p=0.14), but survival was not improved (OS: p=0.89 for the whole cohort; DFS: p=0.45; and RFS: p=0.68 for non-metastatic cases). ALDH1 status at inclusion was not correlated to efficacy.

Conclusions. We observed that the rate of ALDH1+ tumour cells did not increase after Bevacizumab-based chemotherapy. However, as similar results were observed with chemotherapy only, Bevacizumab impact on breast cancer stem cells cannot be confirmed.
Sacituzumab govitecan (anti-Trop-2-SN-38 antibody-drug conjugate) as ≥3rd-line therapeutic option for treatment-refractory HER2-negative metastatic breast cancer (HER2Neg mBC)

1Columbia University-Herbert Irving Comprehensive Cancer Center, New York, NY; 2Massachusetts General Hospital Cancer Center, Harvard Medical School, Boston, MA; 3The Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA; 4Vanderbilt-Ingram Cancer Center, Nashville, TN; 5Weill Cornell Medicine, New York, NY; 6University of Colorado Cancer Center, Aurora, CO; 7Texas Oncology, Baylor University Medical Center, US Oncology, Dallas, TX; 8UF Health Cancer Center, Orlando, FL; 9Yale University School of Medicine, New Haven, CT and 10Immunomedics, Inc., Morris Plains, NJ.

Background: Sacituzumab govitecan is an antibody-drug conjugate consisting of SN-38, the active metabolite of irinotecan, conjugated to a humanized mAb targeting Trop-2 (trophoblastic antigen-2), which is highly expressed in many epithelial cancers. A phase I/II basket trial (NCT01631552) investigated its activity in patients (pts) with advanced epithelial cancers. Herein, we summarize pooled safety and efficacy findings in 162 pts with HER2-negative metastatic breast cancer (mBC) accrued between 7/2013 and 6/2017 who received at least 2 prior therapies for metastatic disease and were treated with sacituzumab govitecan at the 10 mg/kg dose level.

Methods: Patients with triple-negative (N=108) and patients with hormone-receptor positive (N=54) mBC received 10 mg/kg sacituzumab govitecan on days 1 & 8 of a 21-day cycle continued until progression or unacceptable toxicity. All pts had measurable disease by CT or MRI. Efficacy was assessed locally by RECIST 1.1 including overall response rate (ORR) and Kaplan-Meier estimates of duration of response (DOR), progression-free survival (PFS) and overall survival (OS). Adverse events (AE) were evaluated according to CTCAE v4.0

Results: The patient cohort (161 female /1 male; median age 55 yrs, range 31-80) received a median of 4 prior therapies for metastatic disease (range 2-17), with prior chemotherapy agents in the metastatic setting including taxane (68%), capecitabine (60%), platinum (59%), gemcitabine (44%), eribulin (41%), and anthracycline (38%). 77 pts have died, with 57 in long-term follow-up and 28 still on treatment at data cutoff. The median number of administered sacituzumab govitecan doses was 14 (range 1-88). Treatment was generally well tolerated. 29% of pts had dose reductions, 3% discontinued treatment due to drug-related AEs, and there were no treatment-related deaths. Based on currently available AE data, grade ≥ 3 toxicity included neutropenia (43%), anemia (9.5%), diarrhea (7.0%) and febrile neutropenia (6.3%). For the TNBC subgroup, with a median follow-up of 9.3 months, the ORR was 33% (3 CRs + 50 PRs/162) with a median DOR of 8.3 months (95% CI: 4.9 - 10.8). For the ER+ subgroup, with a median follow-up of 10.0 months, the ORR was 31% (17 PRs/54) with a median DOR of 7.4 months (95% CI: 4.4 - 10.8), PFS of 5.6 months (95% CI: 5.1 - 6.9) and OS of 13.0 months (95% CI: 11.5 - 15.0). The ORR was comparable for pts ≤ 50 yrs. old [32.2% (19/59)] vs. > 50 yrs old [33.0% (34/103)] and little different for pts with 2 prior therapies [35.4% (17/48)] vs. >2 prior therapies [31.6% (36/114)].

Conclusions: Monotherapy with sacituzumab govitecan was well tolerated with a manageable safety profile, and achieved a 30+% objective response rate among heavily pre-treated patients with HER2-negative metastatic breast cancer regardless of ER status.
Dose- and exposure-response relationship and biomarker correlation analysis in breast tumors from patients treated with capivasertib, an AKT inhibitor, in the STAKT randomized, placebo controlled pre-surgical study

Julia Gee 1, Robert E Coleman 2, Kwok Leung Cheung 14, Abigail Evans 3, Christopher Holcombe 4, Anthony Skene 5, Daniel Rea 6, Samreen Ahmed 1, Ali Jahan 8, Kieran Horgan 9, Petra Rauchhaus 10, Roberta Littleford 10, Pauline Finlay 1, Amy Cheung 12, Marie Cullberg 11, Elza de Bruin 12, Andrew Foxley 12, Loumpiana Koula 12, Martin Pass 12, Gaia Schiavon 12, Paul Rugman 12, Rahul Deb 13 and John Forsyth Russell Robertson 14. 1Cardiff University, Cardiff, United Kingdom; 2University of Sheffield, Sheffield, United Kingdom; 3Pooles Hospital NHS Foundation Trust, Poole, United Kingdom; 4Royal Liverpool University Hospital, Liverpool, United Kingdom; 5Royal Bournemouth Hospital, Bournemouth, United Kingdom; 6University Hospital Birmingham NHS Foundation Trust, Birmingham, United Kingdom; 7Leicester Royal Infirmary, Leicester, Leicestershire, United Kingdom; 8Kings Mill Hospital, Mansfield, Nottinghamshire, United Kingdom; 9Leeds Teaching Hospitals NHS Trust, Leeds, Yorkshire, United Kingdom; 10University of Dundee, Dundee, United Kingdom; 11AstraZeneca, Pepparedsleden 1, Sweden; 12AstraZeneca, Melbourn, Hertfordshire, United Kingdom; 13Royal Derby Hospital, Derby, Derbyshire, United Kingdom and 14University of Nottingham, Nottingham, Nottinghamshire, United Kingdom.

Background: Capivasertib (AZD5363), an AKT1,2,3 inhibitor, significantly improved progression-free and overall survival when added to paclitaxel in triple negative breast cancer (BC) patients (Schmid et al. ASCO 2018). We have previously reported in STAKT, robust target inhibition at 480mg BD versus placebo, including significant decreases in the primary biomarkers (PBs) - Ki67, pPRAS40 & pGSK3β - in primary BCs (Robertson et al. SABCS 2017). We now report the dose- and exposure-response relationship of capivasertib and the correlation between primary and secondary (pAKT, pS6, nuclear FOXO3a) tumor biomarkers.

Design: STAKT was a two-stage, double blind, randomized, placebo controlled 'window-of-opportunity' trial in newly diagnosed ER+ BC patients. Stage 1 assessed capivasertib at a dose of 480mg BD p.o. versus placebo. Stage 2 assessed capivasertib at two lower doses 360mg and 240mg BD. Tumor biopsies were taken prior to 1st dose and after 4.5 days of dosing. Evaluable patients (who required pre-defined minimum baseline PD values for PBs) included placebo (n=11), capivasertib at 480mg (n=17), 360mg (n=5) and 240mg (n=6). Blood samples for pharmacokinetic (PK) studies were scheduled at pre-dose; 2, 4, optional 6 & 8 hrs post first dose on Day 1; ~2-4 h post last dose on Day 5 (before biopsy). The % change from baseline for PBs were evaluated against the following exposure variables (placebo=0): i) Dose, ii) Observed Cmax Day 1 (~2h post-dose), iii) Observed plasma concentration on Day 5, iv) Model-predicted plasma concentration Day 5 at time of biopsy, and v) Model-predicted AUC on Day 5. Spearman correlation coefficient measured the strength and direction of association between biomarkers.

Results:
· Significant mean reductions in % change from baseline were observed for the PBs pGSK3β (-39%; p<0.006), pPRAS40 (-50%; p<0.0001) and Ki67 (-23%; p=0.052) at 480mg versus placebo. At 360mg and 240mg, mean % changes from baseline in pGSK3β were -27% and -9%, respectively; in pPRAS40 -45% and -28%, respectively; and in Ki67 0% and +22%, respectively.
· Dose-response relationships for individual % change from baseline could be described by an Emax model for all PBs. Overall, the correlation to PK exposure (observed or predicted) was similar to the correlation to dose.
· Correlation coefficient analyses between biomarkers at capivasertib 480mg BD identified- i) Positive correlations for pGSK3β with Ki67 (p = 0.52, p-value < 0.05) & with pS6 (p = 0.54, p-value<0.05); ii) Negative correlations between FOXO3a and Ki67 (p = -0.75, p-value<0.001) pGSK3β (p = -0.71, p-value<0.001) & also pS6 (p = -0.61, p-value<0.001).Correlation coefficients for lower doses are not robust due to small sample size in these groups.

Conclusions
· Capivasertib caused dose- and concentration- dependent effects on biomarkers after only 4.5 days.
· Significant changes in the PBs were demonstrated at 480 mg BD. Biomarker changes was observed at 360mg and 240mg BD, but statistical analysis was limited by the small sample size at lower doses.
· Correlation between a number of tumor biomarkers (relative changes) were identified for capivasertib 480mg BD.
discovery of the β-catenin/Tcf inhibitors for treatment of triple negative breast cancer

Haitao Ji¹, Zhen Wang¹, Cheng Mo¹ and Min Zhang¹. ¹H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL.

In triple negative breast cancers (TNBCs), the autocrine activation of Wnt ligands, the epigenetic silencing of Wnt suppressor genes, and the cross talks between signaling pathways stabilize β-catenin in the dephosphorylated state, increase the level of nuclear β-catenin, and aberrantly activate the Wnt/β-catenin signaling pathway. The design of inhibitors for the upstream effectors of the Wnt/β-catenin signaling pathway cannot confer the inhibitory activities to cancer cells that harbor downstream APC, Axin, or β-catenin activation mutations and can perturb the function of β-catenin in cell–cell adhesion. The formation of the β-catenin/T-cell factor (Tcf) complex in the cell nucleus is the penultimate step of the Wnt/β-catenin signaling pathway. The aberrant formation of this protein–protein interaction (PPI) complex has been recognized as a key driving force for many cancers including TNBCs. Since β-catenin was reported in 1992, significant interest has been paid to screen compound libraries to discover small-molecule inhibitors that can bind β-catenin and disrupt the β-catenin/Tcf interaction. Many high-throughput screening campaigns were conducted, but little to no success was obtained. None of the reported compounds were able to deliver any drug candidates to preclinical and clinical trials. We decided to take a rational drug design approach to design new inhibitors based on the electronic properties of the key structural features for β-catenin/Tcf recognition. Our crystallographic and biochemical analyses revealed that the Tcf4 G13ANDE17 binding site of β-catenin could be targeted to design potent small-molecule inhibitors selective for the β-catenin/Tcf interaction. In combination of peptidomimetic strategy, structure-based drug design, and chemical synthesis, and biochemical and cell-based characterizations, we successfully designed and synthesized potent and selective small-molecule inhibitors for the β-catenin/Tcf interaction. The most potent inhibitor exhibited submicromolar inhibitory potency for disruption of the β-catenin/Tcf interaction. This potent inhibitor also exhibited dozens to hundreds folds of selectivities for the β-catenin/Tcf over the β-catenin/E-cadherin and β-catenin/APC interactions. The binding mode of new inhibitors was characterized by the site-directed mutagenesis and structure-activity relationship studies. The cell-based studies demonstrated that new inhibitors passed the cell membrane, significantly attenuated Wnt/β-catenin signaling in TNBC cells, and suppressed growth of Wnt/β-catenin-dependent TNBC cells. These inhibitors also exhibited cell-based selectivities for the β-catenin/Tcf over β-catenin/cadherin and β-catenin/adenomatous polyposis coli (APC) interactions.
Efficacy of neratinib in hormone receptor-positive patients who initiated treatment within 1 year of completing trastuzumab-based adjuvant therapy in HER2+ early-stage breast cancer: Subgroup analyses from the phase III ExteNET trial

**Background:** The international, randomized, placebo-controlled phase III ExteNET trial showed that 1 year (yr) of neratinib 240 mg/day after trastuzumab-based adjuvant therapy significantly improved invasive disease-free survival (iDFS) in 2840 patients with early-stage HER2+ breast cancer at 2 yr (hazard ratio 0.67; 95% CI 0.50–0.91; p=0.009) [Chan 2016] and 5 yr (hazard ratio 0.73; 95% CI 0.57-0.92; p=0.008) [Martin 2017]. A prespecified subgroup analysis by hormone receptor (HR) status suggested enhanced efficacy with neratinib in patients with HR+ (2-yr hazard ratio 0.51; 95% CI 0.33–0.77) vs. HR− tumors (2-yr hazard ratio 0.93; 95% CI 0.60–1.43). The efficacy of neratinib was also greater in patients who initiated treatment within 1 yr of prior trastuzumab compared with those who started neratinib later. The European Medicines Agency’s Committee for Medicinal Products for Human Use recently recommended neratinib for use in patients with HR+ tumors who initiate treatment within 1 yr of completing trastuzumab-based adjuvant therapy. Subgroup analyses from ExteNET examining iDFS benefits in this patient population are presented here.

**Methods:** Patients with early-stage HER2+ breast cancer who completed trastuzumab-based (neo)adjuvant therapy were assigned to oral neratinib 240 mg/day or placebo for 1 yr. Randomization was stratified by HR status (determined locally before trial entry), nodal status, and trastuzumab regimen. Endocrine therapy was allowed in patients with HR+ disease. The primary endpoint, iDFS, was tested by 2-sided log-rank test and hazard ratios (95% CI) were estimated using Cox proportional hazards models. Kaplan-Meier methods were used to estimate iDFS rates. Secondary endpoints were DFS-DCIS, time to distant recurrence, distant DFS, and CNS recurrences. The primary analysis was conducted at 2 yr, and a sensitivity analysis conducted at 5 yr. Clinicaltrials.gov:NCT00878709.

**Results:** Of the 2840 patients (neratinib, n=1420; placebo, n=1420), 1631 (57%) had HR+ disease (neratinib, n=816; placebo, n=815). Most (93%) HR+ patients were receiving endocrine therapy at baseline. 1334 of 1631 (82%) patients with HR+ tumors were randomized to start neratinib within 1 yr of last trastuzumab dose (neratinib, n=670; placebo, n=664). iDFS benefits from neratinib in this population are shown in the table. Secondary endpoints were also improved with neratinib vs. placebo in this population. Safety data in this subset will be presented at the meeting.

**Table.** iDFS in patients with an interval between last trastuzumab dose and randomization of ≤1 yr

**Conclusions:** Neratinib may have enhanced and sustained efficacy in patients with HR+ disease who initiate treatment within 1 yr of trastuzumab-based adjuvant therapy.
Patient-reported outcomes with trastuzumab monotherapy versus trastuzumab plus standard chemotherapy as a postoperative adjuvant therapy in HER2-positive elderly breast cancer patients (RESPECT): A randomized, open-label, phase 3 clinical trial

Kokoro Kobayashi¹, Naruto Taira², Masataka Sawaki³, Noriko Sagawa⁴, Shinichi Baba⁵, Tsuyoshi Saito⁶, Takuya Kawahara⁷, Yasuhiro Hagiwara⁸, Yukari Uemura⁹, Kojiro Shimozuma⁸, Yasuo Ohashi¹⁰ and Hirofumi Mukai¹¹. ¹The Cancer Institute Hospital of the Japanese Foundation for Cancer Research, Koto-ku, Tokyo, Japan; ²Okayama University Hospital, Okayama, Japan; ³Aichi Cancer Center Hospital, Nagoya, Aichi, Japan; ⁴Kameda Medical Center, Kamogawa, Chiba, Japan; ⁵Sagara Hospital, Kagoshima, Japan; ⁶Japanese Red Cross Saitama Hospital, Saitama, Japan; ⁷Clinical Research Support Center, The University of Tokyo Hospital, Bunkyo-ku, Tokyo, Japan; ⁸Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Tokyo, Japan; ⁹College of Life Sciences, Ritsumeikan University, Kusatsu, Shiga, Japan; ¹⁰Chuo University, Bunkyo-ku, Tokyo, Japan and ¹¹National Cancer Center Hospital East, Kashiwa, Chiba, Japan.

OBJECTIVE: The RESPECT trial compared 1-year trastuzumab monotherapy with trastuzumab plus standard chemotherapy as a postoperative adjuvant therapy in HER2-positive elderly breast cancer patients. Primary objective of this study was to verify the noninferiority of 1-year trastuzumab monotherapy to trastuzumab plus chemotherapy in terms of disease free survival, and the planned analysis showed that the difference of restricted mean survival time between two groups at 3 years was 0.45 months (reported by Sawaki at ASCO2018). This report assesses the patients-reported outcomes and health-related quality of life (HRQoL).

PATIENTS AND METHODS: The study was done at 99 hospitals in Japan. Elderly women (70 to 80 years old) with HER2-positive, stage I-IIIA invasive breast cancer treated by surgery with clear resection margins were randomly assigned to receive either 1-year trastuzumab or 1-year trastuzumab plus standard chemotherapy, stratified by age, hormone-receptor status, pathological lymph node metastasis and institution. Patients completed questionnaires at baseline, 2 months, 1 year, and 3 years after protocol treatment started. The primary outcome was global HRQoL assessed using Functional Assessment of Cancer Therapy-General (FACT-G) total score, and secondary outcomes were chemotherapy-induced peripheral neuropathy (CIPN), instrumental activities of daily living (IADL), anxiety, depression, and subjective happiness. We did the analyses by intention to treat, including patients who completed questionnaires at baseline before start of protocol treatment, and 5point or more change is meaningful in FACT-G total score. This study is registered with ClinicalTrials.gov, NCT01104935.

RESULTS: Between Oct 2009 and Oct 2014, 275 patients were enrolled in the study, of whom 9 patients were excluded: 135 assigned to trastuzumab monotherapy and 131 assigned to trastuzumab plus chemotherapy. We detected significant difference between treatment groups for: clinically meaningful HRQoL deterioration rate at 2 months (31% for trastuzumab monotherapy vs 48% for trastuzumab plus chemotherapy; p=0.016) and at 1 year (19% vs 38%; p=0.009), clinically meaningful HRQoL improvement rate at 2 months (38% for trastuzumab monotherapy vs 15% for trastuzumab plus chemotherapy; p<0.01) and at 1 year (43% vs 25%; p=0.021), severe sensory CIPN rate at 2 months (1.9% for trastuzumab monotherapy vs 14.4% for trastuzumab plus chemotherapy; p=0.001), IADL score at 1 year (11.97 for trastuzumab monotherapy vs 11.54 for trastuzumab plus chemotherapy; p<0.042), Hospital Anxiety and Depression Scale score at 2 months (8.92 for trastuzumab monotherapy vs 10.79 for trastuzumab plus chemotherapy; p=0.003), and subjective happiness score at 1 year (12.8 for trastuzumab monotherapy vs 11.8 for trastuzumab plus chemotherapy; p<0.024).

CONCLUSION: Given the small advantage of adjuvant trastuzumab plus chemotherapy compared to trastuzumab monotherapy for elderly HER-2 positive breast cancer women, decisions about treatment should be informed by the risk for adverse health effects associated with chemotherapy.
The impact of neratinib with or without anti-diarrheal prophylaxis on health-related quality of life in HER2+ early-stage breast cancer: Analyses from the ExteNET and CONTROL trials

Suzette Delaloge¹, Sara Hurvitz², Nancy Chan³, Ron Bose⁴, Rachel C Jankowitz⁵, Michael Thirlwell⁶, István Láng⁷, Albert ten Tije⁸, Maureen Trudeau⁹, Cynthia R Osborne¹⁰, Zhen-Zhou Shen¹¹, Feng Xu¹², Daniel Hunt¹², Elizabeth Olek¹², Debu Tripathy¹³, Hope S Rugo¹⁴, Jo Chien¹⁴, Arlene Chan¹⁵ and Carlos H Barcenas¹³. ¹Institut Gustave Roussy, Villejuif, France; ²UCLA Hematology / Oncology Clinical Research Unit, Los Angeles, CA; ³Rutgers Cancer Institute of New Jersey, New Brunswick, NJ; ⁴Washington University School of Medicine, St. Louis, MO; ⁵UPMC Magee-Womens Hospital, Breast Center, Pittsburgh, PA; ⁶McGill University Health Centre Cedars Cancer Centre, Montréal, Canada; ⁷Orszagos Onkolgiai Intezet ”B” Belgyogyaszati Osztaly, Budapest, Hungary; ⁸Amphia Ziekenhuis, Breda, Netherlands; ⁹Sunnybrook Research Institute, Sunnybrook Health Sciences Centre, Toronto, Canada; ¹⁰Texas Oncology, PA and US Oncology, Dallas, TX; ¹¹Shanghai Cancer Center, Fudan University, Shanghai, China; ¹²Puma Biotechnology Inc., Los Angeles, CA; ¹³MD Anderson Cancer Center, Houston, TX; ¹⁴UCSF Helen Diller Family Comprehensive Cancer Center, San Francisco, CA and ¹⁵Breast Cancer Research Centre-Western Australia and Curtin University, Nedlands, Australia.

Background: Neratinib is an irreversible pan-HER tyrosine kinase inhibitor. ExteNET, a randomized placebo-controlled phase III study, showed that neratinib given for 12 months after trastuzumab-based adjuvant therapy significantly improved 2-year (HR 0.67; 95% CI 0.50–0.91; p=0.0091) and 5-year (HR 0.73; 95% CI 0.57-0.92; p=0.008) iDFS in pts with early-stage HER2+ breast cancer. Anti-diarrheal prophylaxis was not mandated by protocol; grade 3/4 diarrhea occurred in 40% of pts with a median cumulative duration of 5 days. The phase II CONTROL study was initiated to investigate the effectiveness of various prophylactic regimens in the prevention of neratinib-associated diarrhea. Loperamide (L) alone or in combination with add-on agents targeting underlying inflammation [i.e. budesonide (BUD)] or bile acid malabsorption [i.e. colestipol (COL)] were tested. We report longitudinal HRQoL findings from both ExteNET and CONTROL.

Methods: Pts with early-stage HER2+ breast cancer who had received trastuzumab-based adjuvant therapy were eligible for both studies. In ExteNET, pts received neratinib or placebo for 12 months. In CONTROL, pts received neratinib for 13 x 28-day cycles combined with L, L + BUD or L + COL for 1 or 2 cycles (see table for schedules). HRQoL was assessed using Functional Assessment of Cancer Therapy–Breast (FACT-B), v4.0, at baseline, months 1, 3, 6, 9, 12 (ExteNET) or baseline, cycles 2, 4, 7, 10, 13 (CONTROL). Changes in scores from baseline were considered to be clinically meaningful if greater than the lowest estimate for an ‘important difference’ (ID) reported in the literature. Evaluable pts were required to have HRQoL assessments at baseline and at least 1 post-baseline. ClinicalTrials.gov: NCT00878709 (ExteNET); NCT02400476 (CONTROL).

Results: HRQoL findings are summarized in the table. Hospitalization rates due to diarrhea: 1.5% (neratinib + L), 0% (other cohorts) in CONTROL; and 1.4% (neratinib), 0.1% (placebo) in ExteNET.

C, cycle; L, loperamide; M, month; N, neratinib; prn, as needed; PWB, physical well-being. CONTROL cut-off: 1 May 2018. <sup>a</sup>N 240 mg qd for 13 x 28d cycles or 12 months; <sup>b</sup>L 4 mg, then 4 mg tid d1-14, then 4 mg bid d15-28 or d15-56, then prn; <sup>c</sup>BUD 9 mg qd d1-28; <sup>d</sup>COL 2 g qd d1-28; <sup>e</sup>n=1.

Conclusions: Adjuvant neratinib with or without anti-diarrheal prophylaxis was associated with small decreases in HRQoL. With the exception of the FACT-B PWB subscale, HRQoL changes did not reach clinically meaningful thresholds. Follow-up in CONTROL is ongoing.

INTRODUCTION: Although large randomized trials assessing the benefit of adjuvant trastuzumab in HER2-positive (HER2+) breast cancer have clearly demonstrated a significant improvement in long-term survival, it is necessary to know the impact of the use of trastuzumab adjuvant in the real life population, which includes patients frequently excluded from clinical trials, such as those with very small tumors without node involvement, or advanced age. The objective of this study is to describe the outcomes of women who received adjuvant trastuzumab for HER2+ cáncer since it was approved in 2006, compared with a previous cohort of HER2+ patients not treated with trastuzumab in 7 Spanish centers.

METHODS: Women with newly diagnosed stage I-III, HER2+ breast cancer, between 1997 and 2015 were included in the study. Two cohorts were considered: The No-Trastuzumab cohort (No-T), between 1997 and 2005, and the Trastuzumab cohort (T) with trastuzumab-treated women between 2006 and 2015. Kaplan-Meier estimates were used to evaluate DFS and OS. Additionally, cohorts were analyzed by pathologic tumour size, lymph node involvement and hormonal receptor status to stratify outcome measures.

RESULTS: A total of 2134 patients were identified. In 164 cases, data were insufficient or the follow-up incomplete. Therefore, the final analysis included 1970 patients, of whom 539 belong to the "No-T" cohort and 1431 to the "T" cohort. The median follow-up was 81 months. Median age: 53 years [22-98]. A total of 699 patients had T1 tumors [43% in the "No-T" cohort vs 33% in the "T" cohort]. 55% of the cases were N0 [58% and 54% in the "No-T" and "T" cohorts respectively]. The status of the hormonal receptors was well balanced between groups [36% ER negative in both]. Regarding the type of adjuvant treatment administered, in the "T" cohort more patients received adjuvant chemotherapy [65% vs 97%] and also in the "T" group combinations of taxanes and anthracyclines were more frequent [14% vs 72%]. The proportion of adjuvant endocrine therapy was similar in both groups [37% vs 34%].

In the "T" cohort, median Disease Free Survival (DFS) was not-reached, compared with 149 months in the "No-T" group. 5-year DFS was 83% vs 65% respectively [p<0.001]. 5-year DFS was also superior and statistically significant in all the subgroups analyzed, including patients with T1 tumors (87% vs 57%), N0 (87% vs 78%), patients T1N0 (88% vs 74%) and HR positive (86% vs 71%) or negative (78% vs 50%). Similarly, Overall Survival (OS) was increased in patients treated with Trastuzumab (median: 224 months vs not-reached, 5-year OS: 92% vs 75% [p <0.001]). 5-year OS was also statistically superior in the T1 subgroup (92% vs 72%), and N0 (95% vs 88%). [p<0.001 in all subanalysis].

CONCLUSIONS: Adjuvant treatment with Trastuzumab under conditions of real clinical practice in HER2+ early breast cancer, shows a highly significant benefit in terms of DFS and OS, regardless of the stage of the disease or other clinical variables. A very important benefit was reached in patients with small tumors, node-negative disease, or both conditions (T1N0). The benefit was also obtained regardless of the expression of hormonal receptors.
Prevalence of trastuzumab-induced cardiotoxicity in a real-world setting

Oscar Calvillo-Argüelles\textsuperscript{1}, Diana Flores-Díaz\textsuperscript{1}, Juan-Pablo González-Serrano\textsuperscript{1}, Adolfo López-Rojas\textsuperscript{1}, Leticia Mendoza-Galindo\textsuperscript{1}, Juan-Antonio Matus-Santos\textsuperscript{1}, Nancy Reynoso-Noverón\textsuperscript{1}, Paula Cabrera-Galeana\textsuperscript{1}, Enrique Bargalló-Rocha\textsuperscript{1} and Claudia Arce-Salinas\textsuperscript{1}. \textsuperscript{1}Instituto Nacional de Cancerología, Mexico, CDMX, Mexico.

\textbf{Background:} Trastuzumab treatment plus adjuvant or neoadjuvant chemotherapy is the standard of care for women with HER2 positive breast cancer. Despite relative low rates of cardiotoxicity observed in randomized clinical trials, trastuzumab interruption driven by LVEF reduction is a major concern in current clinical practice.

\textbf{Patients and methods:} We retrospectively identified women with stage I-III HER2 positive breast cancer who received 12 months of trastuzumab treatment after adjuvant or neoadjuvant chemotherapy at Instituto Nacional de Cancerología (INCan, Mexico City), between 2006 and 2018. Patients were eligible if a pre-therapy MUGA scan and \geq 2 subsequent follow-up scans were available. Cardiotoxicity was defined as a \geq 10\% LVEF reduction to a value < 50\%, associated with trastuzumab interruption.

\textbf{Results:} 910 patients were included, with a median age at diagnosis of 50 (24-85) years and a median follow up of 7 (2-11) years. Among the whole cohort, 10.3\% of patients had diabetes, 15.4\% had hypertension, 78\% were obese/overweight, and 40\% had positive estrogen and/or progesterone receptor status. Anthracycline-based therapy was used in 819 (90\%) patients, with a median (doxorubicin equivalent) cumulative dose of 200 mg/m\textsuperscript{2} (IQR 180-240). The median baseline LVEF was 61.8\% (50-88.9). In total, 94 (10.3\%) patients developed cardiotoxicity, but symptomatic heart failure was observed in only 31 (3.4\%) individuals. In univariable analyses, the development of cardiotoxicity was not associated significantly with cardiovascular risk factors.

\textbf{Conclusions:} In this large single-center cohort, cardiotoxicity rates remain high, thus, interventions to minimize the risk of cardiotoxicity and trastuzumab treatment interruption should be considered.
Long term clinical follow up of real world HER2-positive patients since the introduction of trastuzumab

Sander Ellegard¹, Mustafa Asowed¹, Kristina Engvall¹², Anna-Lotta Hallbeck¹, Nils Elander¹ and Olle Stål¹. ¹Department of Clinical and Experimental Medicine and Department of Oncology, Linköping, Sweden and ²Ryhov County Hospital, Jönköping, Sweden.

Background: The prognosis for patients with HER2-positive early breast cancer (EBC) has improved dramatically since the introduction of adjuvant trastuzumab therapy. With the addition of pertuzumab the prognosis has improved further. However, there is a need to study how these results from clinical controlled trials are transferred to the real-world clinical setting. In this study we aim to investigate all patients with early HER2-positive breast cancer in our region since the introduction of adjuvant trastuzumab to evaluate the implementation of trastuzumab treatment regarding treatment coverage, prognosis and survival.

Method: All patients with HER2-positive EBC, diagnosed between 2006 and 2014 in South-east Sweden were included in the study. The patients were identified using the Swedish national breast cancer register and then cross-referenced with data from the pathology department at each hospital in order to obtain complete coverage in a retrospective clinical follow up. In addition, data were collected from medical records for each patient to verify the actual given treatments and survival data.

Results: Preliminary data is available. 611 patients were included with a median follow-up time of 5 years. During the follow-up period the number of patients diagnosed with HER2-positive EBC cancer doubled. 73% of all patients received trastuzumab treatment; however the coverage increased successively from 56% in 2006 to 83% in 2013. ER-positive patients did receive trastuzumab therapy to the same extent as ER-negative patients. Local recurrence-free survival (LRFS), distant recurrence-free survival (DRFS) and breast cancer specific survival (BCSS) at 5 years were 85%, 76%, and 75% for patients not receiving trastuzumab. In the trastuzumab treated group LRFS, DRFS and BCSS was 95%, 85% and 83% respectively. The group not receiving trastuzumab was significantly older, had more frequently node negative disease and was not treated with chemotherapy to the same extent.

Conclusion: A significant amount of early HER2-positive breast cancer patients did not receive adjuvant trastuzumab therapy between 2006 and 2014. In this group fewer patients received chemotherapy and despite less nodal involvement LRFS, DRFS and BCSS were poor for these patients.
Efficacy of short-course adjuvant trastuzumab in early stage breast cancer

Maher Saifo1 and Majd Nikoula1. 1Al Bairouny University Hospital, Damascus, Syrian Arab Republic.

**Background:** A total of 12 months adjuvant Trastuzumab is still the optimal choice for patients with human epidermal growth factor receptor 2 (HER2)-positive early breast cancer. Still, the adjuvant short course 9-week trastuzumab may be considered as a cost-effective and safe option in developing countries such as Syria.

**Purpose:** The primary objective was disease-free survival after short course adjuvant Trastuzumab therapy in early breast cancer at Al-Bairouni university hospital compared with 6 month of adjuvant trastuzumab, the secondary objective was assessing toxicities especially cardiac toxicity.

**Patients and methods:** Women with histologically confirmed HER2 positive BC with either positive or negative hormone receptor of stages IA,IIA,IIB,IIIC,IIIA,IIIB and IIIC were eligible for the study. Patients were assigned to 2 groups. The initial systemic treatment was similar in the 2 groups. Thereafter, no further Trastuzumab or chemotherapy was administered in Arm A; 90 patients (loading dose 4 mg/kg; then 2mg/kg weekly to complete 9 weeks of T), whereas in Arm B that included 157 patients single-agent T was administered to complete 6 months (loading dose 8 mg/kg then 6 mg/kg every 3 weeks). The LVEF was measured pretreatment, and every 3 months afterward.

**Results:** After a median follow up of 24 months DFS was 89.06% and 89.81% in groups A and B respectively (P=0.11). No obvious side effects have been noticed during the follow up period in group A. Otherwise congestive heart failure was reported in 2.55% of group B patients.

**Conclusion:** Short course 9 weeks adjuvant Trastuzumab achieved a good 2 years disease-free survival rate (DFS) compared to 6 month of treatment, with acceptable toxicity and good tolerability for treated patients with early-stage invasive breast cancer. Patients are being monitored for a longer follow up period.
The impact of local therapy on locoregional recurrence in women with high risk breast cancer in the neoadjuvant I-SPY2 TRIAL

Jordyn Silverstein1, Leena Suleiman1, Christina Yau1, Elissa R Price1, Ruby Singhrao1, Douglas Yee2, Angela DeMichele3, Claudine Isaacs4, Kathy S Albain5, A Jo Chien1, Andres Forero-Torres6, Anne M Wallace7, Lajos Pusztai8, Erin D Ellis9, Anthony D Elias10, Julie E Lang11, Janice Lu11, Heather S Han12, Amy S Clark3, Larissa Korde13, Rita Nanda14, Donald W Northfelt15, Qamar J Khan16, Rebecca K Viscusi17, David M Euhus18, Kirsten K Edmiston19, Stephen Y Chui20, Kathleen Kemmer21, William C Wood22, John W Park1, Minetta C Liu23, Ofuonumileyo Olopade14, Brian Leyland-Jones24, Debasish Tripathy25, Stacy L Moulder25, Hope S Rugo1, Richard Schwab7, Shelly Lo5, Teresa Helsten7, Heather Beckwith2, I-SPY 2 TRIAL Consortium26, Donald A Berry27, Smita M Asare28, Laura J Esserman1, Judy C Boughey23 and Rita A Mukhtar1. 1University of California, San Francisco, San Francisco, CA; 2Masonic Cancer Center, University of Minnesota, Minneapolis, MN; 3University of Pennsylvania, Philadelphia, PA; 4Georgetown University, Washington, DC; 5Loyola University, Maywood, IL; 6University of Alabama at Birmingham, Birmingham, AL; 7University of California, San Diego, La Jolla, CA; 8Yale Cancer Center, New Haven, CT; 9Swedish Cancer Institute, Seattle, WA; 10University of Colorado, Denver, Aurora, CO; 11University of Southern California, Los Angeles, CA; 12Moffitt Cancer Center, Tampa, FL; 13CTEP, National Cancer Institute, Bethesda, MD; 14The University of Chicago Medical Center, Chicago, IL; 15Mayo Clinic, Scottsdale, Scottsdale, AZ; 16University of Kansas, Westwood, KS; 17University of Arizona, Tucson, AZ; 18Johns Hopkins Medicine, Dallas, TX; 19Inova Health System, Fairfax, VA; 20Genentech, Portland, OR; 21Oregon Health & Science University, Portland, OR; 22Emory University, Atlanta, GA; 23Mayo Clinic, Rochester, Rochester, MN; 24Avera Cancer Institute Center for Precision Oncology, Sioux Falls, SD; 25University of Texas, M.D. Anderson Cancer Center, Houston, TX; 26Quantum Leap Healthcare Collaborative, San Francisco, CA and 27Berry Consultants, LLC, Houston, TX.

Background: In women with breast cancer receiving neoadjuvant chemotherapy, residual cancer burden (RCB) predicts distant recurrence and survival. In those with high risk tumors, locoregional recurrence (LRR) remains a concern, and has been associated with type of local therapy received. We evaluated the impact of local therapy on LRR in the ISPY-2 TRIAL.

Methods: Data were analyzed in Stata 14.2, using Chi2 test, log rank test, and a Cox proportional hazards model. RCB was considered a categorical variable (0/1 versus 2/3), as described in prior publications. Breast surgery categories were lumpectomy + radiation (HR 3.1, 95% CI 1.1-9.2, p=0.043).

Results: Follow up data from the I-SPY2 TRIAL were available for 630 patients (median follow up 2.76 yrs, range 0.4-7.2). Type of local therapy was significantly associated with clinical stage at presentation, with stage III patients most frequently undergoing mastectomy + radiation (p<0.001). Women with higher RCB were more likely to undergo mastectomy than those with lower RCB (61.3% vs 48.8% mastectomy rate, p=0.002), and more likely to receive adjuvant radiotherapy (62.0% vs 53.9%, p=0.048). There was no association between clinical stage, type of surgery, or radiotherapy and LRR (Table). Higher RCB was significantly associated with LRR, with 3 year locoregional recurrence free rate of 95.1% in RCB 0/1 versus 89.9% in RCB 2/3 (p=0.003). In a Cox model adjusting for clinical stage, tumor subtype, surgical therapy, RCB status, nodal radiation, and age, significant predictors for LRR were tumor subtype and RCB status. Hazard ratio (HR) for LRR in those with RCB 0/1 was 0.39 compared to those with RCB 2/3 (95% CI 0.17-0.87, p=0.021). There was no difference in LRR between breast conservation and mastectomy; within the breast conservation group, those who had lumpectomy alone had higher hazard of LRR compared to those having lumpectomy + radiation (HR 3.1, 95% CI 1.1-9.2, p=0.043).

Conclusions: Extent of surgical therapy was not associated with local tumor control, regardless of advanced tumor stage at presentation. Rather, tumor biology and response to therapy were the best predictors of LRR. These data highlight the opportunity to minimize the morbidity of extensive surgical therapy for patients with excellent response to systemic therapy.

Get skin sparing mastectomy right: Reduce local recurrence rate by meticulous removal all breast tissue

Eric H Drabble. Derriford Hospital, Plymouth, United Kingdom.

Background:
Skin sparing mastectomy (SSM) was introduced to allow aesthetically better results when combined with breast reconstruction. However, preservation of a larger skin envelope than that left after standard mastectomy could lead to retention of significant amounts of residual breast tissue in the subcutaneous fat, increasing the risk of local recurrence or new breast cancers developing.

Study method:
Over a 15 year period, subcutaneous fat samples were routinely sampled during SSM and reconstruction performed by one surgeon. SSM was offered to all patients bar those with inflammatory cancers unresponsive to primary chemotherapy and those medically unfit for surgery. Hospital and personal databases of these cases were interrogated for:
- presence of breast epithelial tissue in subcutaneous fat samples
- local recurrence
- systemic recurrence
- aesthetic grade by independent surgeons

Results:
402 SSM were reviewed. Results of subcutaneous samples were recorded for 357.
3 patients had residual breast tissue in subcutaneous fat samples (0.75%),
4 developed a local recurrence (1%), 42 systemic recurrence (11%).
238 patients had G1-3 invasive ductal carcinoma, size range 3-100mm, 25 invasive lobular carcinoma, 12.5-88mm and 87 DCIS, 20-116mm. These included patients who responded to preoperative chemotherapy and hormone therapy. 52 patients had prophylactic procedures.
The aesthetic outcome was judged as good for 76%, moderate for 20%.
The median follow up period was 9 years, giving annual local and systemic recurrence rates of 0.11% and 1.16% respectively.

Conclusions:
There was a low incidence of residual breast tissue in random subcutaneous fat samples collected during SSM (0.75%)
The local recurrence rate was one tenth of the systemic recurrence rate, 1% vs 11%, and annual rates of 0.11% and 1.16% respectively.

Discussion:
Surgery for breast cancer is a local treatment, and though removal of the main tumor will contribute to systemic control, that will be achieved by a combination of local and systemic therapies based on the biology of the individual’s disease. Once surgery is performed, it can have no further influence on systemic control. However, the meticulousness of the surgical procedure can influence subsequent local control. Residual breast tissue left after mastectomy may harbor areas of disease that may not respond to other adjuvant therapies leading to local recurrence, or separate new cancers. Traditionally it has been considered that some breast tissue will be retained in skin flaps post mastectomy, up to 5% with standard mastectomies. This study suggests that this can be avoided, even when a large skin envelope is retained for an aesthetic outcome, and lead to a marked reduction in local recurrence.
Longitudinal changes in psychosocial health in young women following breast cancer surgery: Results from a multi-center cohort study

Shoshana M Rosenberg\textsuperscript{1}, Jiani Hu\textsuperscript{1}, Laura S Dominici\textsuperscript{1,2}, Philip D Poorvu\textsuperscript{1}, Kathryn J Ruddy\textsuperscript{3}, Rulla M Tamimi\textsuperscript{2}, Lidia Schapira\textsuperscript{4}, Steven Come\textsuperscript{5}, Jeffrey M Peppercom\textsuperscript{6}, Virginia F Borges\textsuperscript{7} and Ann H Partridge\textsuperscript{1}. \textsuperscript{1}Dana-Farber Cancer Institute, Boston, MA; \textsuperscript{2}Brigham and Women's Hospital, Boston, MA; \textsuperscript{3}Mayo Clinic, Rochester, MN; \textsuperscript{4}Stanford University, Stanford, CA; \textsuperscript{5}Beth Israel Deaconess Medical Center, Boston, MA; \textsuperscript{6}Massachusetts General Hospital, Boston, MA and \textsuperscript{7}University of Colorado Cancer Center, Aurora, CO.

Background: Young women with breast cancer (BC) are increasingly choosing contralateral prophylactic mastectomy (CPM), yet little is known about the impact of surgical choices on quality of life (QOL) and psychological health. Using a large, prospective cohort of young women with BC, we sought to evaluate psychosocial outcomes following surgery.

Methods: Among participants of the Young Women's BC Study, a multi-center cohort of women dx'd with BC at age ≤40, we identified women with Stage 0-3 unilateral BC who had surgery and completed surveys that included measures of QOL (CARES) and psychological health (HADS). Linear mixed-effects models were fit to assess changes from 1 to 3 years (yrs) post-dx in anxiety, depression, psychosocial, body image, and sexual scores. Adjusted (stage, hormone receptor status, chemotherapy, age) means were estimated and differences compared (Bonferroni adjusted p-values) between CPM vs breast conserving surgery (BCS) and unilateral mastectomy (UM) at 1, 2, and 3 yrs.

Results: Of 863 women, 30% had BCS, 24% UM, 46% CPM. Median age at dx was 37 (range: 22-40). Of women who had UM/CPM, 84% had reconstruction. Among women who had CPM, mean body image (p=.02), psychosocial (p<.0001), sexual (p<.0001), and depression (p=.0007) scores decreased, indicating improvement, from yr 1 to 2 but remained stable from yr 2 to 3 (Table). Anxiety decreased from yr 1 to 2 for women who had BCS (p=.0007) and M (p=.03), and from yr 2 to 3 for women who had CPM (p=.003). Body image scores did not change significantly between any time points among women who had M or BCS. Overall change trajectories for sexual (p=.03) and anxiety scores (p=.008) differed by surgery. Compared to BCS and UM, psychosocial scores were higher in women who had CPM at 1 yr (p<.05) and remained higher compared to BCS at 2 yrs (p=.04). Anxiety was higher among women who had CPM vs UM at 1 and 2 yrs (p<.01), vs BCS at 2 yrs (p=.004). Depression was higher among women who had CPM vs UM in yr 1 (p=.05). By yr 3, there were no significant differences in anxiety, depression, and overall psychosocial scores between groups. Compared to BCS, women who had CPM had higher sexual and body image scores (p<.01), indicating worse QOL, at all timepoints. Compared to UM, women who had CPM had higher sexual scores at 1 and 3 yrs (p<.05) and body image scores at 3 yrs (p=.02).

Conclusions: While psychosocial health improves over time, differences by surgery persist, with women who have CPM experiencing more sexual and body image issues compared to women who undergo BCS or M in the years following surgery. Given that surgical choices may be affected by distress experienced before or at dx, ensuring young women receive adequate support when making surgical decisions as well as after surgery is warranted.

Genetic testing and bilateral mastectomy for women with breast cancer: Does testing matter more than the test result?

Francys C Verdial¹, Matthew A Bartek¹, Benjamin O Anderson¹,² and Sara H Javid¹. ¹University of Washington, Seattle, WA and ²Fred Hutchinson Cancer Research Center, Seattle, WA.

Background: Genetic testing for hereditary breast cancer may allow women with breast cancer to make informed and individualized decisions regarding breast cancer treatment and strategies to reduce the risk of contralateral breast cancer. While rates of bilateral mastectomy (therapeutic mastectomy + contralateral prophylactic mastectomy) among women with unilateral breast cancers are known to be increasing, the factors influencing this decision and the role of genetic testing are poorly understood. We examined bilateral mastectomy rates and factors associated with bilateral mastectomy among women with unilateral breast cancer.

Methods: We identified patients diagnosed with unilateral breast cancer from 2000-2015 from The Health of Women Study, a cohort study led by the Dr. Susan Love Research Foundation. We calculated rates of bilateral mastectomy among women who underwent surgical treatment for breast cancer. We used multivariable logistic regression models to evaluate factors associated with bilateral mastectomy.

Results: Among 2,028 patients who underwent surgery for unilateral breast cancer, 19% underwent bilateral mastectomy. Forty-one percent (n= 84 of 205) of patients who underwent testing and tested positive for a deleterious mutation underwent bilateral mastectomy, compared to 26% (n= 439 of 1,689) of women who tested negative and 12.5% (n= 274 of 2,197) of those not tested. Among those with a negative genetic test, pre-test risk of harboring a genetic mutation (based on family history and age at diagnosis) was not associated with bilateral mastectomy (p=0.250). After adjusting for race, age, level of education, and pre-test mutation risk, the odds of bilateral mastectomy were 69% higher among patients who underwent genetic testing (OR 1.69, 95% CI 1.29–2.22, p<0.001) versus those who did not undergo genetic testing. This finding was consistent regardless of genetic test result.

*Adjusted for age, race, and level of education.

Conclusions: Genetic testing among breast cancer patients, regardless of test result or pre-test mutation risk, is significantly associated with bilateral mastectomy. Many women (~1/4) with a negative genetic test and at low risk of hereditary breast cancer, by family history and age at diagnosis, currently undergo bilateral mastectomy with unclear benefits. Further qualitative research will aim to elucidate reasons driving choice of bilateral mastectomy among women with breast cancer.
Can an internal surgical adhesive facilitate drain-free mastectomy and reduce overall invasiveness? - A prospective, randomized, controlled, multicenter non-inferiority trial

Christian Eichler1, Stefan Paepke7, Ralf Ohlinger4, Warm Mathias1, Iris Scheffen2, Michael Lux3, Sirwan Hadad8, Tamara Kiernan9, Lisa Whisker10, Monika Kaushik5 and Polly King6. 1Kliniken der Stadt Köln, Brustzentrum, Köln, Germany; 2St. Elisabeth Krankenhaus, Brustzentrum, Köln, Köln, Germany; 3Universitätsklinikum Erlangen, Frauenklinik, Erlangen, Erlangen, Germany; 4Universitätsklinik Greifswald, Interdisziplinäres Brustzentrum, Greifswald, Greifswald, Germany; 5University Hospitals of Leicester, Leicester, Leicester, United Kingdom; 6Royal Cornwall Hospital, Cornwall, Cornwall, United Kingdom; 7Klinik und Poliklinik für Frauenheilkunde Technische Universität München, Brustzentrum, München, Germany; 8Royal Hallamshire Hospital, Sheffield, Sheffield, United Kingdom; 9St. Helens and Knowsley Teaching Hospitals, St. Helens, St. Helens, United Kingdom and 10Nottingham University Hospitals, Nottingham, Nottingham, United Kingdom.

Introduction: Mastectomy closure without drains has many potential advantages. Flap fixation techniques have shown to be an effective alternative to drains. This study tested the non-inferiority of a surgical adhesive in overall invasiveness compared to standard wound closure with drains. Methods: This trial (ClinicalTrials.gov Identifier: NCT02958449) recruited seventy-seven patients undergoing eighty-four mastectomies +/- SLNB (n=84) at eleven international centers. Procedures were prospectively randomized to standard wound closure with drains (SWC; n=41) or wound closure without drains using a high strength lysine-based adhesive named TissuGlu® (TG; n= 43). The primary outcome measured assessed overall invasiveness using the number of post-operative clinical interventions, including drain removals and needle aspirations. Secondary endpoints included total wound drainage, cumulative days of treatment, days to drain removal and wound healing related complications. A patient questionnaire evaluating quality of life measures was also administered. Results: Subjects in the TissuGlu® group required significantly fewer post-operative clinical interventions (1.25 ± 1.39 TG vs. 2.03 ± 1.45 SWC, p = <.0001) compared to the Control group and had fewer cumulative days of treatment (defined as days of drains being in place and / or days on which an aspiration occurred; 2.14 ± 4.15 TG vs. 5.76 ± 4.02 SWC, p = <.0001). Presence of a drain was associated with significantly higher pain and lower mobility scores. Conclusion: The study demonstrates that flap fixation with this adhesive can permit drain-free mastectomy closure, reducing overall invasiveness and patient morbidity.
Use of an activatable cell penetrating peptide-fluorescent imaging agent (AVB-620) to identify positive and close margins intraoperatively

Steven L Chen¹, Paul L Baron², Marie C Lee³, Sheldon M Feldman⁴, Sarah A McLaughlin⁵, Alicia M Terando⁶, Alec Harootunian¹, Phillip Poonka¹ and Jesus E Gonzalez¹. ¹Avelas Biosciences, Inc, La Jolla, CA; ²Roper St. Francis, Charleston, SC; ³Moffitt Cancer Center, Tampa, FL; ⁴Montefiore Hospital and Medical Center, Bronx, NY; ⁵Mayo Clinic, Jacksonville, FL and ⁶Ohio State University, Columbus, OH.

Background:
Intra-operative identification of positive margins and lymph nodes continues to be a challenge for breast cancer surgeons. Current techniques such as frozen section or touch prep cytology are time consuming and vary in accuracy across institutions. Our study is the first part of a phase 2 trial of a systemically administered, ratiometric, activatable, cell-penetrating fluorescent peptide dye conjugate that visualizes breast cancer tumor tissue in vivo and ex vivo. We hypothesized that this method would be able to identify breast cancer close to the margin of lumpectomy specimens.

Methods:
AVB-620 is a cell penetrating peptide-fluorescent imaging agent which undergoes proteolytic cleavage by proteases in the matrix metalloproteinase family that have higher activity in cancerous tissue. After cleavage, the predominant fluorescent emission wavelength changes and fluorescent intensity increases, generating a ratiometric readout. AVB-620 was administered 3- 24 hours prior to operation via intravenous infusion to stage 0-III breast cancer patients. Patients were monitored for safety followed by primary breast surgery and either sentinel lymph node biopsy (SLNB) with radiotracer only or axillary lymph node dissection (ALND). Using a near-infrared camera system, fluorescent intensity of two wavelengths was measured intraoperatively both in vivo and ex vivo, including primary tumors, shave margins, and lymph nodes. The ratio of the intensity of these two wavelengths was utilized to distinguish between malignant and non-malignant tissues and visualized on a video monitor. Pathology reports were correlated to a computer-assisted human review of the fluorescent images.

Results:
Thirty-two patients were dosed without adverse events attributable to the agent; 31 were evaluable for fluorescent imaging. The average age of patients was 60 years (range 32-79). All patients underwent lumpectomy and axillary surgery. Two patients received neoadjuvant chemotherapy; 10% of patients had pure DCIS tumors. Among invasive tumors: 94% were ER+; 13% were high grade. All primary tumor images demonstrated fluorescent intensity and ratiometric changes that differentiated malignant and non-malignant tissue. 35% of patients had at least one positive margin (invasive tumor on ink or DCIS ≤2mm from ink). 61% of cases had at least one margin that was considered either close (≤2mm from ink for invasive tumor) or positive on H&E staining. 84% of patients with positive/close margins were identified utilizing fluorescent imaging. Four of the 5 patients with positive nodes had a positive fluorescent image.

Discussion:
These results demonstrate the ability of AVB-620 to identify and visualize malignant tumor and lymph nodes intraoperatively, illustrating the potential of such a tool to decrease reoperation rates. The second part of this phase II study is underway where intraoperative fluorescent imaging will be utilized to guide removal of additional shave margins.
Clinicopathological features and prognosis of nipple–areola and skin flap recurrence after nipple-sparing mastectomy for breast cancer over 20 years

Teruhisa Sakurai1,5, Takaomi Suzuma2, Goro Yoshimura3, Eri Sasaki1, Teiji Umemura4 and Takeo Sakurai5. 1Wakayama Medical University, Kihoku Hospital, Ito Gun Katsuragi Cho, Wakayama, Japan; 2Kushimoto Arida Hospital, Kushimoto, Wakayama, Japan; 3Kishiwada City Hospital, Kishiwada, Osaka, Japan; 4Kiwa Hospital, Hashimoto, Wakayama, Japan and 5Sakurai Breast Clinic, Wakayama, Wakayama, Japan.

Background: Nipple-sparing mastectomy (NSM) is an increasingly popular surgical procedure for treatment of breast cancer. However, NSM is controversial because of its association with locoregional recurrence. We started performing NSM in 1978.

Methods: We investigated the surgical safety including nipple necrosis, and nipple–areola recurrence (NAR) and skin flap recurrence (SFR) after NSM for 1071 patients with breast cancer, including 31 with stage 0, 414 with stage 1, 479 with stage 2, 141 with stage 3 and 6 with stage 4, from 1985 to 2017. Our NSM method involved creating a thick skin flap to avoid surgical complications. No patients received radiotherapy. In 1034 patients with stage 1–3 breast cancer treated with NSM who developed NAR or SFR, we evaluated cancer stage, nuclear grade, lymph node metastasis, tumor–nipple–areola distance, and histological classification as tubule forming, solid and scirrhous type. In 748 patients with early stage 1 and 2A breast cancer treated with NSM, NAR and SFR were evaluated for estrogen receptor and HER2 expression. We evaluated disease-free interval and frequency of late NAR and SFR. Results: Median follow-up after NSM was 87 (3–397) months. There was only one case of total nipple necrosis among all 1071 patients. There were 96 patients (9.0%) with local recurrence, including 44 (4.0%) with NAR and 52 (4.8%) with SFR. NAR was seen in 1 (3.1%), 14 (3.4%), 17 (5.1%), 5 (3.4%), 7 (5.0%) and 0 patients with stage 0, 1, 2A, 2B, 3 and 4 cancer, respectively. SFR was seen in 0, 15 (3.6%), 8 (2.7%), 7 (4.8%), 22 (15.6%) and 0 patients with stage 0, 1, 2A, 2B, 3 and 4 cancer, respectively. Median disease-free interval of NAR and SFR was 3.4 (0.96–22.3) and 2.5 (0.21–21.2) years, respectively. Twenty-three (53%), 12 (27.9%) and 6 (14%) patients had NAR at more than 3, 5 and 10 years after NSM, respectively. Twenty (38%), 13 (25%) and 6 (11.5%) patients had SFR at more than 3, 5 and 10 years after NSM, respectively. Therefore, late NAR and SFR were observed. Patients with stage 1–3 cancer treated with NSM who had significantly more frequent NAR, were characterized by high nuclear grade and tubule-forming type cancer. Patients with significantly more frequent SFR were characterized by stage 3 cancer, positive lymph node metastasis and age ≤40 years. Patients with early stage breast cancer treated with NSM with significantly more frequent NAR had negative estrogen receptor expression, positive HER2 expression and shorter tumor–nipple–areola distance (≤2 cm). Overall survival was significantly better in patients with NAR (97% at 5 years and 80% at 10 years) than SFR (71% at 5 years and 50% at 10 years). Regarding SFR, overall survival was significantly worse for multiple (≥2) and diffuse (clinical inflammatory syndrome) recurrence than for single-nodule recurrence. There was no significant difference in prognosis between NAR and single-nodule SFR. Conclusions: Our data showed that clinicopathological features and prognosis differed between patients with NAR and SFR. There was no significant difference in prognosis between NAR and single-nodule SFR. Late NAR and SFR were seen, and careful long-term follow-up observation is necessary after NSM.
A novel nipple aleolar complex involvement predictive index (NACPI) for indicating nipple sparing mastectomy in breast cancer patients

Hirohito Seki¹, Takashi Sakurai¹, Ken Shimizu², Shyodai Mizuno¹, Toshiki Tokuda¹, Takuji Kaburagi¹, Minako Seki¹, Tsuyoshi Karahashi¹ and Kenichiro Nakajima¹. ¹Saitama Medical Center, 4-9-3 Kitaurawa, Urawa City, Saitama, Japan and ²Division of Pathology, 4-9-3 Kitaurawa, Urawa City, Saitama, Japan.

Background: While Preservation of NAC is concerned to increase the risk of local recurrences in the retroareolar glandular tissue, nipple sparing mastectomy (NSM) is increasing in patients with breast cancer and has been shown to result in better cosmetic outcome and the benefit for quality-of-life. It is necessary to predict accurately NAC involvement in order to select which patients may be candidates to NSM. The distance from the nipple to the tumor (DNT) is proposed as one of the best criteria to select the patient. The purpose of this study is to identify the predictors of NAC involvement retrospectively and to develop a clinical predictive model to select the patients who can be offered preservation of NAC.

Methods: A total of 168 patients with primary operable breast cancer who received subcutaneous mastectomy for breast reconstruction at Saitama Medical Center during July 2013 to December 2017 were selected from the hospital's surgical database. NAC involvement was defined by the presence of invasive carcinoma and/or ductal carcinoma in situ at the subareolar margin.

Results: Of the 148 patients who were preserved NAC, 89.9% (133/148) were NAC involvement negative and 10.1% (15/148) were positive in permanent pathological specimens. Of the 20 patients who were resected NAC, NAC involvement positivity was only 50.0% (10/20). This revealed that NAC involvement with a sensitivity (SN) of 40.0%, a specificity (SP) of 93.0%, a positive predictive value (PPV) of 50.0% and a negative predictive value (NPV) of 89.9% (AUC=0.665, 95%CI: 0.5345-0.796). In 140 patients who were performed intraoperative sub-nipple frozen section biopsy, the findings was significantly associated with NAC involvement (P<0.001), and which predict the NAC involvement with a SN of 93.3%, a SP of 89.6%, a PPV of 51.9%, and a NPV of 99.1% (AUC=0.915, 95%CI: 0.835-0.994). In the concordance rate between frozen section findings and definitive pathologic results, DCIS was 53% (9/17), atypical cell was 50% (2/4) and invasive ductal carcinoma was 100% (3/3). Correlation between NAC involvement and clinicopathological factors, tumor size ≥4cm (P<0.001), DNT <1cm by MMG (P=0.002), DNT <1cm by MRI (P<0.001), nipple contrast findings by MRI (P<0.001), tumor in central portion (P<0.001), multicentric/focal lesion (P<0.001), c(N) positive (P=0.014) were significant relation with NAC involvement. Each predictors were scored 0 or 1, and the total score of 0-3 points was defined as low risk, 4 points as intermediate risk, and 5-7 points as high risk. Depending on this categorized classification, the NAC involvement rate was 3.5% (5/142) in low risk, 68.7% (11/16) in intermediate risk, 90.0% (9/10) in high risk and there was a significant correlation between the risk group and NAC involvement (P <0.001). Notably, assuming that NAC is preserved for low risk patients and is resected for intermediate and high risk patients, NACPI contributes to improve the accuracy of selecting the surgical procedures (SN 80.0%, SP 95.8%, PPV 76.9%, NPV 96.5% (AUC=0.879, 95%CI: 0.784-0.974)).

Conclusion: This study suggests that NACPI can help us indicating subcutaneous mastectomy for the breast cancer patients who request preserve NAC with more oncological safety.
Metastatic pattern discriminates survival benefit of primary surgery for de novo stage IV breast cancer patients: A longitudinal cohort study

Kang Wang1, Yang Shi2, Xiang Zhang1, Guo-Sheng Ren1 and Hong-Yuan Li1. 1The First Affiliated Hospital of Chongqing Medical University, Chongqing, China and 2West China School of Public Health, Sichuan University, Chengdu, Sichuan, China.

**Background:** Primary tumor resection for patients(pts) with de novo stage IV breast cancer(BC) was controversial among recent clinical trials. Indeed, considerable discrepancy in metastatic pattern between those studies was considered as a potential reason for their inconsistent results. We sought to determine the survival benefit of primary surgery on the basis of metastatic pattern.

**Methods:** A retrospective cohort study based on the SEER database was conducted to identify pts with de novo stage IV BC diagnosed between 2010 and 2015. Pts were divided into a surgery and a non-surgery group, and propensity score weighting was used to balance clinicopathologic factors between groups.

**Results:** Of 8,142 de novo stage IV BC pts with a total of 12,737 sites of distant metastases identified in this study, 1,891(23%) cases were managed with surgery and 6,251(77%) cases were managed without surgery. There were 3,821 all-cause deaths and 3,291 BC specific deaths over a median follow-up of 22 months. The weighted 3-year overall survival(OS) for the surgery group was 54.5%, compared to 47.7%(HR=0.82;0.78 to 0.86,P<0.001) for the non-surgery group. The magnitude of the survival difference with surgery was significantly correlated with metastatic patterns(Pinteraction<0.05). Significant survival improvements in surgery group compared with non-surgery group were observed in pts with bone-only metastasis(adjusted HRos=0.83;0.76 to 0.90,P<0.001) or multiple metastases with bone involved (adjusted HRos=0.76;0.70 to 0.83,P<0.001), whereas survival inferiority of surgery was found for pts with multiple visceral organs-only metastases(adjusted HRos=2.08;1.39 to 3.11,P<0.001).

Hazard ratios comparing survival between surgery group and non-surgery group according to metastatic patterns.

(*)Weighted by inverse propensity score.(†)Adjusted for age, year of diagnosis, race, marital status, grade, histologic type, tumor size, ER, PR, HER2 status, chemotherapy. BCSS, breast cancer specific survival.

**Conclusion:** The survival benefit offered by surgery for de novo stage IV BC varies by metastatic patterns. Local surgery for pts
with bone-only metastasis or high metastatic burden accompanied by bone metastasis offers a significant survival advantage over non-operative management, whereas the opposite effect is observed among simultaneous liver and lung metastasis pts. Decisions for primary surgery of de novo stage IV BC pts should be tailored according to metastatic pattern, and mechanisms of bone/visceral organs-only/first metastasis BC are needed further understanding.
Mechanisms involved in hypnosis analgesia explaining potential benefits observed among breast cancer patients undergoing breast surgery

Martine Berliere¹, Nathan Piette¹, Amandine Gerday¹, Fabienne Roelants¹, Marie-Agnes Docquier¹, Philippe Piette², François Duhoux¹ and Christine Watremez¹. ¹Cliniques Universitaires Saint-Luc, Brussels, Belgium and ²Grand Hôpital de Charleroi, Charleroi, Belgium.

Background: Our team has previously highlighted the benefits of hypnosis analgesia on different modalities of breast cancer treatment. In order to confirm these benefits and -in order to try to explain the mechanisms implicated in hypnosis sedation-, we have initiated this new study. Material and methods: This study is a prospective non -randomized multicentric study approved by our local ethics committee which has planned to include 450 consecutive non -metastatic breast cancer patients treated in our breast clinic. The study is divided in 3 arms. In the first arm, patients undergo oncologic breast surgery while on general anesthesia. In the second arm, general anesthesia is preceded by a session of hypnosis relaxation mediated by virtual reality (Aqua program, Oncomfort). In the third arm, the patients undergo breast surgery while on hypnosis analgesia and local anesthesia. To decrease the impact of local anesthesia, on the measured outcomes, this procedure is added to general anesthesia in the first two arms. Different parameters are measured for every patient: anxiety scales (– evaluated by the NCCN DT-National Comprehensive Cancer Network Distress Thermometer- on days 0, 1 and 8), pain scores (measured by NRS (-numerical rating scale-) and VAS (-visual analogue scale-) on days 0, 1 and 8 and biological parameters : NLR( - Neutrophils to lymphocytes ratio- and CRP – C reactive protein- measured on days 0, 1 and 8.) Results: We here present the results of the first 150 patients included in the study between October 2016 and April 2018, i.e 50 patients in each arm. The groups are well balanced for age (mean age of 60 years in the 3 arms), surgical procedures (lumpectomies, mastectomies and sentinel biopsies), tumor and patients' characteristics. Anxiety scales are high and do not differ statistically between the 3 groups on day 0. On the contrary, on days 1 and 8, anxiety scales are lower in the groups of hypnosis analgesia and hypnorelaxation - compared with the group of general anesthesia alone - (p value= 2. 2 e-16). No - statistically significant differences- are observed between the hypnosis and hypnorelaxation groups. Pain scores and analgesics consumption are lower in the groups - using hypnosis analgesia and hypnrelaxation at each time point -. The group using hypnosis analgesia is the most efficient in pain reduction. The variations are statistically significant: p- value -0.009 -on day 0, 0.002 on day 1 and 0.0009 on day 8. The NLR and CRP values do not differ between the 3 groups on day 0. They are statistically lower on day 1 in the arm of hypnosis analgesia compared with the two groups with general anesthesia (p-values 0.00037 for NLR and 0.024 for CRP). On day 8, the variations are not statistically different between the 3 groups.Discussion: Inflammatory reactions associated with breast cancer surgery could exert a negative impact on quality of life (pain, anxiety) and perhaps on breast cancer survival. On the contrary, interventions associated with a decreased inflammatory reaction could be beneficial for breast cancer patients.Conclusion: This preliminary report suggests that hypnosis analgesia can modulate the immune system and exert benefits in this way.
Impact of the time interval between neoadjuvant chemotherapy and surgery in Latin-Americans breast cancer patients

Lia P Rebaza¹, Jose A Galarreta¹, Carlos Castañeda¹, Jose M Cotrina², Sheila Vilchez², Miguel de la Cruz², Jaime Ponce¹, Alfredo Aguilar¹, Claudio Flores¹, Miluska Castillo¹, Marco Galvez² and Carlos Vigil¹. ¹ONCOSALUD - AUNA, Lima, Peru and ²Instituto Nacional de Enfermedades Neoplásicas, Lima, Peru.

Background: Few studies have evaluated the impact of the time interval between neoadjuvant chemotherapy (NAC) and surgery in breast cancer. In Latin America, where the vast majority of hospitals are oversaturated, it is important to define which patients to give priority and to be clear about ideal time or maximum to schedule surgery after NAC without altering the prognosis. The objective of this work is to establish the ideal time interval for post-neoadjuvant surgery and evaluate the impact on patient survival.

Methods: We reviewed the clinical histories of breast cancer with clinical stage II and III who received NAC between 2005 and 2014. Patients were divided into 3 groups according to the time interval to surgery: <4, 4-8 and >8 weeks. Overall survival (OS) and recurrence-free survival (RFS) were estimated using the Kaplan-Meier method, and comparisons of survival curves using the logrank or Breslow test, both globally and by molecular subtypes. The optimal time to surgery has been determined by the Cox model.

Results: During the study period, 583 patients who had post NA surgery before six months were registered. The median age was 49 years (range: 24-85), 82% had clinical stage III, 53% histological grade III, 32.7% were luminal A, 15.6% luminal B, 24.4% Her2 and 27.3% TN. According to the time interval to surgery, 67 (11.5%) patients had surgery before 4 weeks, 204 (35.0%) between 4 to 8 weeks, and 312 (53.5%) after 8 weeks. The groups do not present differences in relation to the clinical characteristics (p> 0.05). The median follow-up time was 4.8 years. The 5-year OS rate according to the time interval was 57.9, 61.5, and 62.7% (p = 0.581) and the RFS rate was 40.6, 52.3, and 51.1% (p = 0.411)

In the multivariate analysis, the effect of the time interval to surgery was not significant in OS and RFS; however, the HR curve suggests that the appropriate cut-off point for surgical time would be 8 weeks.

Conclusion: The time interval between the end of neoadjuvant period and surgery has no impact on recurrence-free survival or on overall survival, despite this we suggest that the period of time between neoadjuvant and surgery not be greater than 8 weeks. More studies will be required to determine the ideal time interval and which cases should be prioritized according to the characteristics of our patients.
Single institute data to assess timing of surgery post neoadjuvant in breast cancer patients

Kausar Suleman¹, Emaan Haque², Ali H Mushtaq², Ahmed Badran¹, Adher Alsayed¹, Dahish Ajarim¹, Taher Twegieri¹, Osama Almalik¹, Noha T Jastaniyah¹, Tusneem Elhassan¹ and Wafa Alkhayal¹. ¹King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia and ²Alfaisal University, Riyadh, Saudi Arabia.

**Background:** This study aims to analyze the impact of the time taken from the completion of neoadjuvant chemotherapy to surgery on patients' outcomes in terms of pathological response, overall survival and disease-free survival. There is no specific guideline for timing of the surgery. This study presents the experience of our institute's unique and large data of locally advanced breast cancer patients who received neoadjuvant systemic therapy.

**Methods:** This retrospective study evaluated patients diagnosed with Stage II and III breast cancer patients who received neoadjuvant chemotherapy, which was FEC and Taxotere +/-Herceptin depending on Her2 status of disease. Evaluation of the treatment outcome was based on the time interval between completion of neoadjuvant chemotherapy and surgery. Patients were selected from the time frame of January 2004 to December 2014. The effect of time interval was studied using two types of stratification. First stratification included time interval less than 4 weeks, 4-6 weeks and more than 6 weeks. Second stratification included patients with time interval <4 weeks, 4-7 weeks, and ≥8 weeks. Patients were also evaluated on the basis of receptor status ER, PR and Her2, and their outcomes.

**Results:** A total of 611 patients were identified. The patients were divided into two cohorts for better analysis. The first cohort showed 94 patients (15.4%) who had surgery within 4 weeks of their last dose of neoadjuvant chemotherapy, 378 (61.9%) within 4-6 weeks, and 139 (22.7%) ≥6 weeks. For the second cohort 94 patients (15.4%) had surgery within 4 weeks, 424 (69.4%) within 4-7 weeks, and 93 (15.2%) ≥8 weeks. Median OS and median DFS is not reached. OS at 5 years was 89.6% and DFS at 5 years was 74%. In both cohorts, OS and DFS were not significant when stratified to timing of surgery but the trend of DFS, although not statistically significant, was poor when patients had surgery more than 6 and 8 weeks. When patients were assessed on pathologic response stratified with timing of surgery, about 15% of patients had surgery ≥8 weeks, only 12.9% of those had complete pathological response compare to patients whose surgery was 6-7 weeks and complete pathologic response was 26% (p=0.02). In terms of receptor status, (ER-/HER-2+) patients had a statistically significant decrease in complete pathologic response if surgery was ≥8 weeks. However, ER+/HER-2-, (ER+/HER-2+), ER-/HER-2- had no difference in complete pathological response.

**Conclusion:** The above data indicates that our patients showed improved complete pathologic response if the surgery was performed within 8-weeks, especially for (ER-/HER-2+) patients. All patients post neoadjuvant had better OS and DFS trends if the surgery was performed between 4-6 weeks. The data suggests that early surgery helps complete pathologic response, and the necessary measures must be taken to identify any obstacles leading to delay in surgery and eliminating these obstacles.
Voice of cancer patients (VoCP): Analysis of experiences of cancer patients undergoing breast cancer surgery

Sangeeta Aggarwal¹, Rishi Sharma², Jyoti Bhoemick², Manish Singh² and Alok Aggarwal³. ¹Santa Clara Valley Medical Center, San Jose, CA; ²Scry Analytics India Pvt. Ltd, Gurgaon, Harayana, India and ³Scry Analytics INC, San Jose, CA.

Surgery is an important part of breast cancer treatment. Most patients either go for mastectomy or lumpectomy + radiation (i.e., breast conserving surgery, BCS). It is well known that mastectomy and BCS have equal long-term outcomes, and more patients are choosing to get breast reconstruction.

In this study, we analyzed experiences, concerns, complications and side effects in patients who have undergone breast cancer surgery and who shared their views on various online forums. Such forums have millions of freely shared messages and are rich sources of such information. However, this data is unstructured. We used our automated system, VoCP, that used techniques from Big Data science and artificial intelligence (e.g., deep learning, topic modeling, information retrieval, natural language processing) to analyze concerns and experiences of patients undergoing breast cancer surgeries.

**Methods**: We collected 5.5 million messages from 174556 distinct users in 21 unrestricted breast cancer forums. We built specific ontology for different surgeries, reconstruction, side effects and sentiments and used our system, VoCP, to extract relevant information from these messages.

**Results**: 52172 users shared 307966 messages regarding surgery and their views are summarized below.

**Lumpectomy (BCS):**
- 25850 users provided 98499 messages
- 15771 users had lumpectomy and shared 50390 messages
- 3760 users shared 6322 messages with complications
- 2760 users mentioned need for additional surgery
- 1447 users mentioned satisfaction with the outcome whereas 117 were dissatisfied

**Mastectomy:**
- 37544 users shared 198494 messages
- 22716 users had mastectomy and shared 94595 messages
- 5065 users shared 8983 messages regarding complications
- 2730 patients expressed satisfaction with outcome whereas 286 patients were dissatisfied

**Reconstruction:**
- 23164 users provided 113568 messages regarding reconstruction
- 9850 users had reconstruction and shared 32472 messages
- 1904 users shared 2734 messages with complication
- 1982 users had immediate reconstruction; 353 users mentioned delayed reconstruction
- 2686 users had autologous tissue reconstruction and 3105 report implant reconstruction
- Type of Autologous Reconstruction reported: 759 TRAM flap, 296 Diep flap, 820 fat grafting, 108 Latissimus Dorsi flap, 89 SGAP Flap/hip Flap
- 418 users expressed satisfaction whereas 40 were dissatisfied with outcome

**Complications reported**

**Conclusions:**

- Despite reports of equal long term outcomes between BCS and mastectomy, more patient had mastectomy.
- Scar issues and pain is the most common complication from any surgery.
- Most patients have expressed satisfaction from their chosen surgery.
- VoCP reliably provides meaningful insights from the patient's point of view; it also gives insight into unmet needs where more resources and research should be focused.
Breast cancer-related lymphedema: Morbidity of sentinel node biopsy

Young Wook Ju¹, Ji Gwang Jung¹, Kyoung Eun Kim¹, Yumi Kim¹, Eunshin Lee¹, Han-Byoel Lee¹, Hyeong-Gon Moon¹, Wonshik Han¹ and Dong-Young Noh¹. ¹Seoul National University College of Medicine, Seoul, Republic of Korea.

Purpose:
Sentinel lymph node biopsy (SLNB) lowers morbidity of lymphedema then axillary lymph node dissection (ALND). However, there has been concern about incidence of lymphedema after SLNB especially when the number of harvested nodes during sentinel node biopsy procedure is more than a few. In this study, we assessed lymphedema incidence and its risk factors including the number excised lymph nodes in patients who underwent SLNB.

Methods:
Between January, 2011 and April, 2012, the records of 910 consecutive patients who underwent breast surgery with axillary staging (SLNB/ALND) for breast cancer at Seoul National University Hospital were reviewed. Lymphedema was assessed by circumferential upper extremity measurements. The lymphedema was defined as > 1cm for either the upper arm or the forearm. Patients with clinical records of the treatment for lymphedema in the rehabilitation clinic were regarded as having lymphedema. Univariate and multivariate analyses were performed to identify potential risk factors associated with lymphedema. Association of number of excised lymph nodes with lymphedema was analyzed by Spearman rank correlation coefficient.

Results:
At median follow-up of 69.8 months, 231 patients (25.4%) presented with lymphedema. In univariate analysis, body mass index (BMI) (P<0.001), T stage (P<0.001), N stage (P<0.001), type of surgery (P<0.001), ALND (P<0.001), neoadjuvant chemotherapy (P<0.001) and adjuvant chemotherapy (P=0.027) were significantly associated with lymphedema. In multivariate analysis BMI (P<0.001), ALND (P<0.001), neoadjuvant chemotherapy (P=0.044), and radiation therapy (P=0.046) were significantly associated with lymphedema. In patients treated with SLNB only (n=595), the incidence of lymphedema was 16.3% (n=97). In SLNB only subgroup, BMI was only significant risk factor of lymphedema. There was no correlation between number of excised lymph nodes during sentinel lymph node biopsy procedure with incidence of lymphedema (P=0.138).

Conclusion:
The risk of lymphedema is multifactorial in breast cancer surgery and adjuvant treatments. In SLNB alone patients, higher BMI was only significant factor correlated with lymphedema. Excised number of lymph nodes during sentinel biopsy procedure was not associated with lymphedema.
Comparison of robotic nipple sparing mastectomy (R-NSM) to endoscopic assisted nipple sparing mastectomy (E-NSM) in the management of breast cancer

Hung-Wen Lai¹, Shou-Tung Chen¹, Dar-Ren Chen¹ and Shou-Jen Kuo¹. Changhua Christian Hospital, Changhua, Taiwan.

Background: Endoscopic assisted nipple sparing mastectomy (E-NSM) alone or followed by immediate breast reconstruction (IBR) with implants or autologous flaps were reported to be associated with small inconspicuous incision and good cosmetic outcome. Robotic nipple sparing mastectomy (R-NSM), which introduce da Vinci surgical platform through a small axillary wound to perform NSM with (or without) IBR, was reported to have potential to overcome the technique difficulty of E-NSM and showed promising cosmetic outcome. However, few evidence was available compared the effectiveness and safety of R-NSM compared with E-NSM in the management of breast cancer.

Methods: Patients with breast cancer received E-NSM or R-NSM performed from July 2010 to June 2018 were searched from breast surgery database at Changhua Christian Hospital (CCH), Taiwan. Data on clinicopathologic characteristics, type of surgery, complications and recurrence were analyzed to determine the effectiveness and oncologic safety of R-NSM and E-NSM. Patient-reported cosmetic outcome result was also obtained and compared.

Results: A total of 127 E-NSM and 36 R-NSM procedures were found and data collected for analysis. About 77.8% of R-NSM group received breast reconstruction, and 78% of E-NSM group received breast reconstruction (P=0.982). The surgical margin involved rate was 2.8%(1/36) in R-NSM versus 3.4%(5/127) in E-NSM (P=1). The overall operation time was 281.5 ± 77.0 mins in R-NSM group versus 210.8 ± 55.5 mins in E-NSM group (P <0.001). Blood loss was mean 36.5 ± 33.7 ml in R-NSM group versus 88.0 ± 61.0 ml in E-NSM group (P <0.001). The hospital stay was 6.8 ± 1.3 days in R-NSM group versus 5.1 ± 1.3 in E-NSM group (<0.001).
-From learning curve analysis, about 15-17 cases needed to significantly decrease operation time in E-NSM group, and in R-NSM group around 10-12 cases needed.
-About 50 E-NSM and 25 R-NSM patients received post-operative questionnaire survey for cosmetic outcome evaluation and acceptance of operations. Patient-reported outcome survey showed that the satisfaction rate of R-NSM 96.4% group versus 94.8 in E-NSM group (p=0.96). The will to receive the same operation again if they could chose again: 100% in E-NSM group versus 96.4% in R-NSM group.
-Cost analysis- The breast cancer operation cost was reimbursed by national insurance in Taiwan. The additional cost of E-NSM and IBR with Gel implant was 4,000-6,000 USD (according to different type of implants used). The cost of R-NSM and IBR with Gel implant was 10,000-12,000 USD (according to different type of implants used). The cost difference was about 2,500-3,300 USD higher in R-NSM group than in E-NSM group.

Conclusion: Both E-NSM and R-NSM were equally effectively in the management of breast cancer with no different surgical margin involved rate, however, longer follow-up remained mandatory for oncologic safety evaluation. Shorter learning curve indicated more friendly operation plateform of robotic surgery in performing NSM. Relative longer operation time, and higher cost of R-NSM compared with E-NSM was observed. Longer hospitalization is biased from personal insurance consideration due to higher cost of R-NSM.
Long-term oncologic safety of nipple-sparing mastectomy with immediate reconstruction

Yuji Yamashita¹, Naoki Hayashi¹, Naomi Nagura¹, Yuka Kajiura¹, Atsushi Yoshida¹, Jyunko Takei¹, Koyu Suzuki¹, Hiroko Tsunoda¹ and Hideko Yamauchi¹. ¹St. Luke's International Hospital, Akashi-cho, Chuo-ku, Tokyo, Japan.

Background
Nipple-sparing mastectomy (NSM) is an alternative procedure to skin-sparing mastectomy (SSM) for selected patients who undergo immediate reconstruction. However, the evidence of long-term oncologic safety of NSM has not been established. In this study, we aimed to compare the prognosis of breast cancer patients who underwent NSM to those who underwent SSM with immediate reconstruction.

Methods
The clinicopathological factors including recurrence site, pathologic stage, nipple-tumor distance, histological type, lymphovascular invasion, margin status, ER, PgR and HER2 status of stage 0–III primary breast cancer patients who underwent NSM or SSM with immediate primary reconstruction with tissue expander from our breast center database was retrospectively assessed. Patients with a nipple tumor distance of <1 cm who underwent NSM were excluded. 190 patients who underwent NSM and 729 patients who underwent SSM were included in the analysis. All patients underwent MRI or US before treatment. Nipple-tumor distance was mainly measured by MRI.

Results
The median follow-up period was 71 months (range: 10 - 131 months) for the NSM group and 79 months (range: 9 - 140 months) for the SSM group. There were no significant difference of clinicopathological factors between the NSM group and the SSM group, except of the larger diameter of tumor in the SSM group. NSM was performed for 60 patients (32%) with stage 0, 71 patients (37%) with stage I, and 59 patients (31%) with stage II/III. SSM was performed for 185 patients (26%) with stage 0, 268 patients (37%) with stage I, and 276 patients (37%) with stage II/III. Local recurrence was found in 11 (5.8%) patients in the NSM group and in 44 (6.0%) patients in the SSM group. In the NSM group, only one (0.5%) patient had local recurrence in the nipple areola complex. In terms of DFS and overall survival (OS) rate, there was no difference between the NSM group and the SSM group (DFS; 89.5% vs 89.2%, HR, 1.044; p = 0.8992; 95% CI, 0.5116–1.9519, and OS; 98.4% vs 96.4%, HR, 0.963; p = 0.9116; 95% CI, 0.473–1.793). According to breast cancer subtype, in the NSM group, all of the 11 patients (100%) who developed local recurrence in the NSM group was hormone receptor (HR)-positive/HER2-negative breast cancer. 29 of the 44 patients (65.9%) who developed local recurrence in the SSM group was HR-positive/HER2-negative, 6 patients (13.6%) was HR-negative/HER2-positive, and 7 patients (15.9%) was triple-negative breast cancer. Among patients who had received neoadjuvant chemotherapy, the NSM group (3 of 14 patients, 21.4%) had a trend for higher local recurrence rate than the SSM group 7 of 116 patients (6.0%) (p = 0.0813). However, no local recurrence in the nipple areola complex was observed for the NSM group. In addition, there was no difference of OS between the NSM group (92.9%) and the SSM group (90.5%) (HR, 0.903; p = 0.9943; 95% CI, 0.049–4.739).

Conclusions
Our results suggested that NSM with immediate reconstruction might be safe as well as SSM for breast cancer with the nipple–tumor distance of >1 cm with respect to their prognosis and local control regardless of breast cancer subtype or invasiveness. Further studies with a large sample size to assess the risk of local recurrence for NSM after neoadjuvant chemotherapy.
Achieving rapid intra-operative diagnosis during breast cancer surgery using high-resolution full-field optical coherence imaging and dynamic cell imaging

Houpu Yang¹, Shuwei Zhang¹, Jiajia Guo¹, Fei Xie¹, Fuzhong Tong¹, Yingming Cao¹, Peng Liu¹, Bo Zhou¹, Lin Cheng¹, Miao Liu¹, Siyuan Wang¹, Yuan Peng¹, Chaobin Wang¹, Yang Yang¹, Yingteng Ma¹, Dingbao Chen¹, Danhua Shen¹ and Shu Wang¹. ¹Peking University Peoples Hospital, Beijing, China.

Background: Intraoperative pathological diagnosis such as frozen section and imprint cytology is not routinely recommended in clinical practice because of time and accuracy concerns. Full-field optical coherence tomography (FF-OCT) is a new optical imaging technique that could generate sectioning tomogram from fresh tissue and provide depiction of the morphological structure and pathological changes in minutes without conventional tissue preparation, slicing, and staining, and dynamic cell imaging (DCI) added the viability information of cells/tissue, which could be more important in cancer diagnosis. This study was to evaluate the feasibility and diagnostic value of FF-OCT and DCI in breast lesions and lymph node specimens during breast cancer surgery.

Methods: We evaluated normal breast tissue, benign breast lesions, breast cancer and axillary lymph node specimens from 107 patients using FF-OCT and DCI. After the optical assessment, the tissue was paraffin embedded and sent to conventional H&E diagnosis. The similar layer of OCT and H&E images were compared and diagnostic criteria were generated. The diagnostic sensitivity and specificity by two trained surgeons without pathology diagnosis experience were evaluated.

Results: A total of 194 specimens were examined, including 143 breast tissue (101 malignant and 42 benign/normal) and 51 lymph nodes (26 metastatic and 25 non-metastatic). On FF-OCT and DCI, normal morphological structures such as adipose, collagen, mammary ducts, and lobules in breast tissue and lymphoid follicle and hilum in lymph nodes were easily recognized. Breast cancer characteristics on H&E imaging correspond to collagen distortion, focal hypointensity, micro-calcification, clustered or linear lively cells etc on FF-OCT or DCI, which could also be easily distinguished. We included the previously mentioned features to build diagnosis criteria for cancer on FF-OCT and DCI. The average acquisition time is 14±11 minutes. The sensitivity and specificity for breast cancer diagnosis were 92.1% and 94.3% respectively. The sensitivity and specificity for lymph node involvement were 92.3% and 84% respectively.

Conclusion: The time- and tissue-saving optical imaging technique yielded high accuracy that was comparable to that of traditional intraoperative and postoperative pathological diagnosis in breast cancer and lymph node metastasis. These results implied the promising application in the intraoperative evaluation and possible decrease of the re-excision rate for breast cancer surgery.
Surgical and long-term outcomes of patients receiving neoadjuvant pertuzumab-containing regimens for HER2-positive localized breast cancer

Stephanie A Haddad¹, Laura M Spring¹, Rachel B Jimenez¹, Neelima Vidula¹, Amy Comander¹, Jennifer A Shin¹, Suzanne B Coopey¹, Michelle A Gadd¹, Kevin S Hughes¹, Alphonse Taghian¹, Barbara L Smith¹, Steven J Isakoff¹, Beverly Moy¹, Aditya Bardia¹ and Michelle C Specht¹. ¹Massachusetts General Hospital, Boston, MA.

**Background:** The addition of pertuzumab to trastuzumab and chemotherapy significantly improves the pathologic complete response (pCR) rate in HER2+ localized breast cancer in the preoperative setting. Although many patients are converted to breast conserving therapy (BCT) candidates by neoadjuvant HER2-directed therapy, a significant proportion opt for a mastectomy for various reasons. Among mastectomy procedures, nipple sparing mastectomy (NSM) is frequently chosen instead of non-nipple sparing mastectomy (NNSM). In this study, we evaluated the surgical and long-term outcomes of HER2+ patients receiving neoadjuvant pertuzumab-containing regimens.

**Methods:** We performed a retrospective review of localized breast cancer patients treated with neoadjuvant pertuzumab-containing regimens from 2011 to 2016, who underwent BCT or mastectomy at an academic institution and two community-based practices. Disease characteristics, treatment regimens, surgical outcomes, and recurrence data were extracted from the electronic medical records.

**Results:** Among 90 patients with stage II-III HER2+ breast cancer, 45 received AC-THP (50.0%), 26 received THP (with adjuvant AC) (29.0%), and 19 received TCHP (21.0%). The majority of patients had grade 3 tumors (61.1%), clinical stage II disease (80.0%), invasive ductal carcinoma (86.7%), and ER+ disease (65.6%). Thirty-seven (41.0%) patients underwent BCT and 53 (59.0%) patients underwent mastectomy. Among the mastectomy patients, 38 (71.7%) patients underwent bilateral mastectomies, specifically 33 (62.0%) patients underwent a NSM and 20 (38.0%) patients underwent a NNSM. The type of surgery that patients underwent stratified by type of neoadjuvant regimen is outlined in the Table 1 below. Most patients who underwent BCT and mastectomy received radiation, including 36 (97.3%) BCT, 24 (72.7%) NSM, and 18 (95.0%) NNSM. Over a median follow-up period of 33 months, 6 patients (6.7%) had recurrences with 2 (2.2%) local recurrences and 4 (4.4%) distant recurrences. The 2 local recurrences occurred in one patient who underwent BCT and one patient who underwent NNSM followed by post-mastectomy radiation.

**Conclusions:** Among mastectomy patients, NSM was more commonly pursued than NNSM. Rates of local recurrence following pertuzumab-containing regimens for HER2-positive localized breast cancer were low overall, regardless of the type of surgery. Data on plastic surgery approaches and complication rates will be presented at the meeting.

Table 1. Type of surgery in patients receiving neoadjuvant HER2-directed therapy.

Early locoregional breast surgery improves overall and progression-free survival in oligometastatic breast cancer

Judicael Hotton\textsuperscript{1,2}, Amelie Lusque\textsuperscript{3}, Philippe Rauch\textsuperscript{1}, Lea Leufflen\textsuperscript{1}, Julie Buhler\textsuperscript{1}, Marion Pierret\textsuperscript{1}, Julia Salleron\textsuperscript{4} and Frederic Marchal\textsuperscript{1,2,5}. \textsuperscript{1}Lorraine Cancer Institute, Vandoeuvre-les-Nancy, France; \textsuperscript{2}Faculté of Medicine, Lorraine University, Vandoeuvre-les-Nancy, France; \textsuperscript{3}Biostatistic Unit, Toulouse University Cancer Institute, Toulouse, France; \textsuperscript{4}Biostatistic Unit, Lorraine Cancer Institute, Vandoeuvre-les-Nancy, France and \textsuperscript{5}CNRS, CRAN, UMR 7039, Vandoeuvre-les-Nancy, France.

Background
Four percent of patients have Metastatic Breast Cancer (MBC) at the time of diagnosis. Surgery in this context is generally not recommended. However, tumour resection may have an effect on tumour load influencing metastatic growth. Some studies have suggested an advantage of locoregional surgery in MBC. The objective was to evaluate the effectiveness of surgery in the year following diagnosis of metastatic disease.

Methods
Data were collected within the ESME breast cancer data platform. Stage IV patients diagnosed between 2008 and 2014 without further personal cancer were included. Patients who died or progressed in 1-year post-diagnosis were excluded. We compared patients operated within the first 12 months after diagnosis with the others.

Results
Among 1977 patients with MBC at diagnosis, alive and progression-free at 12 months, 530 (26.8\%) had surgery within this interval. Patients operated in the year of diagnosis had less oligometastatic disease (less than 3 metastases; 9.2\% vs 21.8\%, \textit{p}<0.01) compared to patients with no surgery. They had less bone metastasis (57.7\% vs 74.4\%, \textit{p}<0.01), more lymph node (33.2\% vs 27.8\%, \textit{p}=0.02), lung (19.8\%, \textit{p}<0.01) and less liver metastasis (17.9\% vs 26.8\%, \textit{p}<0.01) sites. Other treatments included more chemotherapy and HER2-targeted therapy (89.1\% vs 69.6\%, \textit{p}<0.01), locoregional radiotherapy (81.7\% vs 32.5\%, \textit{p}<0.01) and the same frequency of hormone therapy (79.8\% vs 78.6\%, \textit{p}=0.57). Multivariate survival analysis based on Cox model showed that surgery of primary breast lesion performed within 12 months (Hazard Ratio(HR)=0.75, \textit{p}<0.01), HER2 positive status (HR=0.42, \textit{p}<0.01) and the non-visceral metastases (HR=0.80, \textit{p}=0.02) improved overall survival (OS) whereas an older age than 50 (HR=1.50, \textit{p}<0.01) and 3 or more metastases (HR=1.45, \textit{p}<0.01) were associated with poorer survival. Progression-Free Survival (PFS) was also improved for locoregional surgery (HR=0.70, \textit{p}<0.001) after adjustment on HER2 positive status (HR=0.70, \textit{p}<0.01), age greater than 50 (HR=1.18, \textit{p}<0.01) and 3 or more metastases (HR=1.27, \textit{p}<0.01). Propensity score matching analyses confirmed these results.

Discussion
We demonstrated that surgery of primary breast lesion had a benefit on OS (HR=0.75, \textit{p}<0.01), and PFS (HR=0.70, \textit{p}<0.01) in metastatic patient. Metastasis number less than 3 was a complementary protective factor to surgery. Studies have sought to evaluate the population that could benefit from surgery of primary breast lesion in the event of metastatic disease. They showed an increasing morbimortality in plurimetastatic patients. In our study, patients with more than 3 metastases had poorer OS and PFS (HR=1.45, \textit{p}=0.01 and HR=1.27, \textit{p}=0.03 respectively).

Conclusion
Results of our study show that surgical control of primary breast lesion could be considered as an option in the locoregional treatment of MBC, particularly in non-visceral oligometastatic breast cancer.
The effects of poloxamer and sodium alginate mixture (Guardix-SG®) on range of motion after axillary lymph node dissection: A single-center, prospective, randomized, double-blind pilot study

Saebysul Lee1, Sei Hyun Ahn1, Jong Won Lee1, Il Yong Chung1, Beom Seok Ko1, Hee Jeong Kim1, Jisun Kim1, Guiyun Shon1 and Byung Ho Son1. 1Asan Medical Center, Seoul, Republic of Korea.

Purpose:
Restricted shoulder mobility is a major upper extremity dysfunction associated with lower quality of life and disability after breast cancer surgery. We hypothesized that a poloxamer and sodium alginate mixture (Guardix-SG®) applied after axillary lymph node dissection (ALND) would significantly improve shoulder range of motion (ROM) in patients with breast cancer.

Methods:
We conducted a double-blind, randomized, prospective study to evaluate the clinical efficacy and safety of Guardix-SG® for the prevention of upper extremity dysfunction after ALND. The primary outcome measure was shoulder ROM at baseline (T0) and 3 (T1), 6 (T2), and 12 months (T3) after surgery. Secondary outcome measures were the Disabilities of the Arm, Shoulder, and Hand score (DASH), pain associated with movement, which was assessed using a numeric rating scale, and lymphedema assessed using body composition analyzer.

Results:
A total of 83 women with breast cancer were randomly assigned to either the Guardix-SG® group or the control group. In the Guardix-SG® group (n=37), Guardix-SG® was applied to the axillary region after ALND. In the control group (n=46), ALND was performed without using Guardix-SG®.
Compared to the control group, the Guardix-SG® group displayed improved shoulder ROM at 12 months (shoulder abduction of Guardix-SG® 175.5°, $p=0.037$ vs. control group; 168.1°, $p=0.117$). No adverse effect was observed in either group.

Conclusions:
The results indicate that Guardix-SG® tends to relieve pain and improve shoulder ROM. A further large-scale study is needed to obtain a more conclusive conclusion.
Is sentinel lymph node biopsy necessary in breast cancer patients who were diagnosed as initially clinically node-negative before neoadjuvant chemotherapy?

Takashi Fujita¹, Masako Sakuragi¹, Chieko Miyazaki¹, Satomi Shiba¹, Ymiko Tanaka¹ and Saki Nishida¹. ¹Jichi Medical University, Tochigi, Japan.

Background
Neoadjuvant chemotherapy (NAC) is established for treatment of locally advanced disease and is being used increasingly for early-stage breast cancer. And sentinel lymph node biopsy (SLNB) for clinically node-negative breast cancer patients after NAC is performed as a daily procedure. The purpose of this study was to identify the group that can omit SLNB in patients with clinically node-negative breast cancer at diagnosis before NAC.

Materials and Methods
A single institutional retrospective analysis was performed. 126 patients were diagnosed as clinically node-negative before NAC and underwent SLNB between 2005 and 2017.

Before NAC, all patients underwent clinical assessment of lymph-node status by palpation and axillary ultrasound. We judged patients to be node-negative when palpation and ultrasound showed no suspicious nodes. If axillar lymph nodes were swelling, fine-needle aspiration cytology was performed. After NAC, clinical assessment of lymph-node status was performed, again. 119 patients received anthracycline-based (anthracycline alone: 11, anthracycline followed by taxane: 108) chemotherapy and 7 patients received taxane alone. Clinical complete response (cCR) was defined if there was no evidence of tumor in the breast and axillary lymph nodes by US and MRI. SLNB procedure was done after NAC in all patients. Lymphatic mapping was performed with radioactive colloid and/or lymphatic blue dye.

Results
Median follow-up time was 51.2 months. cCR rate was 16.7% (21/126). Success rate for the identification and removal of a SLN was 96.8% (122/126). The median number of SLNs removed was 1.9 (1-5).

15 patients (12.3%) represented SLN positive in patients who were diagnosed as clinically node-negative before NAC. They were performed axillar dissection and the SLNs were the only positive nodes in 9 patients.

No SLNs metastases were observed in 21 patients who were diagnosed as cCR by ultrasound and MRI. And 15 patients (14.9%) had positive SLN in the 101 patients who were diagnosed as clinical partial response or clinical stable disease (p=0.071).

Tumor size, Surgical procedures, hormone receptor status and HER2 status did not influence the positive rate of SLN metastases.

No axillar lymph node recurrence was observed within follow-up period.

Conclusion
Our results show that SLNB is necessary even in breast cancer patients who were diagnosed as initially clinically node-negative before NAC.

However, SLNB may be omitted in breast cancer patients who were diagnosed as clinically node-negative by palpation and axillary ultrasound before NAC and as cCR by ultrasound and MRI after NAC.
Successful intraoperative margin assessment in DCIS and invasive breast cancer with diffusion-weighted MRI using the ClearSight™ system

Marc Thill¹, Katharina Kelling¹, Viviane van Haasteren¹, Lena Traub¹, Josefa Nölke¹, Iris Szwarcfiter², Moshe Shapiro², Armin Schon² and Sebastian Aulmann³. ¹Agaplesion Markus Hospital, Frankfurt am Main, Hessen, Germany; ²Clearcut, Rehovot, Israel and ³OptiPath, Frankfurt am Main, Germany.

Aim
Aim of our study is to evaluate the performance of the ClearSight™ system (ClearCut Medical, Ltd.) in assessing surgical margins for DCIS and IBC in breast conserving surgery

Material and Methods
The ClearSight™ system utilizes a diffusion-weighted-imaging (DWI) protocol to create 2D surface maps showing T2*, a MR parameter related to the tissue's apparent diffusion coefficient (ADC), with a depth penetration of 1.5mm. ADC is a highly accurate differentiator for irregular versus normal tissue.

From November 2017 a prospective, blinded post marketing study (N=63), evaluating the performance of the ClearSight™ system has been conducted in the Breast Centre at the Agaplesion Markus Krankenhaus, Frankfurt, Germany. After standard evaluation with ultrasound and/or X-ray, the specimens were scanned with the ClearSight™ system, and results were compared with the final histopathology results on a margin per margin bases, applying a simple T2* threshold to flag irregular tissue.

Results
Breast specimens' margins from 60 patients were analyzed. Pursuant to the breast conserving surgery (BCS), 348 margins were scanned by the ClearSight™ system. A rigid T2* threshold comparison with the pathology findings resulted in a sensitivity of 80% and specificity of 84%. Accuracy for invasive and in-situ cancers was found to be similar for tissues scanned within one hour after excision. After that sensitivity for DCIS started to drop and was found to be 56% after 2 hours. Further accuracy improvements can be achieved if the reading physician is free to apply an intuitive diffusion map interpretation rather than adhere to a fixed threshold.

Conclusion
The data suggest that ClearSight™ can reduce excision rates by a robust 80% if the excised breast tissue is scanned within one hour. Tissue drying impacts sensitivity for DCIS negatively. Free map interpretation leads to better results than a fixed threshold.
Summary: Surgery is a key part of the treatment of breast cancer. The adoption of electric scalpel began to be used in breast surgeries in 1970 and this equipment uses high frequency electric current to create the following effects: cutting, coagulation or mixing of the two. Data show a decrease in the intraoperative bleeding, however, can also increase complications, such as seroma and thermal lesions in the surgical flaps. A new technique that could be used is the coagulation with argon plasma which is a method of non-contact thermal hemostasis.

Objectives: to compare the electric scalpel with the scalpel by coagulation with argon plasma about aspects surgical and pathological.

Methods: this is a prospective cohort study in which 60 patients with breast cancer were selected at the Discipline of Breast Diseases of the Department of Gynecology of the Federal University of São Paulo (UNIFESP) at any clinical stage where the surgical treatment was indicated, from March 2014 to August 2014. The patients were consecutively selected and randomized into two groups: electric scalpel surgery (ES) and argon plasma coagulation surgery (APC). Inclusion criteria were: 18 to 90 years old patients with breast cancer at any clinical stage where surgical (conservative or radical) treatment was indicated. Intraoperative bleeding was assessed by measuring the weights of the compresses. The patients who underwent surgery were evaluated at 7, 14 and 30 postoperative days. In these returns, the appearance of the surgical wound, the presence and amount of seroma (in mL), hematoma or infection were analyzed. Surgical site infection was considered when there was erythema, increased local or systemic temperature, pain, suture dehiscence or presence of purulent exudate. The surgical specimen was studied in the Department of Pathological Anatomy of UNIFESP. The pathological analysis as recommended by the WHO and particular evaluations were carried out in order to observe the extent and degree of the thermal effect produced in surgical specimens by the two hemostatic techniques (ES and APC).

Results: The mean age of the patients was 56.0 years for the ES group and 54.9 for the APC. There was no significant difference between the groups regarding intraoperative bleeding. However, a statistically significant difference was observed when the days with drain were compared in the postoperative period, with a mean of 10.1 days for the SE group and 7.1 days for the APC group. The study demonstrated that the APC group had a significant greater thermal effect on the margins of the surgical specimen.

Conclusions: the use of argon scalpel, when compared to the electric scalpel, allowed hemostasis to be performed adequately without altering the rates of bleeding, surgical time and postoperative complications, and reduced the number of days with the drain. The thermal effect on the surgical specimen was significant greater with the argon scalpel.
Application of robotic surgery (da Vinci) in the management of breast cancer- Preliminary results and experience sharing

Hung-Wen Lai¹, Shou-Tung Chen¹, Dar-Ren Chen¹, Shou-Jen Kuo¹ and Shih-Lung Lin¹. ¹Changhua Christian Hospital, Changhua, Taiwan.

Background: The experience of application of robotic surgery platform in the management of breast cancer was limited. The preliminary results of robotic surgery (da Vinci) in the management of breast cancer was reported in current study.

Methods: Patients with breast cancer received robotic breast surgeries from March 2017 to June 2018 were searched from robotic breast surgery database at Changhua Christian Hospital, Taiwan. Data on clinicopathologic characteristics, type of surgery, complications and recurrence were analyzed to determine the effectiveness and oncologic safety of robotic breast surgery. Patient-reported cosmetic outcome result was also obtained.

Results: During the study period, a total of 41 robotic breast surgeries were performed in 35 female breast cancer patients, including 6 patients with bilateral disease. Among these 41 robotic breast procedures, 39 were R-NSM related. Four patients with bilateral R-NSM (two patients with bil. breast cancer, and another two patients received contralateral prophylactic mastectomy (CPM)) without breast reconstruction. The other 31 R-NSM were associated with immediate breast reconstruction (IBR). Two patients received R-NSM and IBR with robotic assisted harvest of latissimus dorsi flap (RAHLDF), and 29 patients received R-NSM and IBR with Gel implant procedures. One patient received robotic assisted quadrantectomy for upper outer located large breast cancer and immediate partial breast reconstruction with robotic assisted harvest of omentum flap.

Among those patients who received R-NSM, the mean operation time for R-NSM (after set-up of robotic breast surgery system) was 115.6 ± 50 mins, and 70.2 ± 23.2 mins for Gel implant reconstruction. The docking time was quickly dropped from 20 mins to 6-8 mins, and the time needed to complete R-NSM could usually be completed within 100mins after accumulated cases' experience. The mean blood loss was 35 ± 37.2 ml. The positive surgical margin rate for R-NSM was 2.6%(1/39), which was superficial margin involvement, and no further surgery was performed. About 13% patients suffered from transit nipple ischemia change, and no total nipple areolar complex necrosis case was observed.

Among those 3 patients who received RAHLDF, it took about 267 mins, 97 mins, and 90 mins to complete the 1st, 2nd, and 3rd RAHLDF, separately. All of them were event free, except seroma formation over the back, which relieved after repeat aspiration. No local recurrence, or mortality was found among these 35 patients during mean 8.9 ± 4.2 months follow-up. The patient-reported survey shows that 97%(32/33) of the patients who received robotic breast surgery with breast reconstruction satisfied the cosmetic outcome.

Conclusion: From our preliminary experience, robotic breast surgery is a feasible and safe option for some selected indications of breast cancer patients. R-NSM and IBR with Gel implant or RAHLDF were the most frequent performed operations. Bilateral R-NSM could be safely performed in bilateral breast cancer patients or unilateral breast cancer patients combined with CPM.
Management of infected breast prosthesis with negative pressure wound therapy: A novel technique

Farid Meybodi¹, Negin Sedaghat¹, James French¹ and Elisabeth Elder¹. ¹Westmead Breast Cancer Institute, Sydney, NSW, Australia.

Background: Although treatment of mild peri-prosthetic infection in implant-based breast reconstruction results in high rates of resolution, successful management of severe peri-prosthetic infection remains a significant challenge. Severe infection is defined when the patient has a significant systemic infection, purulent drainage or aggressive or atypical organisms in peri-prosthetic fluid (e.g., Pseudomonas or Gram-negative rods). The traditional management of patients with severe peri-prosthetic infection has been explantation and delayed breast reconstruction.

Methods: A protocol utilising a novel dressing - negative pressure wound therapy with instillation (NPWTi) - for the management of peri-prosthetic infection in breast reconstruction patients has been developed by surgeons in Westmead Breast Cancer Institute. This is an operative technique involving: (1) explantation of the breast prosthesis and application of the NPWTi dressing to the implant pocket, (2) change of the NPWTi dressing, (3) serial intra-operative fluid/tissue cultures, and (4) re-implantation of the breast prosthesis when cultures revealed no growth.

Results: This protocol was utilised in 22 of severe peri-prosthetic infection in 20 patients with immediate breast reconstruction for breast cancer or risk-reducing surgery. Peri-prosthetic infection occurred during the Direct to implant reconstruction in 9 cases, first-stage (expander/implant) in 11 cases and following the second-stage in 2 cases. Cultures of fluid/tissue grew Pseudomonas aeruginosa, Escherichia coli, Serratia Marcescens, Staphylococcus haemolyticus, Staphylococcus aureus and Klebsiella oxytoca. Only 3 cases did not yield an organism on culture. Based on the type of microorganisms, different solutions including normal saline, Prontosan® and 1% acetic acid were used for instillation of the breast prosthesis pocket. Successful implant salvage was achieved in 18 of 22 cases. The median length of stay and time to achieve negative culture were 4(7-18) days and 3(0-14) days respectively.

Conclusions: In patients with severely infected breast prostheses, timely operative intervention and usage of NPWTi can salvage the previously “unsalvageable” implant. This treatment option could be considered for management of suitable candidates with severe peri-prosthetic infection.
Impact of surgery on survival in patients with stage IV breast cancer: A population-based study from the SEER database

Chuan-Gui Song¹, Yu-Xiang Lin¹, Jie Zhang¹, Qiang Zeng², Min-Yan Chen¹, Li-Li Chen¹, Xiao-Xiao Wang³ and Qing-Xia Chen¹.
¹Affiliated Union Hospital of Fujian Medical University, Fuzhou, China; ²First Affiliated Hospital of Fujian Medical University, Fuzhou, China and ³Fujian Provincial Maternity and Children Health Hospital, Fuzhou, China.

Surgical treatment for stage IV breast cancer remains controversial. Therefore, we aimed to further explore the impact of surgery on survival in patients with stage IV breast cancer using the Surveillance, Epidemiology, and End Results (SEER) database. We selected 3,822 patients diagnosed with stage IV breast cancer from 2010 to 2012 in the SEER database who were divided into surgery and non-surgery groups. We assessed the breast cancer-specific survival (BCSS) and overall survival (OS) of the two groups using Kaplan-Meier plots and Cox proportional hazard regression models. In addition, we performed stratification analyses of breast subtype, tumor size and status of distant metastasis to identify the effects of these factors on surgical outcomes. The median survival times were 30 and 24 months in the surgery and non-surgery groups, respectively. The Kaplan-Meier curves showed that the surgery group survived longer than the non-surgery group. The hazard ratios (HR) of the surgery group were 0.504 for BCSS and 0.507 for OS ($P<0.001$). Furthermore, patients in the surgery group still experienced significantly better survival than those in the non-surgery group when stratified according to breast subtype, tumor size and status of distant metastasis. Surgical treatment appears to be associated with improved survival in patients with stage IV breast cancer, independently of breast subtype, tumor size and status of distant metastasis.
Local surgery improves survival in patients with primary metastatic breast cancer: A population-based study

Yuanyuan Zhao\textsuperscript{1,2}, Hefen Sun\textsuperscript{1,2}, Xueli Yang\textsuperscript{1,2}, Yang Zhao\textsuperscript{1,2}, Mengting Chen\textsuperscript{1,2} and Wei Jin\textsuperscript{1,2}. \textsuperscript{1}Fudan University Shanghai Cancer Center, Shanghai, China and \textsuperscript{2}Fudan University, Shanghai, China.

Background
The aim of this study was to assess the prognosis of breast cancer patients with distant metastasis after surgery of the primary tumor and provide new understanding of treatment for these patients.

Methods
We retrospectively analyzed 8922 primary metastatic breast cancer (PMBC) patients from Surveillance, Epidemiology, and End Results (SEER) Database. The patients' clinical and pathological characteristics were investigated. Overall survival (OS) and breast cancer-specific survival (BCSS) were calculated by Kaplan-Meier method. Independent risk factors associated with disease special mortality were identified by Cox regression analysis.

Results
A total of 8922 PMBC patients from SEER database were identified, while 1724 (19.3\%) of them received surgery therapy (ST) and 7198 (80.1\%) patients were identified as no surgery therapy group (NST). Patients' underwent ST had dramatically increased OS (P<0.001) and BCSS (P<0.001) compared with those in NST group. And the result figured out that the patients with 1 or 2 distant metastatic sites might benefit most from local surgery, while the prognosis of patients with 3 or more showed no significant difference (p= 0.073 for OS, p= 0.091 for BCSS).

Furthermore, no differences were found in the survival rates between different surgical procedure groups (p= 0.886 for OS, p= 0.943 for BCSS). PMBC patients with ST tented to have increased OS (hazard ratio [HR] = 0.642; 95\% confidence interval [CI], 0.583-0.707, \( p < 0.001 \)) and BCSS (HR = 0.649; 95\% CI, 0.587-0.718, \( p < 0.001 \)), while age, grade, T stage, breast subtype, radiation, the number of metastatic site were also independent prognostic factors.

Conclusions
The current study demonstrated the survival benefit of ST in PMBC patients, especially those has 1 or 2 distant metastatic sites. Enlarged surgical range could not prolong survival. However, a large randomized clinical trial to validate the efficacy of ST in PMBC is essential in the future.

Image guided surgery for tumor detection in breast cancer using the PH activated micellar tracer ONM-100: The SHINE study

Pieter J Steinkamp¹, Floris J Voskuil¹, Marjory Koller¹, Bert van der Vegt¹, Jan J Doff¹, Tian Zhao², Jeffrey Hartung³, Yalia Jayalakshmi², Baran D Sumer³, Jinming Gao³, Max JH Witjes¹ and Gooitzen M van Dam¹.
¹University Medical Center Groningen, University of Groningen, Groningen, Netherlands; ²Onconano Medicine, Dallas, TX; ³Simmons Comprehensive Cancer Center, University of Texas Southwestern Medical Center, Dallas, TX and ⁴JPH Clinical Development Inc, San Diego, CA.

Background: Currently, no reliable intra-operative tumor detection and margin assessment technologies during breast conserving surgery are available. Fluorescence-guided surgery (FGS) using tumor specific fluorescent tracers can improve intra-operative tumor detection. However, a major limitation is the lack of broad tumor applicability due to complex oncogenotypes and histologic phenotypes. A strategy to overcome this challenge is targeting metabolic vulnerabilities that are more ubiquitous and regarded as generic hallmarks of cancer. The extracellular environment of tumors is relatively acidic compared to healthy tissue due to aerobic glycolysis, the so-called Warburg effect. ONM-100, a micellar polymer tracer labeled with the fluorescent imaging dye Indocyanine Green (ICG), has an exquisitely pH-sensitive binary on/off mechanism. The micelles dissociate in acidic environments causing the unquenching and fluorescent activation of the ICG dye. As most solid cancer types are acidotic, ONM-100 acts as a generic tracer targeting a broad range of tumors. This proof of concept, first in-human study, investigates the safety and feasibility of ONM-100 as an intra-operative fluorescent tracer in breast cancer (BC) patients.

Methods: In this phase 1 study, the pH-activated fluorescent tracer ONM-100 was administered 24±8h prior to surgery in a dose escalation scheme ranging from 0.1 mg/kg to 0.8 mg/kg in groups of 3 patients each. Patients with biopsy proven BC were included. Patients that had undergone neoadjuvant therapy were excluded. Blood was drawn up to day 10 to assess safety and pharmacokinetic data. Intra-operative images were collected of the tumor before and after excision and of the wound bed. Immediately after excision ex vivo fluorescence images were obtained from the serially sliced specimen and the formalin fixated paraffin embedded tissue blocks. Fluorescence images were correlated with histopathological assessment on Hematoxylin and Eosin (H/E) stained sections.

Results: In this ongoing clinical trial, 4 patients with BC were enrolled between March and May 2018. No tracer related (serious) adverse events were observed. A strong and sharply demarcated fluorescent signal in tumor tissue was observed in all 4 patients with in- and ex vivo imaging (median Contrast to Noise Ratio 6.5; IQR 7.25), which correlated with areas of tumor involvement on histopathology. In one BC patient, an intra-operatively unnoticed tumor positive margin was detected using fluorescence imaging. Additionally, a BC satellite lesion was detected, which was otherwise missed by the pathologist.

Conclusion: Preliminary results of this ongoing first in-human study with the pH-activated tracer ONM-100 shows that ONM-100 is well tolerated and safe and allows fluorescent tumor visualization both in- and ex vivo. Here, we provide the first data that this pH-sensitive optical tracer can be used as a tracer for FGS and for margin detection. Further analysis on microscopic biodistribution of ONM-100 is currently being performed and possibilities for metastatic lymph node detection will be explored.
Survival outcomes of breast conserving surgery versus mastectomy for ultrasound detected non-palpable breast cancer in hospital-based screening among Chinese women

Ru Yao1, Bo Pan1, Ying Xu1, Yidong Zhou1, Qingli Zhu1, Jing Zhang1, Huanwen Wu1, Feng Mao1, Yan Lin1, Songjie Shen1 and Qiang Sun1. 1Peking Union Medical College Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, China.

**Background:** Some population-base studies have reported similar or improved survival for breast-conserving surgery (BCS) plus radiotherapy compared with mastectomy (Mx) in early breast cancer [PMID: 22373563, 27344114]. Among the screening detected early breast cancer, ultrasound (US) could detect more invasive non-palpable breast cancer (NPBC) with positive lymph nodes in hospital-based asymptomatic Chinese women, who could achieve comparable 10-year DFS and OS as mammography (MG)-detected NPBC [2016 SABCS P5-02-05, PMID: 27689334]. However, there is little data about the surgical outcomes of BCS verse Mx in the low-risk screening detected NPBC with US as the initial imaging test.

**Methods:** From 2001 to 2017, 6,423 consecutive asymptomatic women underwent mammography or ultrasound guided biopsy in Peking Union Medical College Hospital. Among them, 1130 NPBC including 914 US-detected and 216 MG-detected NPBC were diagnosed and treated. There were 349 (30.9%) patients underwent BCS including 286 (25.3%) patients received radiation therapy and 63 (5.6%) elderly patients (>70 years) who did not. The clinicopathological features, treatment choice, 10-year disease-free survival (DFS) and overall survival (OS) were compared between breast conserving surgery (BCS) versus mastectomy (Mx) in all NPBC and between the US-detected and MG-detected NPBC.

**Result:** Compared to those who received BCS, the 781 (69.1%) patients who underwent Mx had more cancers with relatively higher histologic grade (p=0.003), positive lymph node (18.8% vs 12.0%, p=0.005), ER-negative (22.5% vs 11.5%, p<0.001), PR-negative (29.6% vs 16.3, p<0.001), Her2-positive (16.3% vs 8.9%, p=0.001), and received chemotherapy (37.6% vs 28.7%, p=0.003). The breast conserving rates of US-NPBC were higher than that of MG-NPBC (32.6% vs 23.6%, p=0.010), but the breast conserving rates were similar between ductal carcinoma in situ (DCIS) and invasive cancers. The 10-year DFS and OS were similar among BCS with radiation therapy, BCS without radiation therapy and Mx as well as among US-NPBC with BCS, US-NPBC with Mx, MG-NPBC with BCS and MG-NPBC with Mx.

§ Kaplan-Meier survival curves would be displayed in the poster.

However, MG-NPBC with Mx had favorable 10-year DFS than that of MG-NPBC with BCS (p=0.041).

**Conclusion:** The 10-year DFS and OS of breast conserving surgery versus mastectomy were similar among all NPBC patients. As the current initial imaging test, US-detected NPBC patients would receive significantly more BCS compared to MG. There was no significant difference in surgical outcomes among BCS and Mx in US-detected NPBC. However, among MG-detected NPBC, patients with Mx reached a better DFS but a similar OS than those with BCS. The radiation therapy could be safely omitted in the elderly patients (>70 years) with NPBC.
Circulating tumor cells (CTCs) after neoadjuvant chemotherapy for triple negative breast cancer (TNBC)

Anthony Lucci¹, Carolyn Hall¹, Kenneth Hess¹, Elizabeth Ravenberg¹, Alyson Clayborn¹, Elizabeth Mittendorf², Gaiane Rauch¹, Rosalind Candelaria¹, Stacy Moulder¹ and Alastair Thompson¹. ¹University of Texas MD Anderson Cancer Center, Houston, TX and ²Dana Farber Cancer Institute, Boston, MA.

**Background:** ARTEMIS (A Randomized, TNBC Enrolling trial to confirm Molecular profiling Improves Survival) is a randomized trial to determine if precision guided neoadjuvant chemotherapy (NAC) impacts rates of pathologic complete response in the breast and axillary nodes (pCR). We hypothesized that CTCs in peripheral blood after completion of NAC would provide prognostic information beyond pCR alone in TNBC patients.

**Methods:** Blood was assessed for CTCs after NAC as part of two IRB approved studies, ARTEMIS (2014 – 0185/PA15-1050), and LAB04-0698. CTCs were identified using the Cell Search® System (Menarini Silicon Biosystems). Samples with one or more cells, also having morphologic criteria for malignancy, were deemed CTC positive. Log-rank test and Cox regression analysis were applied to evaluate associations between CTC positive, pCR, and overall survival.

**Results:** pCR was achieved in 24/68 (35%) patients with TNBC. Twenty four patients (35%) were CTC positive. Three year overall survival was evaluated in 4 groups of patients: pCR and no CTCs (n=20), pCR and CTC positive (n=4), non-pCR and no CTCs (n=24) and non-pCR and CTC positive (n=20). Three year overall survival was higher in the pCR and no CTCs cohort (100%), compared to pCR and CTC positive (50%), non-pCR and no CTCs (83%), non-pCR and CTC positive (19%); log rank p<0.0001. In the non-pCR and CTC positive patient cohorts, the presence of CTCs was associated with significant risk of death at 3 years [hazard ratio of 12.3 (95% CI 3.4-454, p=0.00002)], whereas a favorable, but non-significant trend was noted for pCR [hazard ratio of 0.2 (95% CI 0.0, 1.4, p=0.11)].

**Conclusion:** The identification of CTCs after NAC has prognostic significance beyond that of pCR, and should be considered in evaluation of patients for clinical trials of adjuvant therapies.
Detection of circulating tumor cells (CTC) in blood and disseminated tumor cells (DTC) in bone marrow at surgery identifies breast cancer patients (pts) with long-term risk of distant recurrence and breast cancer-specific death

Mark Jesus M Magbanua\(^1\), Christina Yau\(^1\), Denise Wolf\(^1\), Jin Sun Lee\(^1\), Aheli Chattopadhyay\(^1\), Janet H Scott\(^1\), Erin Yoder\(^1\), Shelly Hwang\(^1\), Michael Alvarado\(^1\), Cheryl A Ewing\(^1\), Amy L Delson\(^1\), Laura van't Veer\(^1\), Laura Esserman\(^1\) and John W Park\(^1\).

University of California San Francisco, San Francisco and Duke University, Durham.

We examined the prognostic impact of CTCs and DTCs detected at the time of definitive surgery in pts diagnosed with early breast cancer (EBC).

Methods: Blood and bone marrow samples from 742 treatment-naive EBC pts, not eligible for neoadjuvant therapy, were collected immediately prior to surgery. 87% were hormone receptor (HR)-positive, and 71% were node-negative. DTCs \((n=584)\) were enumerated using an EPCAM-based method involving immunomagnetic enrichment and flow cytometry (IE/FC). CTCs were enumerated either by IE/FC \((n=288)\) or CellSearch \((n=380)\). Optimal cutoffs for CTC-/DTC-positivity were selected using Monte-Carlo cross validation. Multivariate Cox regression analysis was performed to determine correlation between levels of CTCs/DTCs vs. distant recurrence-free survival (DRFS) and breast cancer-specific survival (BCSS). The overall median follow-up was 7.1 years for DRFS and 9.1 years for BCSS, but extended up to 13.3 years in subset analyses (Table 1).

Results: CTC-positivity by CellSearch was associated with HER2-positivity \((p=0.01)\). Using optimized cutoffs in multivariate analyses, we found that CTC-positive pts by CellSearch had a statistically significant increased risk of distant recurrence \((HR=4.93, p=0.0067)\). Moreover, pts who were CTC-positive by IE/FC had a statistically significant increased risk of breast cancer-specific death \((HR=3.54, p=0.0138)\). DTC status, by itself, was not prognostic; however, when combined with CTC status by IE/FC \((n=273)\), positive detection for both \((CTC+DTC+)\) was significantly associated with increased risk of distant recurrence \((HR=3.09, p=0.0270)\) and breast cancer-specific death \((HR=4.55, p=0.0205)\).

Table 1. Multivariate analysis to determine the prognostic significance of CTCs and DTCs detected at the time of surgery in treatment naive early breast cancer patients. Adjusted for age at diagnosis, tumor size, pathologic stage, HR and HER2 status, node status and grade.

\*f/u - follow-up; \**double positive

Conclusions: We demonstrate the impact of quantitative evaluation of CTCs and DTCs by IE/FC. Our large single institution dataset, in which CTCs and DTCs have been contemporaneously quantitated, has the longest patient follow-up. Simultaneous detection of CTCs and DTCs at the time of definitive surgery in treatment naïve EBC pts is an independent prognostic factor associated with increased long-term risk of distant recurrence and death due to breast cancer. Given the lack of early endpoints for low-risk patients, liquid biopsy may be an important consideration for future studies.
Circulating tumor cells (CTCs) with epithelial to mesenchymal transition (EMT) phenotype are associated with inferior outcome in primary breast cancer

Michal Mego1,2, Silvia Jurisova1,2, Marian Karaba2,3, Gabriel Minarík1, Juraj Benca2,4, Tatiana Sedlackova1, Daniel Pindak2,3, Massimo Cristofanilli6, James M Reuben5 and Jozef Mardiak1,2. 1Faculty of Medicine. Comenius University, Bratislava, Slovakia (Slovak Republic); 2National Cancer Institute, Bratislava, Slovakia (Slovak Republic); 3Slovak Medical University, Bratislava, Slovakia (Slovak Republic); 4St. Elizabeth University, Bratislava, Slovakia (Slovak Republic); 5University of Texas MD Anderson Cancer Center, Houston, Slovakia (Slovak Republic) and 6Northwestern University Feinberg School of Medicine. Northwestern University, Chicago, Slovakia (Slovak Republic).

Background: CTCs comprise heterogenous population of cancer cells with different clinical and biological value. Epithelial-mesenchymal transition (EMT) leads to generation of cells with cancer stem cell properties and increased resistance to chemotherapy and radiation therapy. While the prognostic value of CTCs with epithelial phenotype was repeatedly demonstrated in primary as well as metastatic breast cancer, prognostic value of CTCs with EMT phenotype (CTC_EMT) remained unknown. The aim of this study was to evaluate the prognostic value of CTCs with EMT phenotype in primary breast cancer (PBC) patients.

Methods: This study included 432 primary breast cancer patients treated by surgery and adjuvant therapy from March 2012 to February 2015. CTC_EMT were detected before surgery by quantitative RT-PCR assay. Peripheral blood mononuclear cells (PBMC) were depleted of hematopoietic cells using RosetteSep™ negative selection kit. RNA extracted from CD45-depleted PBMC was interrogated for expression of EMT transcription factors (TWIST1, SNAIL1, SLUG, ZEB1) by qRT-PCR. Patient samples with higher EMT genes transcripts than those of healthy donors (n=60) were considered as CTC positive. Herein, we report the impact of CTC_EMT on disease-free survival (DFS).

Results: CTC_EMT were detected in 76 (17.6%) patients. Patients CTC_EMT had significantly inferior DFS compared to patients without CTC_EMT (HR = 2.46, 95%CI 1.29 – 4.68, p = 0.0003). Estimated 2- and 5-year DFS for CTC_EMT negative vs. CTC_EMT positive patients was 93.4% and 85.5% vs. 86.9% and 58.1%, respectively. Prognostic value of CTC_EMT was demonstrated in all subgroups of patients, most pronounced in hormone receptor positive, HER2 negative subgroup. In multivariate analysis, presence of CTC_EMT, axillary nodal involvement and hormone receptor status were independently associated with DFS (Table 1). Presence of CTC_EMT was not associated with any patients/tumor characteristics except p53 status (CTC_EMT were present in 20.7% of p53 negative vs. 12.4% p53 positive tumors, p = 0.04).

Conclusions: In this translational study, we demonstrate for the first time the prognostic value of CTC with EMT phenotype in primary breast cancer. Presence of CTC_EMT could lead to better identification of patients with increased risk of recurrence, especially in hormone receptor positive, HER-2 negative primary breast cancer patients.

DETECT V – Expression analysis of human epidermal growth factor receptor 2 and estrogen receptor on circulating tumor cells of metastatic breast cancer patients

Tanja Fehm¹, Franziska Meier-Stiegen², Sabine Riethdorf², Brigitte Rack³, Florin-Andrei Taran⁴, Klaus Pantel³, Volkmar Müller², Wolfgang Janni³ and Jens Huober³. ¹University Hospital Duesseldorf, Duesseldorf, Germany; ²University Hospital Hamburg-Eppendorf, Hamburg, Germany; ³University Hospital Ulm, Ulm, Germany and ⁴University Hospital Tuebingen, Tuebingen, Germany.

Introduction: The prognostic relevance of Circulating Tumor Cells (CTCs) in patients with metastatic breast cancer (MBC) has been shown in multiple clinical trials. Beside their quantification it is of particular interest to analyze the predictive value of these cells and investigate if therapeutic decisions can be based on the phenotype of CTCs. The DETECT study concept evaluates this possible implication of CTCs. The DETECT V study compares endocrine therapy vs. chemotherapy, both combined with Trastuzumab and Pertuzumab in MBC patients with a HER2-positive (Human Epidermal Growth Factor Receptor 2), hormone receptor-positive tumor. Translational projects to identify potential predictive markers are associated to the study program. The expression of predictive markers HER2 and estrogen receptor (ER) on CTCs is analyzed to establish and validate an “Endocrine Responsiveness Score” (ERS). The ERS is aiming to estimate the potential benefit of endocrine therapy.

Methods: Quantification and characterization of CTCs was performed using Cell Search® CXC Kit. The staining protocol was validated using cell lines with known expression of ER and HER2. CTCs were quantified at randomization, after six weeks and at the end of treatment in two samples. Staining intensities of both markers were specified.

Results: Staining was successfully established. ER staining intensity was specified as negative or positive; HER2 staining intensity as negative, weak, moderate or strong. Detection and characterization of CTCs was analyzed for the first 30 patients. At time of randomization 17 of 26 samples were CTC positive with ≥1 CTC in one sample (HER2 and ER), 6/25 in both samples. After six weeks 8 of 26 patients contained ≥1 CTC in one sample and 5 of 26 in both samples. 11 of 15 CTC positive patients at time of randomization were CTC negative in the subsequent sample after six weeks. The cumulative frequency of ER- and HER2-positivity regarding CTCs detected in all samples was analyzed. 13% of all CTCs detected were ER positive (14/115). The percentage of HER2 3+ CTCs decreased from 27% at time of randomization (25/92) to 0% after six weeks (0/87). Analyzing the distribution of the expression of ER and HER2 in all CTCs of one sample, 10 of 19 samples containing ≥2 CTC showed heterogenic intensity of HER2-specific immunofluorescence. 8 of 14 samples containing ≥2 CTC showed heterogenic intensity of ER-specific immunofluorescence, respectively.

Conclusion: The implementation of “Endocrine Responsiveness Score” ERS aims to predict the potential benefit of endocrine therapy in patients with a HER2-positive, hormone receptor-positive tumor. Descriptive analysis of first patient samples has shown to detect heterogenic expression of HER2 and ER in CTCs of patients participating in the DETECT V study.
Circulating tumor cell detection predicts early recurrence in patients with non-metastatic breast cancer

Carolyn Hall\textsuperscript{1}, Salyna Meas\textsuperscript{1}, Jessica Bowman Bauldry\textsuperscript{1}, Henry Kuerer\textsuperscript{1} and Anthony Lucci\textsuperscript{1}. \textsuperscript{1}University of Texas MD Anderson Cancer Center, Houston, TX.

Background:
Our group and others have shown that CTCs are identified in 20-25\% of non-metastatic breast cancer patients. Recent data suggests that circulating tumor cell (CTC) detection at 5 years follow-up predicts late recurrence for non-metastatic, estrogen receptor positive, HER2/neu negative (ER+/HER2-) breast cancer patients. The aim of this study was to determine if CTC detection at time of surgery in ER+/HER2- predicts early (less than or equal to 5 years) recurrence, and to compare the median recurrence-free survival (RFS) to triple negative (TN) patients.

Methods:
We performed CTC enumeration on 506 patients with non-metastatic breast cancer just prior to surgical resection as part of an IRB approved study. CTCs (per 7.5 ml blood) were identified using the Cell SearchSystem (Menarini Silicon Biosystems). The presence of one or more CTC meeting morphological criteria for malignancy was considered a positive result. Patients with inflammatory breast cancer were excluded from our analysis. Log-rank test and Cox regression analysis were applied to establish the association of CTCs with RFS.

Results:
Median follow-up was 68 months and mean age was 53 years. Eighty-four percent of patients (417/498) had T1/T2 tumors, 63\% (307/487) had grade 1 or 2 tumors, and 58\% (292/501) had negative lymph nodes. Eighty-three percent (419/506) had ER+/HER2- tumors, and 17\% (87/506) were TN. One or more CTC was identified in 22\% (91/419) ER+/HER2- patients, and in 28\% (24/87) of TN patients. Nine percent (45/506) of patients recurred within 5 years of CTC assessment. Of the 45 patients who relapsed, detection of one or more CTCs predicted shortened RFS. Median RFS for CTC-positive patients was 1.2 years, vs. 2.5 years for CTC-negative patients, irrespective of ER+/HER2- or TN subtype (log-rank \( P<0.001 \), HR = 2.71, 95\% CI, 1.50 to 4.87).

Conclusions: One or more CTCs identified at surgical resection predicted shortened RFS, irrespective of subtype, in non-metastatic breast cancer patients. This data warrants larger studies to determine if CTC positivity can be used to stratify both ER+ and TN patients who are at increased risk for early recurrence.
Correlation of disseminated or circulating tumor cells with the OncotypeDX recurrence score

Sarah E Tevis¹, Carolyn Hall¹, Salyna Meas¹, Rosa Hwang¹ and Anthony Lucci¹. ¹MD Anderson Cancer Center, Houston, TX and ²University of Colorado, Denver, CO.

Background: New biomarkers continue to emerge to predict the risk of recurrence in women with early stage breast cancer. A high OncotypeDX Recurrence Score (RS)® has been found to be associated with worse disease-free and overall survival in patients with early stage breast cancer. Similarly, circulating tumor cells (CTCs, blood) and disseminated tumor cells (DTCs, bone marrow) have prognostic value in patients with breast cancer. We sought to evaluate the association between high RS and CTCs and DTCs.

Methods: We evaluated patients with hormone receptor positive, HER2 negative, node-negative invasive breast cancer from a prospective database from 1/2005 to 1/2017. RS was classified based on the new TAILORx study cutoff points as low (<11), intermediate (11-25), and high (>25). CTCs were assessed using CellSearch. For DTCs cytospin specimens of bone marrow aspirates, enriched for epithelial cells by density gradient separation, were immunostained using a pancytokeratin cocktail of antibodies, including AE1/AE3, CAM5.2, MNF116, cytokeratin 8 (CK8), and CK18. CTCs and DTCs were considered to be positive if one or more CTCs or DTCs were identified, respectively. Chi square analyses were utilized to evaluate for a relationship between OncotypeDX RS and CTCs or DTCs. Statistical analyses were performed in SPSS version 24 with p value <0.05 considered significant.

Results: Two hundred and thirty patients meeting the above criteria were identified from a prospective database, of which 106 had OncotypeDX testing results. Of the patients with available OncotypeDX data, 93 patients had CTC results and 60 patients had DTC results. CTCs were detected in the blood of 18/93 (19.4%) patients, while DTCs were detected in the bone marrow of 20/60 (33.3%) patients. Patients with high RS were not more likely to have CTCs as compared with patients who had low or intermediate RS (16.7% vs 19.8%, p=0.801). Similarly, high RS was not associated with the detection of DTCs, with DTCs present in 44.4% of patients with high RS, compared with 31.4% of patients with low or intermediate RS (p=0.443). In the subgroup of patients ≤50 years of age no associations were found between high RS and CTCs (p=0.720) or DTCs (p=0.151).

Conclusions: High OncotypeDX RS did not correlate with CTCs in the blood or DTCs in the bone marrow in our study.
Enabling HER2 and androgen receptor (AR) protein expression and localization in circulating tumor cells (CTCs) of ER(+/-)/HER2(-) metastatic breast cancer (MBC) patients (pts)

Priscilla Ontiveros¹, Connie Landaverde¹, Ryon Graf¹, Maren K Levin², Sarah Hippely², Yipeng Wang¹, Mark Landers¹, Ryan Dittamore¹ and Joyce A O'Shaughnessy². ¹Epic Sciences, San Diego, CA and ²Baylor Scott & White Research Institute, Dallas, TX.

Background:
Upregulation of HER2 and AR are mechanisms of acquired resistance to endocrine therapy, and are being investigated as treatment-guiding biomarkers. However, measurement of these proteins and their localization requires metastatic biopsies, which are costly, invasive, and prone to under-sampling which limits their utility to guide treatment in late stage metastatic patients. A CTC-based test could expand the clinical utility of these biomarkers. Here we utilized the Epic Sciences CTC platform for CTC detection and characterization. MBC blood samples were characterized for CTC prevalence, HER2 and AR expression at time of disease progression.

Material and methods:
HER2 and AR expression levels were determined based on model cell lines. A total of 72 blood samples were acquired from ER(+/-)/HER2(-) patients (by standard tissue pathology) at disease progression. 72 samples were analyzed for HER2 and 64 were analyzed for AR using the Epic Platform. Single-cell whole genome sequencing was performed to assess clonality and inter-patient heterogeneity of CTCs detected.

Results:
55/72 (76.4%) of patients had CTCs detected across two slides. 13/72 (18.1%) had at least one HER2(+) CTC, 14/64 (21.9%) had at least one AR(+) CTC, and 7/64 (10.9%) had at both AR(+) and HER2(+) CTCs detected on replicate slides. HER2 expression on individual CTCs showed distinctive cytoplasmic membrane staining, and AR expression on individual CTCs showed frequent nuclear localization. Most patient samples showed heterogeneous expression of these markers at disease progression indicating subclonal sensitivity to targeted therapies. Subsequently, these cells will be individually sequenced to better determine the clonality of resistance.

Conclusions:
CTCs are detected in most MBC pts upon disease progression, with expression of known endocrine therapy resistance markers, HER2 and AR, observed that CTCs could guide subsequent therapy selection. Prospective evaluation of HER2 and AR on MBC pts' CTCs as predictive biomarkers of benefit from inhibitors of these proteins is needed.
HER2-negative metastatic breast cancer with HER2-positive circulating tumor cells (CTCs): A new CTC-defined HER2-positive subgroup

Ami N Shah1, Lorenzo Gerratana1, Qiang Zhang1, Andrew A Davis1, Youbin Zhang1, Lisa Flaum1, Amir Behdad1, Leon Platanias1, William J Gradishar1 and Massimo Cristofanilli1. 1Northwestern University, Robert H. Lurie Comprehensive Cancer Center, Chicago, IL.

Introduction: CTCs can overexpress HER2 discordant from tumor HER2 expression. We aimed to describe characteristics of a CTC-defined group of pts with metastatic breast cancer (MBC) that is tumor HER2- and CTC HER2+ (HER2 tumor- CTC+).

Methods: We retrospectively analyzed data from pts treated at Northwestern University who had serial evaluation of CTCs and circulating tumor DNA (ctDNA). We included pts with pathologically confirmed HER2- MBC and HER2+ CTCs. CTCs were enumerated with the CellSearch immunomagnetic kit (Menarini Silicon Biosystems), HER2 expression on CTCs was determined using the CellSearch CXC Kit in 7.5 cc whole blood, and ctDNA was analyzed using the Guardant360 NGS assay (Guardant Health).

Results: Among 98 pts with HER2- MBC and CTC analysis, 46 (47%) had at least 1 HER2+ CTC. In this cohort the median age was 53. At initial BC diagnosis, 80% had early stage or locally advanced BC and 20% had de-novo metastatic disease. Baseline histology was 65% ductal, 20% lobular, 2% mixed ductal and lobular, and 13% unknown. Pathology of metastatic tumor was hormone receptor positive (HR+)/HER2- in 78% and triple negative in 22%. Detailed HER2 immunohistochemistry (IHC) and FISH results from metastases were available from 63% of pts of whom 72% had an IHC score of 0 or 1 and 28% had an IHC score of 2 with negative FISH testing. The median time from the most recent pathologic metastatic tumor assessment to the detection of a HER2+ CTC was 6.5 mo. Twenty-two pts had simultaneous (within 8 weeks) HER2- tumor confirmation and HER2+ CTC detection. The median lines of endocrine therapy (ET) for MBC prior to detection of HER2+ CTCs was 1 (range 0-5, 41% no ET, 17% 1 line, 41% ≥2 lines). Pts received a median of 2 (range 0-10) prior systemic therapies for MBC prior to detection of HER2+ CTCs, (20% 0 lines, 41% 1-3 lines, and 39% ≥4 lines). Among these 46 pts, CTCs were analyzed longitudinally in 104 samples, with HER2+ CTCs detected in 77 samples. Number of HER2+ CTCs at initial detection ranged from <5 in 24%, 5-50 in 43%, and >50 in 33%, with a median of 11.5 HER2+ CTCs. CTC clusters were noted in 37% of pts. At initial detection the proportion of CTCs that were HER2+ was 0-25% in 13% of pts, 26-50% in 46% of pts, and 51-100% in 41% of pts. Seven pts had ERBB2 aberrations in ctDNA. Of 12 pts with tumor sequencing, 2 had ERBB2 mutations, 1 had ERBB3 amplification, and 1 had overexpression of ERBB3 RNA. After detection of HER2+ CTCs, 18 pts received HER2 directed therapy (with chemotherapy in 13 pts, with endocrine therapy in 4 pts, and as monotherapy in 1 pt). Imaging demonstrated a partial response or stable disease in 9 pts (clinical benefit rate 50%), including in 1 pt with trastuzumab monotherapy, progressive disease in 8 pts, and not evaluated in 1 pt.

Conclusions: HER2+ CTCs are frequently detected simultaneously or soon after HER2- tumor assessment in MBC. Within this newly defined subgroup, the several responses seen with HER2 targeted therapy serve as a proof of concept that HER2 tumor-CTC+ patients can benefit from HER2 targeted therapy. Future studies are needed to determine a clinically relevant threshold for HER2+ CTCs to guide further study of HER2 therapy combinations in HER2 tumor- CTC+ pts.
Tracing clonal evolution of circulating tumor cells and cell-free DNA in a metastatic breast cancer patient

Lisa Welter¹, Liya Xu¹, Dillon McKinley¹, Angel Ernesto Dago², Sara Restrepo-Vassalli¹, Mariam Rodriguez Lee¹, Anand Kolatkar¹, Jorge Nieva³, James Hicks¹ and Peter Kuhn¹. ¹University of Southern California, Los Angeles; ²The Scripps Research Institute, La Jolla and ³Keck School of Medicine, University of Southern California, Los Angeles.

Background: Copy number variation analysis has been shown as a valuable tool to infer clonal evolution of tumor cells. While bulk genomic analysis of FFPE tissue can provide information about the characteristics of a primary tumor or a metastatic nodule, these biopsies are rarely repeated due to their invasive nature. Liquid biopsies on the other hand, provide minimally invasive access to tumor derived cells and DNA and can therefore be used to monitor genomic changes of the tumor longitudinally and in real time. Here we evaluate the kinetics of liquid biopsy biomarkers and monitor genomic changes in single circulating tumor cells (CTCs) and cell-free DNA (cfDNA) from 17 longitudinal blood draws collected from a metastatic breast cancer patient over seven treatment regimes. FFPE tissue from the primary tumor and two metastatic sites in liver and bone are available for comparative analysis.

Methods: We used the high definition – single cell assay (HD-SCA) platform to detect and enumerate CTCs of the blood of one metastatic breast cancer patient followed for 4 years. CTCs were characterized morphometrically and single CTCs of each draw were sequenced for copy number variation (CNV). cfDNA was extracted from plasma and tissue samples of the primary breast, bone and liver metastasis were micro-dissected. Extracted DNA from tissue samples and plasma underwent CNV analysis and were compared with CNV data of CTCs.

Results: CTCs were identified in 14/17 draws and varied from 0 to >3000 cells/ml, spiking at two different times concordant with clinical progression. Changes in cell free tumor DNA fraction (ctDNA) correlated strongly with CTC count. Comparative CNV analysis of CTCs, cfDNA and FFPE tissue confirmed the tumorous origin of both cells and cfDNA. Single cell CNV analysis found four genomically related sub-clones in the patient's blood, three of which were present at time of enrollment, while the fourth clone emerged 3.5 years later concordant with the decline in the patient's health. Genomic copy number losses included tumor suppressor genes such as ARID1A, FOXP1, ATM, BRCA2, RB1, CDH11 and CDH1. Genomic gains were limited but included the proto-oncogenes BCL9, ABL2 and MDM4. It is striking that the sub-clonal structure persisted nearly unchanged for 3.5 years throughout various hormone and cytotoxic treatments, indicating high genomic stability. Despite their genomic differences, cells from the different clones are indistinguishable by immunofluorescence or morphometric analysis. CNV profiles of cfDNA reflect the most abundant CTC clone at each time-point.

Conclusion: Using the HD-SCA assay cellular (CTC), and soluble (cfDNA) fractions of liquid biopsies can be compared at the molecular level over a long time course, and verified by comparison with tissue biopsy. This work confirms that liquid biopsies can be used to access the molecular state of a patient's cancer in near real-time and provide insight into the response to treatment years after the original characterization of the primary tissue. Here we show in a single patient example the power of single CTC analysis and highlight how CNV analysis of liquid biopsies could serve as minimally invasive tool to monitor tumor evolution longitudinally.
Associations between plasma Interleukin 2 (IL-2) and HER2 expression in circulating tumor cell (CTC) and MYC alterations in circulation tumor DNA (ctDNA) open a new insight on immune microenvironment for patients with metastatic breast cancer (MBC)

Qiang Zhang1, Lorenzo Gerratana1, Youbin Zhang1, Lisa Flaum1, Ami Shah1, Andrew Davis1, Amir Behdad1, William Gradishar1, Leonidas Platanias1 and Massimo Cristofanilli1. Lurie Cancer Center, Northwestern University, Chicago, IL.

**Introduction:** Overexpression of HER2 has been reported to be associated with metastasis and poor prognosis of patients with MBC. We reported in AACR 2018 that HER2 overexpression is associated with CTC-cluster. Preclinical data suggested that MYC and HER2 cooperate to drive stem cell phenotype and poor prognosis in MBC (Nair R). Furthermore, IL-2 upregulates the transcription of MYC (Grigorieva I) and gets involved into its alterations. We reasoned that further understanding of interactions of HER2 in CTC and MYC will be important to elucidate the mechanism of metastasis of MBC. Herein, we report a significant correlation between the plasma IL-2 level and HER2 expression in CTCs, and the IL-2 related MYC ctDNA alterations in MBC.

**Methods:** This study enrolled 43 patients with stage III/IV BCa at the Northwestern Memorial Hospital (2016-2017) that had longitudinally detection of CTCs and ctDNA. Whole blood samples (7.5ml/each) were collected for CTCs enumeration by using CELLTRACKS ANALYZERII® System (Menarini) contains antibodies of anti-EpCAM for capturing CTCs, anti-CK-PE for epithelial cells, DAPI for nucleus, anti-CD45-APC for leukocytes and anti-HER-2/neu-FLU. The CTCs were classified based on phenotype as CK+, EpCAM+, DAPI+ and CD45-. Plasma ctDNA was analyzed using the Guardant360™ NGS-based assay (Guardant Health), a 73 genes panel. ELISA for IL-2 was performed by using patients' plasma. Database of IL-2, HER2, CTCs and ctDNA was linked with clinical database and analyzed by Kruskal-Wallis test.

**Results:** CTCs ≥ 5 were found in 20 patients (46%). There were 15 patients that had HER2 negative CTCs (Group 1), and 5 patients had HER2 positive (Group 2) CTCs. The level of IL-2 was much higher in Group 1 (88.17pg) compared to Group 2 (66.81pg), indicating that patients with HER2 positive CTCs have significant lower IL-2 than patients with negative CTCs (P=0.02). Meanwhile, ctDNA MYC alterations were detected in 10 patients (including 1 L114R mutation, 7 CNV and 2 SNV) who have the average IL-2 level as 94.00pg. There were 11 patients without any alterations of MYC had average IL-2 level of 70.17pg, which indicated that patients with alterations in the ctDNA MYC have significant higher level of IL-2 in compared with patients without MYC alterations (P=0.02).

**Conclusions:** Findings of the correlation between overexpression of HER2 in CTCs and low IL-2 level indicated that low immunity may contribute to more aggressive MBC. And the higher level of IL-2 appear associated predominantly with MYC genomic alterations indicated that overexpression of MYC may also stimulate the immune response by upregulating IL-2 via a reverse feedback pathway. We postulated that increasing IL-2 suppresses the HER2 expression in CTC and breaks cooperation between HER2 and MYC. Although the interactions between them still unknown, our results suggest that IL-2 related immune microenvironment acts as a key player to suppress HER2- and MYC-mediated progress in MBC, including the formation of CTC-cluster. Monitoring and administration of IL-2 may benefit pretreated MBC patients and predict disease metastasis.
A novel six-parameter assay for comprehensive phenotyping of circulating tumor cells

Minetta C Liu¹, Yao Sun², Arturo Ramirez², Daniel Campton², Tad George², Keegan E Haselkorn¹, Alisa Clein³, VK Gadi³, Daniel Sabath³ and Eric Kaldjian². ¹Mayo Clinic, Rochester, MN; ²RareCyte, Inc., Seattle, WA and ³University of Washington, Seattle, WA.

Background. The presence and number of circulating tumor cells (CTCs) are prognostic for breast cancer treatment outcome. Direct imaging assays traditionally employ four markers to identify canonical epithelial CTCs: nucleus, exclusion (CD45), and inclusion (EpCAM and cytokeratin). There is intense interest in the ability to phenotype CTCs in order to provide a noninvasive means by which to predict treatment benefit from endocrine therapy and/or HER2-directed therapy in breast cancer. To address this, a 6-parameter assay for detection of ER and HER2 expression on CTCs was developed. We applied this assay to four well characterized breast cancer cell lines representative of various ER and HER2 phenotypes. Methods. BT474, MCF-7, SKBR3, or MDA-MB-231 cells were spiked into peripheral blood from healthy donors and processed using the AccuCyte® sample preparation system; nucleated cells, including CTCs, are captured onto glass slides (8 slides per 7.5 mL blood sample) for subsequent immunofluorescent staining. Slides were stained using the combined epithelial marker and ER/HER2 CTC assay and then analyzed with the CyteFinder® imaging system. CTCs were identified as nucleated cells with positive EpCAM and/or cytokeratin staining, and negative CD45 staining. ER and HER2 expression were assessed as present or absent. Results. All cell lines expressed both cytokeratin and EpCAM, except for MDA-MB-231 which was EpCAM-negative. The ER / HER2 expression patterns observed were consistent with reported phenotype: BT474 (+/+), MCF-7 (+/-), SKBR3 (-/+), and MDA-MB-231 (-/-). Conclusions. Identification of epithelial CTCs and phenotypic characterization of ER and HER2 status are feasible in a combined assay applied to a single blood sample. This approach has implications for efficiency and cost effectiveness, which are of particular importance given the interest in longitudinal testing. Assay evaluation is currently underway using blood samples from breast cancer patients with known receptor status, treatment history, and clinical outcomes. Results will be available for presentation at the meeting.
Clinical safety of diagnostic leukapheresis as a liquid biopsy to collect circulating tumor cells in primary and metastatic breast cancer patients

Tanja Fehm1, Franziska Meier-Stiegen1, Bernadette Jaeger1, Florian Reinhardt1, Johanna Naskou1, André Franken1, Hans Neubauer1, Christiane Driemel1, Eugen Ruckhaeberle1, Dieter Niederacher1, Johannes Fischer2 and Nikolas Stoecklein1.

1University Hospital Duesseldorf, Duesseldorf, Germany and 2Institute for Transplantation Diagnostics and Cell Therapeutics, University Hospital Duesseldorf, Duesseldorf, Germany.

Introduction: The enumeration of circulating tumor cells (CTCs) has been shown to be of prognostic relevance for neoadjuvant, adjuvant and metastatic setting of breast cancer in multiple clinical trials. Moreover, the serial determination of CTCs enables therapy monitoring in the metastatic setting. One major caveat is the low number of CTCs detected by established methods which limits the possibility for further evaluation including phenotyping and genotyping. Therefore, the clinical use of CTCs as liquid biopsy for making therapy decisions is still under discussion. Diagnostic leukapheresis (DLA) has been previously established by our research group and implemented in the workflow for isolation and detection of CTCs enabling a reliable detection of CTCs at high frequency. The aim of this clinical study was to assess the safety of leukapheresis in 39 patients with primary and metastatic breast cancer.

Methods: DLA was performed at least 1d before surgery or chemotherapy. A median blood volume of 2.7 L (range, 1.0 L–5.3 L) was processed. Citrate dextrose solution A was used for anticoagulation with ratios ranging from 11:1 to 24:1. Complete blood count as well as measuring blood pressure and heart rate was performed before start of DLA and immediately after DLA. CTCs were enumerated using the CellSearch system. DLA products containing a median number of 1,8x10^8 MNCs were processed.

Results: 41 patients were eligible for DLA. Only in two patients DLA could not be performed due to technical problems. Thirty-nine patients underwent leukapheresis. Twenty-six patients had non metastatic breast cancer. Thirteen patients were diagnosed with metastatic breast cancer. Severe adverse events including hypotension, nausea, tingling e.g. resulting in interruption of apheresis were not observed. The DLA did not interfere with the start of chemotherapy or surgery. Complete blood count before and after DLA showed statistic significant but clinically irrelevant decrease in numbers of leukocytes, thrombocytes, hemoglobin and the percentage of hematocrit. In 11/21 DLA samples (52%) of patients with primary breast cancer CTCs were detected. Number of CTCs ranged from 1 to 51. In 11/13 DLA samples (85%) of patients with MBC CTCs were detected. Number of CTCs ranged from 1 to 2913.

Conclusion: Establishing a routine DLA protocol we demonstrated that this procedure is clinically safe and can be implemented into the clinical workflow of breast cancer patient care.
Co-expression of molecules associated with innate and adaptive immune response on single CTCs of patients with metastatic breast cancer (mBC)

Dimitrios Mavroudis\textsuperscript{1,2}, Maria A Papadaki\textsuperscript{2}, Panormitis G Tsoufas\textsuperscript{2}, Katerina Troullinou\textsuperscript{2}, Christina A Apostolopoulou\textsuperscript{2}, Chara Papadaki\textsuperscript{2} and Sofia Agelaki\textsuperscript{1,2}. \textsuperscript{1}University General Hospital of Heraklion, Heraklion, Greece and \textsuperscript{2}Laboratory of Translational Oncology, School of Medicine, University of Crete, Heraklion, Greece.

Introduction
The expression of CD47 on tumor cells can act as a "don't eat me signal" against phagocytosis by macrophages and dendritic cells. Moreover, PD-L1-expressing tumor cells inhibit the anti-tumor activity of cytotoxic T cells. Circulating tumor cells (CTCs) expressing these molecules could overcome elimination by the immune system. In the current study, we evaluated for the first time the co-expression of CD47 and PD-L1 on single CTCs from patients with metastatic breast cancer (mBC).

Methods
Triple immunofluorescence staining was performed on peripheral blood mononuclear cells (PBMC) cytospin preparations from 18 CTC-positive patients with mBC, using antibodies against cytokeratins (for CTC detection), CD47 and PD-L1. Blood samples were obtained before the initiation of first-line chemotherapy. A total of $1\times10^6$ PBMCs were analyzed per patient using the Ariol microscopy system. The expression levels of CD47 and PD-L1 were characterized as high or low/−, after quantification by the Ariol system, using the MDA.MB.231 breast cancer cell line as positive control.

Results
A total of 23 CTCs (median: 1, range: 1-4) were identified. CD47-expressing CTCs were detected in 94.4% of patients and represented 91.3% of total CTCs. However, high CD47 expression was confirmed in 38.9% and 43.5% of patients and CTCs, respectively. PD-L1 expression was evident in 27.8% of patients and in 21.7% of CTCs, whereas CTCs expressing high levels of PD-L1 were identified in 16.% of patients and represented 13% of total CTCs. Co-expression of CD47 and PD-L1 (CD47\textsuperscript{+/−}/PD-L1\textsuperscript{+/−}) was observed in 21.7% of CTCs, whereas 69.6% of CTCs expressed CD47 only (CD47\textsuperscript{+/−}/PD-L1\textsuperscript{−}). No CTCs expressing only PD-L1 (CD47\textsuperscript{−}/PD-L1\textsuperscript{+/−}) were detected and 2 of 23 cells were negative for both markers (CD47\textsuperscript{−}/PD-L1\textsuperscript{−}).

Regarding the differential expression levels of CD47 and PD-L1, the phenotype CD47\textsuperscript{low/−}/PD-L1\textsuperscript{low/−} was the most abundant both at the patient (61.1%) and the CTC level (52.2%). CD47\textsuperscript{high}/PD-L1\textsuperscript{low/−} CTCs were observed in 33.3% and 34.8% of patients and CTCs, respectively whereas only 1 CD47\textsuperscript{low/−}/PD-L1\textsuperscript{high} CTC was detected in one patient. Interestingly, CD47\textsuperscript{high}/PD-L1\textsuperscript{high} CTCs were identified in only 8.7% of CTCs.

Conclusions
CD47 expression is identified in the great majority of CTCs in mBC and could represent a potent signal to facilitate the escape from innate immune response. PD-L1 expression on CTCs is less commonly observed and could serve for the attenuation of an adaptive anti-tumor immune response. Interestingly, CD47 and PD-L1 are co-expressed in a subset of CTCs, whereas simultaneous high expression on single CTCs is even less common. The expression of these molecules is currently further investigated in a larger cohort of patients with mBC and in patients with early disease, in order to evaluate their differential distribution that potentially reflects the equilibrium and/or escape from the immune surveillance.
Diverse inter- and intra-patient circulating tumor cells (CTCs) phenotypic heterogeneity identified in metastatic breast cancer (MBC) cohort

Yipeng Wang¹, Beverly Hom¹, Priscilla Ontiveros¹, Connie Landaverde¹, Emma Roth¹, Maren K Levin², Sarah Hippely², Mark Landers¹, Ryan Dittamore¹ and Joyce A O'Shaughnessy². ¹Epic Sciences, San Diego, CA and ²Baylor Scott & White Research Institute, Dallas, TX.

**Background:** There is unmet need for biomarkers to guide the treatment selection in MBC. We described phenotypic CTC heterogeneity in metastatic castrate resistant prostate cancer (mCRPC), and showed that pts with CTC high heterogeneity have improved OS with chemotherapy, while with pts low CTC heterogeneity pts have longer OS with AR inhibitors (Scher et al. 2017 Cancer Research). Here, the same methodology was applied to evaluate the feasibility of CTC heterogeneity analysis in MBC pts.

**Material and methods:** 92 blood samples from MBC pts were processed for HER2 CTC analysis utilizing the Epic Sciences platform. Following enumeration, multi-dimensional phenotypic characterization analysis was performed utilizing protein expression and digital pathology features. 20 features from each CTC were clustered using unsupervised approach (K-means) and the optimal number of clusters was determined using the elbow method with greater than 85% of variance taken into account. Shannon Index was used to score intra-patient CTC heterogeneity.

**Results:** CTCs were detected in 77.2% (71/92) of the MBC pts. 1501 CTCs from 60 pts were clustered into phenotypic subtypes which are distinctively different in nuclear size, circularity, CK and HER2 intensity etc. HER2 expression was enriched in cell types that had higher CK intensity and was more circular morphologies often associated with replicative stress. A wide range of CTC phenotypic heterogeneity was observed across pts, Shannon Index scores from 0 (low heterogeneity) to 1.67 (high heterogeneity) with a median of 0.60. CTC heterogeneity was independent of CTC counts, some low count pts had heterogeneous CTC subtypes while some high count pts had homogeneous CTC subtypes.

**Conclusions:** Diverse inter- and intra-patient phenotypic CTC heterogeneity were observed in this MBC cohort, consistent with that seen in mCRPC and other MBC cohorts (Beverly H et al, ASCO 2018). Studies linking degree and patterns of CTC heterogeneity to therapeutic outcomes are ongoing.
Circulating tumor cell subset analysis to assess lifestyle interventions for breast cancer patients after neoadjuvant chemotherapy

Hui Gao\textsuperscript{1}, Evan N Cohen\textsuperscript{1}, Peiying Yang\textsuperscript{1}, Taylor A Austin\textsuperscript{1}, Robin Haddad\textsuperscript{1}, Qiong Wu\textsuperscript{1}, Karen M Basen-Engquist\textsuperscript{1}, Jewel M Ochoa\textsuperscript{1}, Banu K Arun\textsuperscript{1}, George H Perkins\textsuperscript{1}, Sarda Tin\textsuperscript{1}, Veronica S Vallone\textsuperscript{1}, Smitha G Mallaiah\textsuperscript{1}, Courtney B West\textsuperscript{1}, Angela S Thompson\textsuperscript{1}, Alejandro Chaoul\textsuperscript{1}, Lorenzo Cohen\textsuperscript{1} and James M Reuben\textsuperscript{1}. \textsuperscript{1}UT-MD Anderson Cancer Center, Houston, TX.

Background: Circulating tumor cells (CTCs) are an independent predictor of survival in patients with breast cancer. In addition, mesenchymal (EMT-CTC) and stem-like (Stem-CTC) CTCs contribute to disease progression. The objective of the overall study is to determine whether a comprehensive lifestyle intervention program started prior to radiotherapy can modulate changes in CTC subsets that are correlated with disease recurrence and progression. For these analyses we examined the association between medical and treatment-related factors and CTCs.

Patients and Methods: Seventy-eight patients with stage II/III breast cancer were recruited and randomized to either the intervention group or a standard care group. The intervention group (n=42) had in-person lifestyle counseling across the 4-6 weeks of radiotherapy (XRT) followed by video counseling for the subsequent 12 months. The standard care group (n=36) was provided patient-education materials for cancer prevention including information on diet, exercise, and stress management, without counseling. Blood samples were collected prior to initiation of XRT, end of XRT, and at 3-month intervals thereafter for up to 5 years. CTC subsets were detected by AdnaTest EMT2 kit (Qiagen, Venlo, Netherlands). Samples were considered positive for CTCs if any one of breast (EPCAM, MUC1, and HER2), EMT (TWIST1), or stem cell-related (ALDH1, AKT2, and PI3Kalpha) genes were detected by PCR above the manufacturer's suggested threshold.

Results: The median age of patients was 49 years (range 26-82 years). Thirty-four patients were overweight (BMI 24.4-30) and 44 patients were obese (BMI >30). Forty-five patients were HR\textsuperscript{+}Her2\textsuperscript{-}, 12 patients were HR\textsuperscript{+}Her2\textsuperscript{+}, 5 patients were HR\textsuperscript{-}Her2\textsuperscript{+}, and 16 patients were TNBC. Sixteen patients were stage IIA or IIB, 34 patients were stage IIIA or IIIB, 27 patients were stage IIIIC, and 1 was stage IV. Sixty-seven of 78 patients received neoadjuvant chemotherapy (NACT); 13 patients achieved a complete pathological response (pCR). The median follow-up was 21.6 months. CTC data of both intervention and standard groups were similar at baseline. Presence of CTCs at baseline or follow-up time points was not correlated to HR/Her2 status, stage, obesity, or pCR, but was significantly correlated with receiving NACT. Patients without NACT had significantly higher CTCs than patients who underwent NACT (Fisher Exact Test p=0.010). Furthermore, CTCs by the detection of any gene 3 months after completing XRT was associated with shorter PFS (log-rank p=0.016) and OS (p=0.03).

Conclusions: This is an interim analysis of the prognostic potential of CTCs detected by AdnaTest EMT2 kit in non-metastatic breast cancer. We observed a lower proportion of patients with CTCs following neoadjuvant chemotherapy. However, the relative small sample size and short follow-up time preclude drawing conclusions to the efficacy of using CTCs as surrogate measures for lifestyle interventions, although the presence of CTCs in peripheral blood of patients 3 months after radiation therapy can be a promising indicator of disease relapse and overall survival.
Micro-cavity array system for size-based enrichment of circulating tumor cells and circulating cancer associated fibroblasts from blood of patients with breast cancer

Ritesh Parajuli¹, Randy Ly¹, Argyrios Ziogas¹, Ann Eapen¹, Karen Lane¹, Joanna Chen¹, Erin Lin¹, Rita Mehta¹ and Anthony Tsai¹. 
¹University of California, Irvine, Irvine, CA.

Background: Circulating Tumor Cells (CTCs) have prognostic implications in patients with metastatic breast cancer (MBC). During the Epithelial Mesenchymal Transition (EMT), CTCs acquire a more mesenchymal phenotype. Hence, methodologies such as the Cell search that rely on the expression of an epithelial marker EpCAM in CTCs fail to capture a subset of CTCs undergoing the process of EMT and therefore do not adequately represent the true circulatory metastatic load. Hitachi chemicals has invented a size based micro cavity array (MCA) system that allows for the isolation of tumor cells based on the differences in size and deformability between tumor and blood cells. Photolithography and the metal plating can precisely control the filter pore size of our system. Our platform is more sensitive than the Cell Search method in detecting CTCs in Lung Cancer. Cancer Associated Fibroblasts (CAFs) are a major component of the breast tumor microenvironment. Using a micro filter capture technique, our co-authors have demonstrated that CAFs can be enumerated as circulating CAFs (cCAFs). Hitachi’s Micro cavity Array System has not been evaluated in the detection of CTCs and cCAFs in patients with Breast Cancer. The purpose of this study is to demonstrate that CTCs and cCAFs can be enumerated using our platform and the cCAFs can serve as biomarkers of metastasis simultaneously with CTCs.

Method: We undertook a Pilot study of 20 patients each with breast cancer across Stage I, Stage II, Stage III and Stage IV. A total of 10ml of peripheral blood was obtained from each patient. Enumeration of CTCs and cCAFs was carried out by the size based microcavity array system invented by Hitachi Chemicals. Identification of these cells was done by a triple Immunofluorescence staining for pan-CK (cytokeratin), FAP (Fibroblast Activated Protein) and CD45. CTCs were identified as CK+, CD45-, FAP- cells and cCAFs were identified as FAP+, CK- and CD 45 negative cells.

Result: Our method had a high cell recovery rate (90%or higher) and efficient white blood cells depletion rate (99.99%). We present the data from a total of 13 patients in this abstract, (two with stage III and eleven with stage IV breast cancer) . Data from rest of the subjects will be presented at the actual meeting. We detected the presence of CTCs in 11/11(100%) in patients with stage IV(mean of 44) and in 2 out of 2 (100%) patients with Stage III Breast Cancer. We detected the presence of cCAFs in 1 out of 2 patients( 50%) with stage III and in 8 of 11(81.8%) (mean of 9)patients with stage IV breast cancer( Fisher’s exact test p-value= 0.42). The number of CTCs and cCAFs was significantly elevated in patients with MBC and the number was clinically associated with a high metastatic burden.

Conclusions: CTCs and cCAFs can be enumerated using a size based size based micro cavity array invented by Hitachi Chemicals that does not rely on the expression of epithelial markers in CTCs. CTCs and cCAFs can be detected in patients with stage III and stage IV breast cancer. CTCs and cCAFs were associated with high metastatic burden and their numbers were significantly elevated in patients with MBC. cCAFs could serve as biomarkers alongside of CTCs in MBC.
PD-L1 expression on circulating epithelial tumor cells (CETCs) correlates with aggressiveness of tumor in breast cancer patients

Dorothea Schott¹, Monika Pizon¹, Ulrich Pachmann¹ and Katharina Pachmann¹. ¹Transfusion Center Bayreuth, Bayreuth, Bavaria, Germany.

Background: Strategies to improve the efficacy of the immune system against malignant tumors represent a major innovation focusing on the programmed death-1 receptor (PD-1), with its two ligands PD-L1 and PD-L2. The expression of PD-L1 has been evaluated in a number of different tumor types and can be used as a predictive biomarker for PD-1/PD-L1 checkpoint inhibitor treatment response. We used a non-invasive, real-time liquid biopsy to better characterize PD-L1 expression on circulating epithelial tumor cells (CETCs) in breast cancer patients.

Methods: CETCs were determined from blood of 72 patients suffering from breast cancer. The number of vital CETCs and their expression of PD-L1 was investigated using the maintrac® method.

Results: PD-L1 expressing CETCs were detected in 94.5 % of breast cancer patients. Breast cancer patients with metastatic disease had significantly more PD-L1 positive CETCs as compared to patients without metastasis (median 75% vs. 61.1%; p<0.05). Furthermore, patients with positive lymph node status had significantly more PD-L1 positive CETCs as compared to patients with negative lymph nodes (median 60% vs. 93%, p<0.05). Moreover, we observed a significant heterogeneity in PD-L1 immunostaining intensity across CETCs from the same patients.

Conclusion: Breast cancer patients have detectable CETCs with a high frequency of PD-L1 which correlates with progression of cancer disease. PD-L1 seems to be a major factor in immune evasion and may be a promising target of anticancer therapies. Monitoring the frequency of PD-L1 positive CETCs could reflect individual patient's response to an anti-PD-1/PD-L1 therapy.
In vivo isolation of circulating tumour cells using CellCollector and detection of gene mutations in different metastasis organ sites in breast cancer

Cuizhi Geng\textsuperscript{1}, Sianan Li\textsuperscript{1}, Shan Yang\textsuperscript{1}, Jiajie Shi\textsuperscript{1}, Yawen Ding\textsuperscript{1}, Wei Gao\textsuperscript{1}, Meng Cheng\textsuperscript{1}, Yuqiao Sun\textsuperscript{1}, Yanli Xie\textsuperscript{1} and Meixiang Sang\textsuperscript{1}. \textsuperscript{1}Hebei Medical University Fourth Affiliated Hospital and Hebei Provincial Tumor Hospital, Shijiazhuang, Hebei, China.

Introduction: Metastasis is thought to result from tumour cell entry into the circulation and migration to distant organs, where the mutation landscape of metastatic breast cancer (MBC) may shift and vary. The genotypic features of circulating tumour cells (CTCs) typically differ from those of primary breast cancer (BC) cells. Gene mutation analysis of CTCs in MBC may benefit patients by identifying those amenable to specific therapies. Currently, CTCs are primarily isolated \textit{in vitro} from small volumes of blood. The aim of this study was to isolate CTCs \textit{in vivo} using CellCollector and screen for specific gene mutations in cells from different metastasis organ sites and molecular subtypes in MBC patients.

Methods: In this study, we used a novel technology, CellCollector, to collect peripheral CTCs. Thirty MBC patients were enrolled, and 17 were analysed with next-generation sequencing (NGS) methods. Clinical characteristics were analysed along with CTC enumeration and detection rates. Whole-genome amplification (WGA) was used to amplify the CTC genomic DNA of 127 genes.

Results: We isolated CTCs \textit{in vivo} from 20 of 30 MBC patients (66.7%), with a median and mean (range) of 2 (0-15) CTCs. In non-cancer patients, no CTCs were detected. We analysed CTC enumeration and the detection rate in different clinical characteristic subgroups. We found that in their corresponding subgroups, patients younger than 45 years old, with brain metastasis, with three or more metastasis organ sites, or with HER2-positive subtypes had the highest CTC medians and means. As far as clinical characteristics were concerned, the number of CTCs seemed correlated with more advanced clinical characteristics. In the one metastasis organ, two metastasis organs and three or more metastasis organs subgroups, the CTC detection rates were 38.5% (5/13), 77.8% (7/9), and 100.0% (8/8), respectively. The CTC detection rate correlated with the number of metastasis organs; patients with more metastasis organ sites had higher CTC detection rates. We also found that different metastasis organs and molecular subtypes contain high-frequency mutation genes, and also contain unique gene mutations.

Conclusions: In MBC, CellCollector can be used to collect intact CTCs, from which we can obtain gene mutation information. Different metastasis organs and molecular subtypes may have corresponding unique mutations, which may provide a basis for future gene therapy.

HER2, human epidermal growth factor receptor 2
HER2-positive circulating tumor cells (CTCs) in advanced breast cancer (BC): A feature independent of BC subtype

Ami N Shah¹, Lorenzo Gerratana¹, Andrew A Davis¹, Qiang Zhang¹, Youbin Zhang¹, Giovanna Rossi², Chun Wang², Kimberly Strickland², Hushan Yang², Lisa Flaum¹, Maysa Abu-Khalaf¹, Amir Behdad¹, Zhong Ye², Leon Platanias¹, William J Gradishar¹ and Massimo Cristofanilli¹. ¹Northwestern University, Robert H. Lurie Comprehensive Cancer Center, Chicago, IL and ²Thomas Jefferson University, Sidney Kimmel Cancer Center, Philadelphia, PA.

**Introduction:** HER2 overexpression is observed on CTCs in advanced BC (ABC), but their significance is not known. We aimed to describe clinical, pathologic, and molecular associations with HER2 overexpression on CTCs in ABC patients (pts).

**Methods:** We conducted a retrospective analysis of data from ABC pts treated at Thomas Jefferson University and Northwestern University who had evaluation of CTCs and circulating tumor DNA (ctDNA). CTCs were enumerated with the CellSearch immunomagnetic kit (Menarini Silicon Biosystems), HER2 expression on CTCs was evaluated using the CellSearch CXC Kit, and ctDNA was analyzed using the Guardant360 NGS assay (Guardant Health). Associations with the presence of HER2+ CTCs were explored through univariate and multivariate logistic regression. Kruskal-Wallis testing evaluating HER2+ CTCs as a continuous variable was also conducted to confirm consistency of findings. Time to development of HER2+ CTCs was evaluated using Cox proportional hazards regression analysis.

**Results:** Baseline CTCs were evaluated in 209 pts (10% stage III, 90% stage IV) of whom 41% had no detectable CTCs, 23% had 1-4 CTCs, and 36% had >5 CTCs (stage IV aggressive). Twelve percent had CTC clusters. At least 1 HER2+ CTC was seen in 33% of pts at baseline draw. Of 39 patients with HER2+ BC, only 18% had HER2+ CTCs. Of patients with HER2+ CTCs, 55% had hormone receptor positive BC, 28% had triple negative BC, and 18% had HER2+ BC. On univariate logistic analysis, BC subtype or HER2 status was not associated with the presence of HER2+ CTCs. IBC pts represented 52% of pts and were less likely to have HER2+ CTCs (OR 0.40 95% CI 0.19-0.84). Bone metastases were associated with an increased likelihood of HER2+ CTCs (OR 2.46, 95% CI 1.12-5.38); however, other sites of metastases and number of metastatic sites were not correlated with HER2+ CTCs. Aggressive disease features including >5 CTCs and presence of CTC clusters were strongly associated with HER2+ CTCs (OR 15.72, 95% CI 6.89-35.8 and 8.97, 95% CI 3.23-24.89, respectively). Of 168 pts with ctDNA analysis, ERBB2 aberrations were seen in 22% of pts and were significantly associated with HER2+ CTCs (OR of 3.74, 95% CI 1.45-9.63). On multivariate analysis, the associations with >5 CTCs and ERBB2 alterations in ctDNA remained statistically significant. The associations of HER2+ CTCs with bone disease, >5 CTCs, CTC clusters, and ERBB2 alterations in ctDNA, and the inverse relationship with IBC were consistent when HER2+ CTCs were evaluated as a continuous variable with Kruskal-Wallis testing. Among pts without HER2+ CTCs at baseline, the time to detection of HER2+ CTCs correlated with the presence of bone metastases (HR 3.40, 95% CI 1.14-10.19), >5 CTCs (3.77, 95% CI 1.33-10.70), and visceral disease (HR 3.00, 95% CI 1.07-8.44).

**Conclusions:** HER2+ CTCs are common in ABC, independent of HER2 status of the tumor, and, in fact, common in the luminal BC. HER2+ CTCs were also strongly associated with CTC characteristics of aggressive disease with poor survival (CTCs clusters and >5 CTCs) and ERBB2 aberrations in ctDNA. Further studies will be investigating the role of HER2+ CTCs in endocrine resistance and the potential of anti-HER2 therapy in this unique CTC-defined setting.
proof-of-concept of a 4-marker system for improved CTC analysis of metastatic triple-negative breast cancer

Bradley A Hancock¹, Chun-Li Chang², Yuan Zhong², Jeffrey P Solzak¹, Yu-Hsiang Chen¹, Cagri Savran² and Milan Radovich¹.
¹Indiana University School of Medicine, Indianapolis, IN and ²Purdue University, West Lafayette, IN.

Introduction: Circulating tumor cells (CTCs) represent a potent opportunity to glean important information about in vivo breast cancer biology in a non-invasive fashion. A current limitation to CTC analysis is the inability of positive-selection systems to capture EpCAM-low/negative CTCs, a phenotype that is enriched in the CTCs of metastatic triple negative breast cancers (mTNBCs). This proof-of-concept study aims to increase CTC capture for downstream molecular analysis though the inclusion of additional markers specifically relevant to TNBC.

Methods: For inclusion in the analysis, marker candidates were: (1) sufficiently characterized in TNBC, (2) exclusively surface markers to avoid permeabilization, (3) not reported on leukocytes if a cluster of differentiation (CD) nomenclature was associated, and (4) targetable with commercially available antibodies. Cell lines were purchased as part of the TNBC Panel 3 (ATCC) and were characterized as positive or negative across the selected markers by flow cytometry. Capture efficiency of cell lines from culture medium was conducted using antibodies conjugated to magnetic beads in concert with an immunomagnetic detection system developed by the Savran Research Group at Purdue University. Comparisons to EpCAM-only based detection in capture efficiency experiments were completed using Student's t-test. EDTA-anticoagulated blood drawn from normal subjects was assessed for CTCs using the 4-marker capture and parallel 4-marker fluorescent cross-stain. This study was approved by the Institutional Review Board at Indiana University.

Results: We assessed surface expression of 4 markers (TROP2, N-Cadherin, EGFR, EpCAM) across 11 TNBC cell lines using flow cytometry. 100% of cell lines were positive for at least 1 of 4 markers in the panel. 7 of 11 cell lines were characterized by EpCAM positivity. The remaining 4 EpCAM-negative cell lines were positive for N-Cadherin, EGFR, or both in the absence of EpCAM. Immunomagnetic capture experiments performed across the 4 EpCAM-negative cell lines revealed a significant increase in capture efficiency yielded by the 4-marker panel as compared to EpCAM-only capture (p=0.0006). Capture efficiency for EpCAM-positive cell lines with the 4-marker panel was equivalent to EpCAM-only. The 4-marker panel was highly specific as CTC assessment of blood samples collected from 5 normal women without cancer yielded 0 positive cells.

Discussion: Compared to EpCAM-only based capture, the 4-marker experimental system presented here has potential to enhance CTC analysis by more completely representing the heterogeneity of TNBC. This results in better overall capture efficiency, while still maintaining sufficient specificity. The primary limitation of our study is that in vivo characterization of the system is incomplete. To address this, a clinical protocol for the performance assessment of this method compared to EpCAM-based detection in patients with mTNBC has been initiated at Indiana University and will begin enrolling patients in July 2018.
Circulating tumor cells of breast cancer origin identified by fluorescence in situ hybridization and may be an early predictor of therapy failure in early breast cancer

Cassie Liu\(^1,2\), Pamela A Althof\(^3\), Dulce Maroni\(^1,2\), Jadd M Stevens\(^3\), Corinn E Grabow\(^3\), Amaris Z VanDyke\(^3\), Jeffrey D Price\(^1,2\), Jennifer N Sanmann\(^3\) and Sarah P Thayer\(^1,2\). \(^1\)University of Nebraska Medical Center, Omaha, NE; \(^2\)Fred and Pamela Buffett Cancer Center, Omaha, NE and \(^3\)Human Genetics Laboratory, Munroe-Meyer Institute for Genetics and Rehabilitation, University of Nebraska Medical Center, Omaha, NE.

Background: Most modern methods of detecting circulating tumor cells (CTCs) involve identifying cells with epithelial markers. This approach presents challenges, as not all epithelial cells found in circulation originate from the tumor and not all CTCs express epithelial markers. We propose using a size-exclusion filtration system to enrich for CTCs in peripheral blood followed by fluorescence in situ hybridization (FISH) of the filtered cells to identify cells of tumor origin in the early-stage breast cancer patients. We further hypothesize that the presence of CTCs may be indicators of therapy failure in early-stage breast cancer patients.

Methods: Patients diagnosed with breast cancer (n = 9) were consented for CTC evaluation. Primary tumor DNA was analyzed by the Affymetrix Oncoscan\(^\text{TM}\) genome-wide microarray platform and investigated for somatic copy-number alterations (SCNAs). For each patient, two FISH probes were then identified for two regions of gain or a region of gain and a region of loss from the microarray results. Blood samples from patients were obtained before surgery, radiation therapy, endocrine therapy, and at 6-month or 1-year follow-up visits. Blood samples were filtered using ScreenCell\(^\text{®}\) Cyto V2 devices, and FISH was performed. Cells were categorized as normal (diploid for all FISH probes), suspicious (single SCNA detected by FISH), or CTC (two SCNAs detected by FISH). Patients were identified as having CTCs present in their circulation when \(\geq 2\) CTCs were observed or when one CTC and >15 suspicious cells were observed.

Results: The microarray data revealed that luminal A tumors ranged from 2-43 SCNAs; luminal B tumors ranged from 15-20 SCNAs; and ER+, PR+, HER2+ tumors ranged from 46-98 SCNAs. Although a correlation appears to exist between tumor genetic complexity and molecular subtype, the degree of complexity was highly varied within each subtype. We found that neither complexity of tumor profile, molecular subtype, nor stage could predict the presence of CTCs in patients.

Although limited in number, ongoing investigation revealed that one of our patients in early follow-up with a luminal A, stage IB tumor was identified to have persistent CTCs at 1-year after starting hormonal adjuvant therapy, suggesting residual tumor burden not detected by standard clinical modalities; this finding also suggests that this patient may be at highest risk for relapse and should be considered for additional therapies.

**Conclusion:** Size-exclusion filtration followed by FISH analysis can accurately identify CTCs in early-stage breast cancer patients. Tumor complexity, molecular subtype, and stage did not predict the presence of CTCs in circulation. Our method for CTC detection may be able to serve as a diagnostic tool for treatment failure.
Isolation and expansion the circulating tumor cells from patients' peripheral blood in vitro

Wenbin Zhou¹, Chang Zou¹, Pan Zhao¹, Chang Liu¹, Huirong Zhang¹, Hong Hu¹, Caineng Zhong¹, Yayuan Zhang¹ and Dongxian Zhou¹. ¹Shenzhen People's Hospital, Shenzhen, China.

Background: Circulating tumor cells (CTCs) are rare tumor cells disseminated in peripheral blood from either original sites or metastatic sites. Current studies on CTCs are mainly focused on its diagnosis and prognosis significances by liquid biopsy, although controversial results were reported elsewhere. Actually, as a few studies showed that CTCs would be a kind of intriguing drug targets and more beneficial for cancer patients if there genomic and proteomic information could be deciphered dynamically. However, the rarity, challenging isolation as well as the primary culture procedures limited the analysis of CTCs insightfully.

Methods: All patients' samples were referred to the regulation of ethnic commission of Shenzhen People's Hospital and informed parental consent was then collected also for this study. The density gradient centrifugation was used to obtain PBMCs. Cells adherent and suspension culture for collected the circulating tumor cells. Immunofluorescence, kayyotypeing, mude mouse tumorigenesis were verify the tumor cells. Also characteristic and functional of CTCs were analyzed.

Results: It was showed that the morphology of CTC-3 is clustered growth and the CTCs were DAPI-positive, Cytokeratin-positive, and CD45-negative with the immunofluorescence identification. The karyotyping results showed that the chromosome number of CTC-3 varied from 56-60 and the chromosomes were aneuploid. This cell line, which was named as CTC-3, formed clones and displayed stable epithelial phenotype and showed stem-cell like properties. CTC-3 had larger nuclear/cytoplasmic ratio and limitless replicative potential. The growth curve of CTC-3 was similar with that of MCF-7, and CTC-3 grew faster than MCF-7 since the fifth day. Furthermore, the sphere formation ability of CTC-3 was significantly higher than MCF-7 in vitro. Besides, the tumorigenesis of CTC-3 cells was almost the same as MCF-7 in vivo by the analysis of xenografting in immunodeficient mice. STR analysis showed that the similarity of CTC-3 and MCF-7 on the standard site alignment is 20%, which indicated that CTC-3 was a totally new breast cancer cell line. For drug resistance, CTC-3 cells were more resistant to anti-tumor drugs after 3D culture compared with 2D, survive rates of 3D-CTC-3 cells after treatment were more than 80%. Finally, the RT-PCR results shows that the expression of Nanog, E-cadherin and ABCG2 were significantly higher in CTC3, also Oct3/4, CD44, CD133, Vimentin, MMP2, MMP9 no significant differences were found between other genes.

Conclusion: We have successfully isolated and expanded a new breast cancer cell line from the breast cancer patient, which could provide more drug sensitivity information of the patient and open up novel avenues towards the understanding of breast cancer.
Targeting of endocrine therapy-induced estrogen-receptor/HER2-cross-talk in circulating tumor cells from metastatic ER+/HER2-breast cancer: Implications for treatment of ER+/HER2-breast cancer

Sonja Thaler¹, Sven Roßwag¹, Klaus Pantel², Jonathan P Sleeman¹,³, Marcus Schmidt⁴ and Cristina L Cotarelo⁵. ¹European Center for Angioscience (ECAS), Medical Faculty Mannheim, University of Heidelberg, Mannheim, Germany; ²University Medical Center Hamburg-Eppendorf, Hamburg, Germany; ³Karlsruhe Institute of Technology (KIT) Campus Nord, Institute for Toxicology and Genetics, Karlsruhe, Germany; ⁴University Medical Center, Johannes Gutenberg University, Mainz, Germany and ⁵Institute of Pathology, University Medical Center, Johannes Gutenberg University, Mainz, Germany.

Background: Transient induction of HER2 expression upon inhibition of the estrogen-receptor (ERα) might be an underestimated rescue mechanism that enables ER+/HER2- breast cancer cells to survive and to grow in the presence of endocrine therapies. Besides protecting ER+/HER2- BC cells from endocrine treatment, transient HER2 expression is also considered to save circulating, disseminated and dormant ER+/HER2- BC cells from apoptotic cell death in hostile environments and might therefore be of importance for ER+ BC progression, metastasis formation and recurrence. Thus therapeutic strategies that efficiently target both ERα and HER2 simultaneously might improve treatment of patient with ER+/HER2- BCs.

Methods: Circulating tumor cells (CTCs) were originally isolated from a patient with bilateral ER+/HER2- metastatic BC. These cells have been treated with either the proteasome inhibitor (PI) carfilzomib or fulvestrant alone or with both drugs in combination. The consequences of these drugs upon ERα and HER2 expression were monitored by western blotting or qPCR. Induction of cell death upon treatment was measured by PARP and caspase cleavage or by quantification of SubG1 cells using propidium iodide staining or by the use of colony forming assays.

Results: Fulvestrant treatment of CTCs decreases the amount of ERα but immediately increases HER2 expression whereas carfilzomib markedly inhibits the expression of both ERα and HER2 simultaneously. Combined treatment of CTCs with carfilzomib + fulvestrant cause reduced expression of HER2 and lead to a much stronger decrease of ERα than carfilzomib or fulvestrant alone. Fulvestrant causes no significant reduction of proliferation and no induction of cell death. Conversely the combination of carfilzomib and fulvestrant causes a significant induction of apoptotic cell death and a massive reduction of colonies in colony forming assays.

Conclusion: These findings suggest that rapid and transient up-regulation of HER2 expression following endocrine treatment might be an important so far underestimated adaptive mechanism which enables ER+/HER2- BC cells to sustain proliferation in the presence of ERα-inhibitory drugs and to stay alive during the metastatic process. Furthermore these data also lead to the assumption that PIs such as carfilzomib in combination with ERα degraders could be a potential therapeutic strategy for efficient targeting of metastatic ER+/HER2- BC cells.
Sensitivity and dynamic range of CellSearch based DTC enumeration in the CSF in patients with leptomingeal metastases (LMM)

Alice Van Goethem¹, Charlotte Rypens¹, Annemie Rutten¹, Annemie Prove¹, Tom Van den Mooter¹, Katrien Erven¹, Tony Van Havenbergh¹, Steven Van Laere¹, Peter Vermeulen¹ and Luc Dirix¹. 'Sint-Augustinus, Antwerp, Belgium.

Improvements in the treatment of patients with MBC and the inefficiency of many drugs in crossing the BBB have led to an increased incidence of symptomatic CNS metastasis. CNS metastases are clinically characterized by two distinct phenotypes, although their combined occurrence is possible. Most patients suffer from solid CNS metastases, but metastatic deposits limited to the leptomeningeal surfaces occur (LMM). In addition to its poor prognosis, neurological impairment in LMM is devastating.

Methods: 27 patients with breast cancer (MBC) were diagnosed with LMM and treated with intrathecal (IT) therapy from 2008 to 2018 in a single centre (GZA Hospitals Antwerp). Clinicopathologic and treatment information were collected. Conventional diagnosis was based on positive cytology on CSF and/or on the combination of clinical signs and neuro-imaging findings. For a subset of patients (n=12), we have enumerated circulating tumor cells (CTCs) and CSF DTCs at time of LMM diagnosis. Whole blood and CSF was processed on the CellSearch platform according to the standard method for CTC enumeration in blood.

Results: The 27 MBC pts diagnosed with LMM had a median time to LMM of 70.5 months (6.5-241) from the diagnosis of BC. Median age at LMM diagnosis was 56 y (36-75). At time of last follow-up, 23 patients (85%) had died. The median OS from LMM diagnosis was 27 months (4.5-128). From the 27 patients, 52% (14/27) were hormone receptor-positive (HR+), 33% (9/27) were HER2 overexpressing and 15% (4/27) were triple-negative. Coexisting brain metastases are present in 37% of patients. In 11 cases (41%), LMM was not accompanied by extra cranial disease at time of diagnosis. The biochemical data matched the classic CSF findings of LMM including a high protein concentration (75%, 9/12) and a low glucose concentration (42%, 5/12) (Table 1.). CSF lactate was elevated (>2.2 mmol/l) in 100% (10/10). In 70% (7/10) CSF lactate was >3.5 mmol/l. Cytologic evaluation of the CSF demonstrated unequivocal malignant cells in 10/12 (83%). DTC enumeration in the CSF of these patients, however, revealed the presence of tumor cells 12/12 (100%).

Results off the CSF analysis in 12 patients with LMM

Furthermore, the cell count ranged between 10 to 3523 Epcam-positive cells/mL CSF. Additional evaluation proved these to be cancer cells. Conclusion: Symptomatic LMM has a variable prognosis, with some patients experiencing prolonged survival. LMM occurs in all
breast cancer subtypes and can be the sole location (40%). CSF lactate is a sensitive but aspecific marker. DTC enumeration in
the CSF is a robust tool to diagnose LMM with apparently a superior sensitivity over conventional cytology. It furthermore has a
broad dynamic range rendering it more suitable for treatment effect evaluation. This methodology should be considered in routine
workup in MBC patients with suspected LMM.
Comparison of sentinel lymph node detection performances using methylene blue in conjunction with indocyanine green or radioisotope in breast cancer patients: A prospective single-center cohort study

Xiaowei Qi¹, Long Yuan¹, Yi Zhang¹ and Jun Jiang¹. ¹Breast and Thyroid Surgery, Southwest Hospital, Third Military Medical University, Chongqing, China.

**Aim:** This cohort study aimed to compare the clinical efficacies between the novel dual tracer composed of indocyanine green (ICG) and blue dye (BD) and the conventional dual tracer composed of radioisotope and BD for sentinel lymph node (SLN) mapping in breast cancer patients.

**Methods:** This study enrolled 471 clinically lymph node-negative patients with primary breast cancer. All the patients received mastectomy, while, for the sentinel lymph node biopsy (SLNB), they were randomized to receive BD plus radioisotope or BD plus ICG. Two hundred and twenty-seven patients received radioisotope plus BD (Control, RB group) for SLNB, while, 200 patients underwent the ICG plus BD (IB group) for SLNB. The detection performances on SLN identification rate, positive SLN counts, detection sensitivity, and false-negative rate were compared between the two groups. Following SLNB, axillary lymph node dissection (ALND) was performed only on patients with metastatic SLNs. Injection safety and potential side-effects of the two dual tracers were evaluated by a 24-month follow-up after the SLNB procedure.

**Results:** In the IB group, 97% (194/200) of the patients who underwent the ICG and BD dual tracer injection showed fluorescent-positive lymphatic vessels within 2-5 minutes. The identification rate of SLNs was comparable between the IB group (99.0%, 198/200) and the RB group (99.6%, 270/271) \( (P=0.79) \). No significant differences were observed in identification rate of metastatic SLNs (22.5% versus 22.9%, \( P>0.05 \), RB group versus IB group, the same below), positive SLN counts (3.72±2.13 versus 3.91±2.13, \( P>0.05 \)), positive metastatic SLN counts (0.38±0.84 versus 0.34±0.78, \( P>0.05 \)), SLNB detection sensitivity (94.4% vs. 92.5%, \( P>0.05 \)), or false-negative rate (5.6% versus 7.5%, \( P>0.05 \)) between the two groups. No obvious allergic reaction or anaphylaxis, infection at the injection sites, skin necrosis or distal metastasis was reported in either group during the 24-month follow-up.

**Conclusions:** ICG can be used as a promising alternative tracer for radioisotope in SLN mapping, and when it is combined with BD in lymphangiography, it offers comparable detection sensitivity compared to the conventional lymphatic mapping strategies that are widely used in clinical practice.

Redo sentinel lymph node biopsy for ipsilateral breast tumor recurrence after breast conserving surgery with negative sentinel nodes: A pooled analysis from a systematic review and two institutes

Chang-ik Yoon\(^1\), Soong June Bae\(^1\), Jung Eun Choi\(^2\), Chi Hwan Cha\(^1\), So Eun Park\(^1\), Sung Gwe Ahn\(^1\) and Joon Jeong\(^1\). \(^1\)Gangnam Severance Hospital, Seoul, Republic of Korea and \(^2\)Yeungnam University Hospital, Daegu, Republic of Korea.

**Background:** Cases of redo sentinel lymph node biopsy (SLNB) are growing according to the increase of ipsilateral breast tumor recurrence (IBTR) after breast-conservative surgery (BCS). To evaluate a feasibility of redo SLNB in patients with IBTR after negative SLN, we conveyed a pooled analysis using data from a systematic review and two institutes.

**Materials and methods:** A systematic search of PubMed was conducted to identify data of patient level from publications evaluating redo SLNB for cases with IBTR. Eligible patients who underwent BCS and were confirmed as negative axilla after SLNB were identified. An identification rate (IR) and a false-negative rate (FNR) were calculated. To identify FNR, we only included cases with back-up axillary node dissection (ALND) from retrieved data.

**Results:** In a systematic review, a total of 197 peer-reviewed publications were retrieved, of which 19 papers included patients who met eligibility criteria. Data from 464 patients were collected. In two-institutes, 38 cases with same criteria were identified. A total of 502 patient's data were pooled. The IR of redo-SLNB was 71.7\% (360/502) in pooled data. For the FNR, data from 147 patients with back-up ALND after SLNB was analyzed. The FNR and accuracy of redo-SLNB were 9.8\% (5/51) and 97\% (142/147).

**Conclusions:** We found that the IR and the FNR of redo SLNB were 71.7\% and 9.8\%, respectively. Redo SLNB is reliable procedure for axillary staging in patients with IBTR after negative SLN.
Sentinel node biopsy (SNB) vs Low axillary sampling (LAS) in predicting nodal status of post-chemotherapy axilla in women with breast cancer

Vani Parmar1, Nita S Nair1, Vaibhav Vanamali1, Rohini W Hawaldar1, Shabina Siddique1, Tanuja Shet1, Sangeeta B Desai1, Venkatesh Rangarajan1, Asawari Patil1, Sudeep Gupta1 and Rajendra A Badwe1. 1Tata Memorial Centre, Mumbai, Maharashtra, India.

Introduction

There is no safe method of avoiding complete axillary lymph node dissection in women with breast cancer after neo-adjuvant chemotherapy. sentinel node biopsy (SNB) has had prohibitively high false negative rate. We tested low axillary sampling (LAS) and SNB performed in same patient to predict axillary lymph node status in clinically node negative women undergoing breast conservation or modified radical mastectomy after neo-adjuvant chemotherapy.

Methodology

Post neo-adjuvant chemotherapy 751 women who had no palpable axillary lymph node underwent LAS (all lymph nodes below intercosto-brachial nerve). Of these 751 women, 730 also underwent SNB by dual technique after injection of blue dye as well as radio-isotope. SN was identified within and outside axillary sampling specimen. SN as well as LAS specimens were distinctly examined for nodal metastasis. The rest of the axillary dissection was completed in all patients. Post NACT 292/751(38.9%) had residual positive lymph nodes on pathology. The identification rate, false negative rate (FNR), and negative predictive value (NPV) of SNB and LAS were compared for predicting negative axillary lymph node status.

Results

The median clinical tumor size was 5cm (1-15cm) and 533(71%) patients were N1 or N2 at presentation. The SNB identification rate was 87.1% (636 of 730), with a median of 5 nodes and node positive in 238 of 636 (37.4%). LAS identification rate was 98% (736 of 751), with a median of 7 nodes and node positive in 292 of 736 (39.6%). In all but one case, the SN was found within the LAS specimen. The FNR of SNB (blue, hot and adjacent palpable nodes) was 19.7% (47 of 238, one sided 95% upper CI 24.0) compared to LAS with FNR of 9.9% (29 of 292, one-sided 95% upper CI 12.8) (p<0.001). Comparative NPV for SNB and LAS were 89.4% and 93.9% respectively. If SNB was confined to blue/hot node excluding adjacent palpable nodes, FNR was 31.6% (74 of 234, 95% upper CI 36.6).

Conclusions

LAS is superior to SNB in identification rate, FNR and NPV in predicting node negative axilla post-neoadjuvant chemotherapy. LAS can be safely used to predict negative axilla with less than 10% chance of leaving residual disease.
Intraoperative touch imprint cytology in targeted axillary dissection after neoadjuvant chemotherapy among breast cancer patients with initial axillary metastasis

Siyu Wu¹, Yujie Wang¹, Jianwei Li¹, Na Zhang¹ and Guangyu Liu¹. ¹Fudan University Shanghai Cancer Center, Shanghai, China.

Background: A false-negative rate of <10% can be achieved if targeted axillary dissection (TAD) is performed, which includes the excision of both biopsy-proven positive lymph nodes (BxLNs) and sentinel lymph nodes (SLNs). However, little evidence exists on the accuracy of intraoperative touch imprint cytology (ITPC) applied in TAD after neoadjuvant chemotherapy (NAC) among breast cancer patients with initial axillary metastasis. We aimed to investigate the accuracy of ITPC in TAD after NAC.

Methods: Breast cancer patients with biopsy-confirmed nodal metastasis were prospectively enrolled. After the completion of NAC, all patients underwent TAD followed by axillary lymph node dissection. ITPC was carried out to evaluate BxLNs and SLNs. The accuracy of TAD and ITPC was calculated in comparison with haematoxylin and eosin staining of ALNs. The results of ITPC over 6 months in our centre in the adjuvant setting were used for comparison.

Results: Overall, the false-negative rate of TAD was 10.8%. ITPC was tested in 92 patients. Accuracy, sensitivity, and specificity of ITPC were 92.4%, 87.9% and 94.9%, respectively.

In the non-NAC group, ITPC showed a similar accuracy (91.2%) and specificity (97.9%) but a significantly lower sensitivity (68.9%, P=0.03). Multivariate analysis indicated that NAC, age and size of metastases was independent risk factors associated with false-negative ITPC (P<0.05).

**Abbreviations**: NAC, neoadjuvant chemotherapy; ITC, isolated tumor cell; LN, lymph node

**Conclusions**: ITPC was feasible in TAD among breast cancer patients with biopsy-confirmed axillary metastasis who were treated with NAC. All the misses in the ITPC were in patients with micrometastases or isolated tumour cells. ITPC can help decrease the number of second operations in patients with residual disease in ALNs after NAC.
Comparison of sentinel lymph node biopsy by dual method of indocyanine green fluorescence and radioisotope versus radioisotope only in breast cancer patients after neoadjuvant chemotherapy: A randomized controlled trial

So-Youn Jung¹, Jai Hong Han¹, Soo Jin Park², Eun-Gyeong Lee¹, Moo Hyun Lee³, Eun Sook Lee¹, Han-Sung Kang¹, Keun Seok Lee¹, In Hae Park¹, Sung Hoon Sim¹, Hae Jeong Jeong¹, Youngmee Kwon¹, Dong-Eun Lee¹, Jungnam Joo¹, Seok-Ki Kim¹ and Seeyoun Lee¹. ¹National Cancer Center, Goyang, Republic of Korea; ²Wonkwang University Sanbon Hospital, Gunpo, Republic of Korea and ³Keimyung University School of Medicine, Daegu, Republic of Korea.

Objectives: This study aimed to evaluate the identification rate of sentinel lymph node (SLN) in breast cancer patients after neoadjuvant chemotherapy (NAC) by dual method (DM) using a mixture of indocyanine green (ICG) and radioisotope (RI) compared with the RI alone.

Methods: In this randomized study, 130 patients after NAC for breast cancer were enrolled and 122 patients received SLNB with either DM (N=58) or RI only (N=64). We compared the identification rate, the number of SLNs, and detection time of SLN biopsy (SLNB) and evaluated the safety.

Results: The mean age of the DM group and RI group was 49.9 and 47.8 years (p=0.22), respectively. Among 122 patients, 113 (92.6%) were clinically node positive before NAC. There were no differences in clinical T stage, hormone receptor positivity, and type of operation between groups. The identification rates of SLNs were 98.3% in DM group and 93.8% in RI group (p=0.14), respectively. The average number of SLNs in DM group was similar with that in the RI group (2.19±1.13 vs. 1.94±1.33, respectively; p=0.26). The time to detect the first sentinel lymph node was similar in each group (8.7±4.98 vs. 8.3±4.31 min; p=0.30). In the DM group, transcutaneous lymphatic drainage was visualized by fluorescent imaging in 65.5% (38 of 58 patients) and 94.7% of first SLN were detected by ICG-F and 93.0% by RI (p=0.79). During and after the operation, there were no complications, including allergic reactions, skin staining, or necrosis.

Conclusions: This study is the first randomized trial that compared DM using ICG-F and RI and the conventional RI method for SLNB in breast cancer patients after NAC. DM could be a feasible and safe method for SLNB in initially node positive breast cancer patients with NAC.
Internal mammary chain sentinel nodes in early stage breast cancer patients: Towards selective removal

Ariane A van Loevezijn¹, Sanne AL Bartels¹, Frederieke H van Duijnhoven¹, Wilma D Heemsbergen², Sophie CJ Bosma¹, Paula HM Elkhuizen¹, Maarten L Donswijk¹, Emiel JTh Rutgers¹, Hester SA Oldenburg¹, Marie-Jeanne TFD Vrancken Peeters¹ and Iris MC van der Ploeg¹. ¹Antoni van Leeuwenhoek, Amsterdam, Netherlands and ²Erasmus MC, Rotterdam, Netherlands.

Background
Internal mammary chain (IMC) sentinel nodes (SN) are visible in 1 out of 5 breast cancer patients on lymph scintigraphy after intra- or peritumoral injection of a radiopharmaceutical. The IMC SN status affects prognosis and treatment of breast cancer and IMC radiotherapy improves survival in selected patients. In contrast to the axillary SN, removal of the IMC SN is not routinely performed and often technically challenging. This study aims at determining the effect of IMC SN biopsy on recurrence-free survival (RFS) and overall survival (OS) and the identification of predictive factors for the development of IMC- and distant metastases.

Methods
All patients with IMC SNs were selected from a prospective database from 1999 to 2007. Following intratumoral injection of technetium-99m, conventional lymphoscintigraphy was performed. Sentinel nodes were removed in all regions with lymphatic drainage on scintigraphy. The RFS and OS were calculated for the total group and subgroups with tumor-positive, tumor-negative or non-removed IMC SN. Predictive factors were identified for tumor-positive IMC SN and for distant metastasis by regression analysis.

Results
Internal mammary chain SN biopsy was performed in 287 out of 336 patients (85%). The IMC SN was tumor-positive in 38 patients (13%). Patients with IMC metastasis had poorer OS compared to patients without IMC metastasis or a non-removed IMC SN (57%, 82% and 59% 10- year OS, respectively, p = 0.002). These patients also had worse RFS, mainly due to the development of distant metastases (68%, 84% and 61% RFS, respectively, p = 0.002). Multivariable predictive for tumor-positive IMC SN were axillary metastases (PPV = 38.5%). Predictive factors for distant metastasis were tumor-positive IMC SN (HR 2.5, 95% CI; 1.0 - 5.8, p = 0.04), not removed IMC SN (HR 2.3, 95% CI; 1.0 - 5.1, P = 0.05), tumor diameter >1.5cm (HR 3.5, 95% CI; 1.6 - 8.4, p < 0.00) and age >65 years (HR 3.1, 95% CI; 1.2 - 7.7, p = 0.02, reference <50 years).

Conclusion
Breast cancer patients with tumor-positive IMC SN have worse 10- year survival than patients with tumor-negative IMC SN, mainly due to the development of distant metastasis. The clinically relevant predictive factor for distant metastasis is tumor size >1.5cm. Radiotherapy of the IMC can improve survival. However, the cardiotoxicity of parastral radiotherapy must be weighed against the expected survival benefit. Therefore, our current protocol is to perform IMC SN biopsy in patients younger than 70 years with a tumor diameter >1.5cm.
Indocyanine green (ICG) fluorescence mapping for sentinel lymph node (SLN) localisation in early breast cancer

John R Benson¹, Sujit Gnanakumar¹, Dorin Dumitru¹ and Elena Provenzano¹. ¹Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom.

Background: Dual localization methods with blue dye and radioisotope are commonly employed for SLN identification but allergic reactions together with staining of skin and surgical tissues disadvantage blue dye. Fluorescence mapping is consistently associated with high rates of identification (exceeding 95%) and sensitivity compared with standard agents. A feasibility study using blue dye, radioisotope and ICG confirmed high sensitivity of ICG fluorescence for SLN detection with three-quarters of nodes both radioactive and fluorescent (Wishart GC, et al. EJSO 2012; 38: 651 - 656). This follow-on study has specifically evaluated a combination of ICG with radioisotope for SLN identification.

Methods: In a prospective observational study, 50 patients with unilateral clinically node negative patients scheduled to undergo routine SLN biopsy for core-biopsy proven invasive (n= 49) or non-invasive (n = 1) breast cancer were identified at the multidisciplinary team meeting [26 screen-detected; 24 symptomatic]. All patients received dual localization with radiocolloid (Technetium nanocolloid, 4MBq) and ICG (0.5%). All patients had pre-operative axillary ultrasound and the number of nodes recorded numerically and whether radioactive, fluorescent or both. Subcutaneous lymphatics and nodal tissue were visualized with a Photodynamic Eye camera and sensitivity of individual tracers alone and in combination calculated. Approval was granted by the Joint Committee on Drugs and Therapeutics for use of ICG as a replacement tracer for blue dye.

Results: A total of 102 nodes were retrieved from 50 patients with an average nodal count of 2.04 (range 1 – 4) and an overall identification rate of 98% (49/50). Amongst these excised nodes, 94 displayed uptake of tracer and were either fluorescent, radioactive or both (8 nodes were removed incidentally or were palpably suspicious and tracer negative). More than 90% (94/102) of nodes were fluorescent and 61.8% (63/102) were radioactive with at least 10% activity of the hottest node. These results yielded an overall concordance rate of 69.6%. Nodal detection rates for ICG alone or combined with radioisotope were 92.2% (94/102) and 61.8% (63/102) respectively whilst procedural detection rates were 98% (49/50) for radioisotope and 100% (50/50) for ICG. Metastases were present in 9 nodes (all fluorescent and hot) with 9 patients having a single positive node containing macrometastases (n= 5), micrometastases (n = 2) or isolated tumor cells (n = 2). The node positivity rate was 14% (macro- or micrometastases) and the 4% of patients with isolated tumor cells testifies to removal of biologically important nodes. No serious adverse reactions were recorded.

Conclusion: ICG fluorescence imaging permits real-time visualization of lymphatics and provides an additional dimension to SLN biopsy that appears to be safe and effective. These results confirm high sensitivity for fluorescence in SLN identification with comparable performance parameters to the gold standard of radioisotope localization. With further refinements in technique may it may be possible to eventually rely on ICG as a sole tracer agent that avoids potential drawbacks of standard tracer agents including availability and costs of radioisotope.
Preoperative positive axillary lymph node biopsy, node metastasis burden, and possible sentinel lymph node biopsy for breast cancer patients in the post-ACOSOG Z0011 trial era

Yue Liang¹, Xiaosong Chen¹, Weiwei Zhan², Ying Zhu², Jiayi Wu¹, Ou Huang¹, Jianrong He¹, Li Zhu¹, Yafen Li¹, Weiguo Chen¹ and Kunwei Shen¹. ¹Comprehensive Breast Health Center, Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China and ²Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China.

Background. Breast cancer patients with suspicious axillary lymph node (ALN) at ultrasound and positive fine needle aspiration (FNA) results were required to receive ALN dissection (ALND), which was not certain in the post-ACOSOG Z0011 era. We aim to evaluate the ALN metastasis burden in these patients, thus to illustrate whether they can follow the ACOSOG Z0011 trial procedure.

Methods. Clinically T1-2N0 breast cancer patients with positive preoperative ALN biopsy (FNA group) or 1-2 positive sentinel nodes (SLNB group) were retrospectively analyzed. ALN metastasis burden were compared between two groups, which were further analyzed in certain subtypes. Association between clinicopathological factors and ≥ 3 ALNs metastasis were also analyzed.

Results. A total of 388 patients were included: 202 in the FNA group and 186 in the SLNB group. The FNA group had a significantly higher number of positive ALN (5.18 vs. 1.77, P < 0.001) and a larger proportion of patients with ≥ 3 ALNs metastasis (58.42% vs. 11.83%, P < 0.001) than the SLNB group

**Conclusions.** Patients with positive preoperative ALN biopsy had a higher ALN metastasis burden than patients with 1-2 positive SLNs, which was also the strongest factor associated with \( \geq 3 \) ALNs metastasis, indicating these patients are not appropriate to receive SLNB in the post-ACOSOG Z0011 trial era.
A nomogram predicting lymph node metastasis in T1 breast cancer based on the surveillance, epidemiology, and end results program

Ya-Xin Zhao\textsuperscript{1,2}, Yi-Rong Liu\textsuperscript{1,2}, Yi-Zhou Jiang\textsuperscript{1,2}, Shao Xie\textsuperscript{1,2} and Zhi-Ming Shao\textsuperscript{1,2}. \textsuperscript{1}Fudan University Shanghai Cancer Center, Shanghai, China and \textsuperscript{2}Cancer Institute, Fudan University Shanghai Cancer Center, Shanghai, China.

Background: In developed countries, T1 stage breast cancers have become the most frequently diagnosed invasive breast diseases. Patients with early stage breast cancer with lymph nodes metastasis have been proven to have more aggressive biologically phenotypes. The risk of missing metastases using sentinel lymph node biopsy can range from 1% to 4%, with a false negative rate of 10%. This evidence implies that SLNB might not be sufficient for the diagnosis of lymph node metastasis in T1 breast cancer patients. The aim of this study was to build a nomogram to predict lymph node metastasis in patients with T1 breast cancer.

Methods: We identified female patients with T1 breast cancer diagnosed between 2010 and 2014 in the Surveillance, Epidemiology and End Results database. The patients were randomized into training and validation sets. Univariate and multivariate logistic regressions were carried out to assess the relationships between lymph node metastasis and age, race, and tumour size, primary site, pathological grade, histologic type, and molecular subtype. A nomogram was developed in the training set and validated by a calibration curve with the bootstrapping method and receptor operating characteristic curve analysis.

Result: A total of 91,364 T1 breast cancer patients were included in the present study. For patients with T1 breast cancer, age, race, tumour size, tumour primary site, pathological grade, oestrogen receptor status, progesterone receptor status and human epidermal growth factor receptor 2 status were independent predictive factors of positive lymph node metastasis (P<0.001). Increasing age, tumour size and pathological grade were positively correlated with the risk of lymph node metastasis. Based on multivariate logistic regression analysis, we successfully developed a nomogram to predict lymph node metastasis by summing the scores of each variables. The nomogram was further validated it in a validation set, with areas under the receiver operating characteristic curves of 0.733 (95% CI: 0.722-0.744) and 0.741 (95% CI: 0.731-0.752) in the training and validation sets, respectively. We determined the cut-off value of total points to predict lymph node metastasis according to Youden’s index in the training set. Both the training set and validation set were divided into two groups: the low score group (total points≤182) and the high score group (total points>182). We found a significant difference in the probability of lymph node metastasis between the high and low score groups in univariate analysis in both the training set (OR=4.15, 95% CI:3.77-4.57, P<0.001) and the validation set (OR=4.53, 95% CI 4.10-5.00, P<0.001).

Conclusions: A better understanding of the clinicopathological characteristics of T1 breast cancer patients could be vital for the assessment of their metastatic lymph node status. The nomogram developed here, if further validated in other large T1 patient cohorts, might provide additional information regarding lymph node metastasis. Together with sentinel lymph node biopsy, this nomogram can help comprehensively predict lymph node metastasis.
Pre-operative lymphoscintigraphy for sentinel lymph node localisation: Is it necessary?

Stephanie L Clark¹, Dilsan Yilmaz¹, Kirupakaran Arun¹, Shagayegh Javadzadeh¹, Samerah Saeed¹ and Md Zaker Ullah¹. ¹Whipps Cross University Hospital, Barts Health NHS Trust, London, United Kingdom.

Introduction
Sentinel lymph node biopsy (SLNB) has replaced lymph node clearance for staging of the axilla in patients with early invasive breast cancer and no evidence of lymph node involvement on ultrasound or needle biopsy. It is recommended that a dual technique, using isotope and blue dye, is used to locate the sentinel lymph node (SLN) intra-operatively. Often, at the time of radioisotope injection, a lymphoscintigram (nuclear medicine scan) is obtained to demonstrate the 'hot' sentinel lymph node with or without skin marking of its anatomical position.
Performing a lymphoscintigram adds time and cost to the localisation process. In our centre, this investigation costs £899-999 (~US $1180-1300).

Aims
The aim of this study is to find out whether obtaining a pre-operative lymphoscintigram aids the surgeon in the localisation of the SLN or affects the number of sentinel lymph nodes biopsied in the axillary staging of patients with early invasive breast cancer.

Methods
We carried out a retrospective study of patients who underwent SLNB for breast cancer in our hospital Trust between March 2012 and November 2017. We identified those patients who had a lymphoscintigram performed pre-operatively for SLN localisation. We recorded the number of SLNs identified on imaging and compared this with the number of SLNs biopsied during the operation.

Results
349 patients underwent 354 SLNBs during the study period. One patient was male, the remainders were female. The mean age of patients was 57.2 years (range 25 to 98 years).
In 295 (83.3%) cases, a lymphoscintigram was obtained prior to SLNB for node localisation, and 268 (90.8%) of these scans were able to identify one or more SLNs. In 173 (58.6%) scans, a single SLN was identified. In 27 (9.1%) scans it was either unclear how many SLNs were demonstrated or no SLNs were seen (16/295 no SLN identified, 11/295 unclear how many SLNs).
In 102 (34.6%) cases, the number of SLNs biopsied matched the number of SLNs identified on imaging. Of those that did not match, 76.2% had more and 15.0% fewer SLNs excised than shown on imaging. In 8.8% it was unknown if the number of SLNs matched that seen on imaging due to lack of histopathology results.

Conclusion
Lymphoscintigraphy for SLN localisation is costly and time consuming. In a high proportion of cases, number of SLNs identified on imaging does not match the number biopsied and thus, we suggest, that it is not required prior to SLNB and should be removed from practice.
Intraoperative assessment of the sentinel node in breast cancer by one step nucleic acid assay: Experience of over 1100 patients

Dayalan Clarke¹, Aaditya Sinha¹, Lottie Ion¹, Sam Weston¹, Lucie Jones¹, Mashuk Kham¹ and Simon Harries¹. ¹Warwick Hospital, Warwick, Warwickshire, United Kingdom.

Introduction
The intraoperative assessment of the sentinel node in women with breast cancer enables an immediate axillary node clearance to be done as part of the same operative procedure if the sentinel node is positive. This has significant benefits for the Patient, the Surgeon and the Health Care Provider. There are a variety of methods for the intra-operative assessment of the sentinel node which include: Touch Imprint Cytology, Frozen Section Analysis and Polymerase Chain Reaction (PCR) based molecular assays. OSNA is an automated molecular assay using a Polymerase Chain Reaction (PCR), which detects the presence of cytokeratin 19 in the sentinel node. We report our experience of OSNA for the intraoperative assessment of the sentinel node in our institution with 1148 patients.

Methods
All patients with operable breast cancer who were found to be node negative on clinical and radiological assessment of the axilla, and who had their axilla staged by a sentinel node biopsy at the Breast Unit at Warwick Hospital, UK over a 7 year period were included in this study. Data was collected from a prospective database maintained at the Breast Unit. The axillary node positivity rate and the number of patients with macrometastatic and micrometastatic disease as detected by OSNA was collected and compared with a group of 411 patients who had the intraoperative assessment by Touch Imprint Cytology and final histology by conventional Haematoxylin & Eosin (H&E) assessment, prior to the introduction of OSNA. The Chi-square test were used for statistical significance.

Results
1148 patients had their sentinel node assessed intraoperatively using OSNA in this 7 year study period. The sentinel node was positive in 376 patients (32.8%). Of those who had a positive node, 183 (15.9%) had macro-metastatic disease and 193 (16.8%) had micro-metastatic disease. When compared to 411 patients in the pre-OSNA period, that were assessed by Touch Imprint Cytology and H&E sections, the node positivity rate increased from 23.8% to 32.8% (p<0.05) with the introduction of OSNA. Whilst there was no significant increase in the rate of macrometastatic disease – 20.4% versus 15.9 % (p0.038), there was a significant increase in the patients who had micrometastases detected on OSNA - 3.4% versus 16.8 % (p<0.05) as shown in the table.

Conclusion
Our results demonstrate that OSNA is a more sensitive test for picking up metastatic disease, especially micrometastatic disease, in the sentinel node. Whilst this did cause some anxiety initially, the results of recent trials like ACSOG Z-11 and IBCSG 23-01 have shown that small volume disease or micrometastases in the sentinel node do not require an axillary node clearance. Intraoperative assessment of the sentinel node with OSNA significantly upstages the axillary nodal status, especially with regard to micrometastatic disease, but the ability to proceed to an axillary node clearance at the same operation as the sentinel node biopsy, still has significant advantages for the Patient, Surgeon and Health Care Providers.
SentiDose interim analysis. A dose optimizing study with a super paramagnetic iron oxide for sentinel node detection

Abdi-Fatah Hersi¹, Christine Obondo², Lida Pistioli³, Shahin Abdsaleh³, Fredrik Nilsson³, Iman Mohammed³, Staffan Eriksson¹, Fredrik Wärnberg³ and Andreas Karakatsanis². ¹Centre for Clinical Research, County of Västmanland, Uppsala University, Västmanland County Hospital, Västerås, Sweden; ²Uppsala University, Uppsala, Sweden; ³Sahlgrenska University Hospital, Gothenburg, Sweden; ⁴Umeå University, Umeå, Sweden and ⁵Kalmar Hospital, Kalmar, Sweden.

Background
Superparamagnetic iron oxide nanoparticles (SPIO) is a novel tracer for axillary mapping in breast cancer with comparable performance to the dual standard of isotope and blue dye. The earlier SPIO (Sienna+®) required 2 ml of SPIO diluted in 3 ml NaCl and was injected retro-areolarly. This was considered to be associated with the discoloration observed in 40% of breast conservation cases. Subsequently, a new form was developed (SiennaXP™) in a volume of 2 ml without dilution. The aim of the ongoing SentiDose study is to compare smaller doses of SiennaXP™ injected in different time-frames (1.5 ml periareolarly on the operation day vs 1 ml peritumourally 1-7 days preoperatively) and compare it to the performance of the original SPIO (Sienna+®). A background mapping with isotope and blue dye was performed for assessment of concordance.

Method
In all, 330 patients will be recruited from six sites in Sweden, divided in two isonumerical cohorts injected as described above. Results from the 1.5 ml cohort are presented and compared on a patient-level analysis to the SentiMag Nordic trial that used Sienna+®, on a 2-sided non-inferiority margin of 5%. Study endpoints are detection rate per patient, number of sentinel nodes (SN) retrieved and discoloration at 3 weeks postoperatively.

Results
Detection rate for SiennaXP™, 1.5 ml, was comparable with Sienna+® (96.9 vs 97.6%, p=0.76), even in multivariate analysis adjusting for age and metastasis rate (Exp(B)=0.68; 95% CI: 0.18-2.60, p=0.58). with a high concordance between isotope and SiennaXP™. The number of SNs were similar (1.91 vs. 1.83, p=0.08) for Sienna+® and SiennaXP™. Discoloration rate was lower for SiennaXP™ compared to Sienna+® (14.3% vs. 38.2%, p<0.001) after breast conserving surgery. Furthermore, two patients were excluded in the SentiDose cohort due to protocol violation.

Demographics and outcomes are illustrated in Table 1

Conclusion
The periareolar injection of 1.5 ml SiennaXP™ on the day of the operation provides comparable detection rates with much less
skin discoloration, providing effectiveness and flexibility. The completion of the SentiDose study will allow for more definitive results on the dose, timeframe and injection site of SPIO.
Preoperative positive axillary lymph node biopsy, predictors of node metastasis burden, and possible sentinel lymph node biopsy for breast cancer patients in the post-ACOSOG Z0011 trial era

Yue Liang, Xiaosong Chen, Weiwei Zhan, Jiejie Yao, Jiayi Wu, Ou Huang, Jianrong He, Li Zhu, Yafen Li, Weiguo Chen and Kunwei Shen. 1 Comprehensive Breast Health Center, Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China and 2 Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China.

Background. Breast cancer patients with suspicious axillary lymph node (ALN) at ultrasound and positive fine needle aspiration (FNA) results were required to receive ALN dissection (ALND), which may lead to overtreatment for patients with 1-2 ALN metastasis in the post-ACOSOG Z0011 era. We aim to identify clinicopathologic and imaging characteristics associated with ≥3 ALNs metastasis in these patients, thus to illustrate whether FNA positive patients could be selected to follow the ACOSOG Z0011 trial procedure.

Methods. Clinically T1-2N0 breast cancer patients with positive FNA results were retrospectively analyzed. Clinicopathologic and imaging characteristics were compared between patients with 1-2 or ≥3 ALNs, association between characteristics and ≥3 ALNs metastasis were also analyzed.

Results. A total of 165 patients were included. Having lymphovascular invasion (LVI) positivity (OR = 4.96, 95% CI 1.79-13.73, P = 0.002), >1 suspicious ALNs at ultrasound (OR = 6.21, 95% CI 2.24-17.23, P < 0.001), MRI (OR = 2.57, 95% CI 1.28-5.15, P = 0.008), and cortical thickness of the suspicious ALN at ultrasound > 4.5 mm (OR = 2.28, 95% CI 1.11-4.67, P = 0.025) were independently associated with ≥3 ALNs metastasis.

Abbreviation: ALN axillary lymph node, OR odds ratio, CI confidence interval, LVI lymph vascular invasion, US ultrasound, MRI magnetic resonance imaging, CT computed tomographic, MMG mammogram

**Conclusions.** For patients with positive FNA results, having LVI positivity, > 1 suspicious ALNs at ultrasound, MRI, and cortical thickness of the suspicious ALN at ultrasound > 4.5 mm were associated with ≥ 3 ALNs metastasis. Indicating these factors can help select patients to receive SLNB in the post-ACOSOG Z0011 trial era.
Clinical utility of one-step nucleic acid amplification (OSNA) in axillary surgery after neoadjuvant chemotherapy (NAC)

Francesca Muscara1, George Christaki1, Caroline Richardson1, Rachel O'Connell1, Pooja Padmanabhan1, Jane Warwick2, Yujin Lee2, Ian Smith1, Ashutosh Nerurkar1, Peter Osin1, Katherine Krupa1, Jennifer Rusby1, Nichola Roche1, Gerald Gui1, Fiona MacNeil1 and Peter Barry1. 1Royal Marsden Hospital, London, United Kingdom and 2University of Warwick, Warwick, United Kingdom.

Introduction
NAC has been used for downsizing of the tumour in breast and axilla to allow more conservative surgery. In the NAC setting, intraoperative assessment of sentinel lymph node(s) (SLN) is still considered necessary1. Current awareness of the prognostic value for axillary nodal down-staging has renewed interest in analysis of SLN post-NAC.

In this study we want to examine the clinical utility of OSNA (based on CK19 mRNA detection) as a method of intra-operative analysis of SLN to assist real-time decision-making for axillary surgery post-NAC in early breast cancer (EBC).

Methods
Retrospective analysis of prospective data on 399 consecutive patients with EBC who received NAC followed by breast surgery with SLN biopsy (408 axillae) and assessment by OSNA, from September 2011 to January 2018 at the Royal Marsden Hospital (UK). OSNA readouts from the Sysmex RD-100i were collected separate to and blinded from clinico-pathological data. A negative or benign pre-treatment axillary ultrasound scan or indeterminate ultrasound with negative or benign axillary cytology/histology prior to NAC was considered cN0. Univariate analysis (significance at p<0.05) was used to identify risk of recurrence. Patients had a median (mean) follow up of 32.5 (36) months.

Results
The median age at diagnosis was 49 years, median BMI 26, 41 EBC (10%) were screen-detected, 292 (72%) were grade 3 and the most frequent phenotype was receptor triple negative (n=132, 32%).

Of 408 axillae, 248 (60%) were initially cN0, of which 113 (46%) had a pathological complete response (pCR) in the breast. SLN in 54 (22%) cN0 patients were positive on OSNA, of which only 6 (9%) had further involved axillary nodes all 6 of which were ER+ Her2-.

The remaining 160 (40%) axillae were cN1 of which 87 (54%) had conversion to ypN0 including 55 (34%) with both ypT0ypN0. Axillary lymphadenectomy (AL) was performed in 79 (19%) patients overall, of which n=22 (28%) were cN0 and 57 (72%) were cN1. Of these, 30 (53%) of the cN1 and 6 of 22 (45%) of cN0 had at least 1 additional positive AL node.

Overall 59 (14.4%) patients relapsed. A significantly worse rate of relapse was observed in cN1 compared to cN0 patients (37/159 (23.3%) versus 22/244 (9%), p<0.001). Combined pCR of both breast and axilla (in cN1, n=54) was associated with a significantly reduced risk of relapse and death (p<0.001) compared to those without pCR of either breast or axilla (n=62). Of the latter 18 (29%) relapsed (including 10 deaths).

The mean of both the single highest node tumour load (and total nodal tumour load), as measured by CK19mRNA copies/ul on OSNA, were significantly higher at 90,000 (98,300) for those who relapsed versus 23,100 (25,100) for those without relapse (p=0.027).

Conclusions
The OSNA assay is an accurate tool for axillary SLN analysis in patients after NAC and was helpful in intra-operative axillary management. OSNA reduces the need for a second surgery for AL in 20% of breast cancer patients with a positive-SLN after NAC and might offer additional prognostic value.

Patient reported outcomes in women undergoing sentinel lymph node biopsy in the SUNrISE randomized trial evaluating different doses of superparamagnetic iron oxide

Isabel T Rubio¹, Antonio Esgueva¹, Martin Espinosa-Bravo², Roberto Rodriguez-Revuelto², Christian Siso² and Joaquin Rivero².
¹Clinica Universidad de Navarra, Madrid, Spain and ²Hospital Universitario Vall d’Hebron, Barcelona, Spain.

Background. Sentinel lymph node biopsy (SLNB) with 2 mL of superparamagnetic iron oxide (SPIO) tracer has shown to be non-inferior to the standard radioisotope technique in several studies. The SUNrISE randomized trial has shown non inferiority of 1mL vs. 1.5 mL vs. 2 mL dose of SPIO with the standard use of radioisotope ⁹⁹ᵐ Tc. We present patient reported outcomes from this randomized trial.

Material and methods. Patients with stage I breast cancer who underwent breast conservative surgery and sentinel lymph node biopsy were assigned consecutively (1:1:1) to one of the three groups defined by the different SPIO dose, group 1 (1mL), group 2 (1.5 mL) and group 3 (2 mL). Patients filled a questionnaire related to the presence of skin staining, staining intensity (mild, moderate, intense) and whether the stain worried them. Patient also completed a quality of life (QoL) EORTC C30 questionnaire at 1 month postoperative visit, at 6 months and at 12 months. First analysis from the 1 month postoperative outcomes are reported here. Follow up on the 6 months will be available for the meeting.

Results. One hundred and thirty five patients were included in the trial, 45 in each group. Median age in group 1 was 58 years old, 63 y/o in group 2 and 65 y/o in group 3 (p=0.03) At 1 month follow up, patients in group 1 had less skin tattoo when compared with patients in group 2 and 3 (p= 0.02). There were no significant differences related to skin staining intensity by doses. Seventy percent of patients felt no concern about the tattoo.

On the multivariate analysis including age, SPIO dose, body mass index and breast density, only younger age (p = 0.037), and higher SPIO doses (p= 0.029) were significantly associated with increased skin staining.

There were no statistically significant differences in responses in the QoL questionnaire at 1 month postoperative visit. There were no severe reactions to the procedure or complications in any patient.

Conclusions. SLN with 1mL dose of SPIO has shown non-inferiority in the detection of SLN when compared to 1.5 and 2 mL. Being young and the use of 1.5 and 2 mL increased the risk of developing skin staining. Even though, most of the patients were not concern about the skin staining. Rates of discontinuation of skin discoloration will be assessed at 6 months follow up.
Intraoperative evaluation of sentinel lymph nodes after neoadjuvant systemic therapy in breast cancer

Sunati Sahoo1, Mariam Mir1, Venetia Sarode1, Yisheng Fang1, Yan Peng1, Katja Gwin1 and Helen Hwang1. 1UT Southwestern Medical Center, Dallas, TX.

Introduction:
Intraoperative evaluation of sentinel lymph nodes (SLN) in breast cancer patients are performed using Touch preparation (TP) and/or frozen section (FS). Touch preparation for intraoperative evaluation of SLN is quick and known to be a highly sensitive and specific method for detection of metastasis. Detecting metastases in SLN intraoperatively can be challenging in patients who receive neoadjuvant systemic therapy (NST). In our hospitals, we have been routinely evaluating SLN intraoperatively in patients who have undergone (NST), including those with known metastasis to an axillary lymph node (LN) prior to therapy.

Objective:
To compare the sensitivity and specificity of TP and frozen section (FS) in the intraoperative evaluation of SLN in the neoadjuvant setting.

Material and Methods:
This retrospective review study was approved by the institutional review board. Four hundred ninety-eight SLN from 142 patients were included in this study. The intraoperative results for TP and FS were compared with the final pathology results. Relevant clinical and pathological findings such as type of surgery, tumor grade, histologic subtype, and size of metastasis were reviewed.

Results:
Of the 498 SLN evaluated intraoperatively, 341 were by TP only, 57 by FS only and 100 by both.
Of the 341 SLN examined by TP only, 313 (92%) were interpreted as negative and 28 (8%) as positive for carcinoma intraoperatively. Eighteen LN turned out to be false negative (FN) with no false positives (FP) (sensitivity=62%, specificity=100%). In the false negative cases, 12 LN had micrometastasis, 6 macrometastasis and 1 showed isolated tumor cells (ITC). The size of the macrometastatic ranged from 3 mm to 10 mm.
Of the 57 LN examined by FS only, 48 were true negative and 9 were true positive (sensitivity=100%, specificity=100%). Of the 100 LN evaluated by both TP and FS, 59 were interpreted as negative and 41 as positive for carcinoma. There were 8 false negatives and 1 false positive (sensitivity=83%, specificity=98%). Of the 8 false negatives, 7 showed micrometastasis and 1 LN had ITC.

Discussion:
In neoadjuvant cases, both the primary tumor as well as lymph node metastases can show therapy effect such as fibrosis, necrosis and/or histiocytic aggregates. Evaluating SLN in NST cases can be challenging secondary to these effects. The TP slides are often paucicellular in SLN with treatment effect. Residual tumor cells are often trapped in a fibrotic scar and do not transfer onto the TP slide leading to low sensitivity. Therefore, for optimal intraoperative evaluation of SLN in NST cases, frozen section with or without touch preparation, is recommended.
No relationship of axillary total tumor load (TTL) by PCR (OSNA) in early breast cancer and local and distant clinical outcomes

Raquel Tur1,2, Juan Parra2,3, Rocio Martin1,2 and José Enrique Alés-Martinez1. 1Complejo Asistencial de Ávila, Ávila, Spain; 2UICBE: Investigation Unit, Ávila, Spain and 3CIBER: Investigation Unit, Ávila, Spain.

BACKGROUND
The study of sentinel lymph nodes (SLN) assessed by One Step Nucleic Acid Amplification (OSNA, Sysmex, Kobe, Japan) creates a new variable, Total Tumor Load (TTL). This variable is defined as the total number of CK19 mRNA copies in all positive SLN (copies/microL). The latest edition of the Spanish Oncological Gynecology Society (SEGO) Guideline (2017) proposes complete axillary lymph node dissection (ALND) when TTL is 15,000 copies or more in early breast cancer. In our center we are using OSNA to ascertain if there is axillary node involvement but the decision to proceed to ALND is based on Z0011 criteria. We want to determine if there is a correlation between clinical outcomes and TTL values, between TTL and pathological variables and if TTL is a useful tool to decide when to complete an ALND.

METHODS
Clinicopathological and follow up data were obtained from all patients with invasive breast cancer and SLN assessed by OSNA between 2011 and end of 2016 at our center.

RESULTS
A total of 277 patients underwent SNB assessed by OSNA with an average follow-up of 56.4 months. 276 were female and 1 male. Age range 27-88 years (mean 58,7). 86,2 % were ductal, 10,8 % lobular and 2,8 % other. 51.9% were luminal A, 51.98% luminal B, 28.51%, triple negative, 5% Her2 positive and 5% luminal B-Her2 positive. TTL was equal to 0 in 155 cases and greater than zero in 122 cases. 68 cases showed a TTL higher than 15,000 copies. Only 19 cases met Z0011 criteria and had ALND. As of now, 3 patients have had locoregional relapse (TTL = 0 in 2 cases and 18,000 copies in one) and 5 metastatic disease (none with simultaneous locoregional recurrence). 7 patients have died (one from metastatic breast cancer, 1 febrile neutropenia, 2 septic shock unrelated to chemotherapy, 2 from other tumors, 1 encephalopathy).

CONCLUSIONS
1. Using Z0011 criteria, we have adequate clinical outcomes with a very low rate of ALND and locoregional recurrences.
2. If we had based the axillary management on TTL values we would have multiplied the number of ALND by a factor of 2.7 (from 18 to 50).
3. We have observed a tendency to higher TTL in luminal phenotypes and to lower TTL in HER2 positive and triple negative subtypes.
4. Work is in progress to increase our sample size.
Invasive lobular carcinoma does not fit to axillary lymph node management according to NCCN guideline influenced by ACOSOG Z0011 criteria

Takeshi Miyamoto¹, Tomomi Fujisawa¹, Akiko Morishita¹, Yasuhiro Yanagita¹ and Taka-aki Fujii². ¹Gunma Prefectural Cancer Center, Ota, Gunma, Japan and ²Graduate School of Medicine, Gunma University, Maebashi, Gunma, Japan.

[Introduction] Surgery for breast cancer (BC) became less invasion, from radical mastectomy to modified or breast conserving surgery (BCS). Axillary lymph node (ALN) management for cN0 also became less, from ALN dissection (ALND) to sentinel lymph node (SLN) biopsy. In some cases, management without ALND is allowed even if ALN macro-metastasis exist.

[Background] ALND for SLN metastasis positive case is useful for local control, staging and decision making for post-operative treatment. Since the ACOSOG Z0011 trial (Z11) result was reported, however, the necessity of ALND, even if SLN metastasis, became less. In the NCCN guideline (NCCN), strongly influenced by Z11, for cN0 BC with SLN metastasis, operations without ALND are allowed in cases of T1 or T2, the number of metastatic ALN 1 or 2, BCS with whole breast radiation and no-neoadjuvant therapy. This does not mean ALND was abolished but the position of ALND changed, from the perspective that over invasive procedure must be prohibited with appropriate pre-operative and intra-operative diagnosis. If there are some discordance between clinical and pathological diagnosis of tumor size or ALN metastasis, however, the criteria for axillary operation by NCCN will not be recommended. We have major two types of invasive carcinoma, ductal (IDC) and lobular (ILC). Z11 or NCCN did not describe about these two phenotypes. We compared these at the point of suitable axillary management.

[Subjects] Out of 1320 invasive BC (IDC; 1212, ILC; 108) cases in our hospital from January 2008 to January 2018, 1210 cases (IDC; 1113, ILC; 97) with T1/T2 and cN0 were reviewed in two points, the judgment of the competence for BCS was appropriate or not, and cN0 reflected the condition for the omission of ALND (ALN metastasis within 2) or not.

[Results] The difference of diameter between cT and pT; dT (=pT-cT) were measured significantly larger in ILC (0.68±1.97cm) than IDC (0.01±1.08cm)(p<0.01, t-test) with the wide scattering. We can make proper evaluation for the cT of IDC, but underestimate for ILC. The conversion rate from cN0 to pN1 was significantly higher in ILC (33/97; 34.0%) than IDC (238/1113; 21.4%)(p<0.01, χ² test). In addition, the cases with 3 or more ALN metastasis, this means ALND is necessary, was observed with significantly higher frequent in ILC (13/97; 13.4%) than IDC (74/1113; 7.1%)(p=0.02, χ² test). Clinical evaluation for ALN in ILC was difficult and inaccurate.

[Discussion] Commonly, ILC makes diffuse spread into the breast tissue. This feature will make it difficult to evaluate the clinical appropriate tumor size. Because of not only underestimation but wide scattering, the diagnosis for safety BCS may not be guaranteed in ILC. For ALN, cN0 did not reflect adequately the condition of omission for ALND in ILC compared with IDC. ILC patients with SLN metastasis have to be performed ALND at higher risk. These facts will mean that ILC does not fit to ALN management according to NCCN. Few guidelines separate ILC from IDC for the axillary management. The validation of clinical trials for ALND should be done in histological subtype as well as intrinsic again. Clinically, we must observe carefully in cases of ILC without ALND according to Z11.
Tumor cell detection and immune profiling of lymph nodes from breast cancer patients by mass cytometry

Hege G Russnes¹, Inga H Rye¹, Kanutte Huse¹, Ellen Schlichting¹, Øystein Garred¹ and June H Mykelbust¹. ¹Oslo University Hospital, Oslo, Norway.

Introduction:
A sentinel lymph node (SN) is the primary node draining the tumor and is assumed to be affected early in the metastatic process. Detection of metastases in SN is a standard procedure in breast cancer diagnostics based on microscopic evaluation (morphology and immunohistochemistry), determining the need for removal of all axillary glands for inspection which again is crucial for tailoring adjuvant therapy. The identification by microscopy is time-consuming and has a risk for false negative results. We hypothesize that the immune profile of SN changes with the presence of tumor cells, even at very low frequencies (micrometastases). By using a multi marker approach to characterize millions of cells from sentinel lymph nodes with and without metastases we aimed at identifying both tumor cells but also characterize a tumor specific immune response. This dual approach might provide an opportunity for a more sensitive test for SN diagnostics.

Material and Methods:
We established a mass cytometry assay containing 38 markers (antibodies) using CyTOF technology to combine immune profiling with identification of breast cancer cells. Cell suspensions from 14 metastatic axillary lymph nodes (ALNmet), 16 metastatic sentinel lymph nodes (Snmet) and 14 non-metastatic sentinel lymph nodes (SN) from breast cancer patients from the clinical observational trial Oslo2 (early, operable breast cancer patients representing all subtypes) were successfully analyzed by the multimarker panel (single cell resolution).

Results:
By using mass cytometry, we detected tumor cells (gated as PanKeratin+/CD45- cells) in 86% (26/30) metastatic lymph nodes (ALNmet and Snmet) and in 14% (2/14) non-metastatic lymph nodes (SN). Further, the leukocyte population, identified as CD45+ cells, was gated into 15 subpopulations, mainly comprising different subsets of B and T cells, monocytes and NK cells. By comparing the leukocyte composition in the ALNmet with those in SN samples we identified a significant increase in the abundance of CD8+ memory phenotype, TFH and TCRγδ cells and a decrease in the CD4+ subpopulation in ALNmet compared to the SN samples. The Snmet samples had smaller deposits of tumor cells than the ALNmet samples, and we found no significant differences in leukocyte composition between Snmet and SN samples. Interestingly, when looking at the activation marker CD56, we observed a significant higher expression in the CD4RO, CD8RO, TFH and Treg subpopulations of Snmet samples compared to SN samples.

Conclusion:
In this study we identified a significant difference in immune cell composition in lymph nodes with and without metastases (ALNmet compared to SN samples). We also identified activation markers unique for subpopulations of lymphocytes in Snmet, but not in negative lymph nodes (SN). We were also able to detect and identify micrometastases in most lymph nodes where morphological examination had identified them, but in addition found tumor cells in two samples scored as negative. The results will be validated in a larger sample series.
Which biopsy is preferred to stage the axilla under ultrasound guidance in early breast cancer patients: Fine-needle aspiration cytology or core needle biopsy?

Meiqi Zhou¹, Jili Qiu¹, Jiani Chen¹, Yue Hu¹, Yongchuan Deng¹ and Shu Zheng¹. ¹Second Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou, Zhejiang, China.

Background:
Preoperative axillary ultrasound (AUS) offers the potential to identify clinically axillary negative patients with axillary lymph node (ALN) metastasis directly to axillary lymph node dissection (ALND) with avoid of unnecessary sentinel lymph node biopsy (SLNB) except Z0011 candidates. Which biopsy should be preferred is pendent with lack of enough prospective studies. The purpose of our study was to compare the accuracy of ultrasound guided fine-needle aspiration cytology (FNAC) and core needle biopsy (CNB) for the designated ALN prospectively.

Methods:
Consecutive patients with histologically confirmed breast cancer from April, 2010 to December, 2014 were preliminary screened for our study. All the candidate patients were prospectively assessed by ipsilateral AUS before initial treatment regardless of clinical ALN status. Abnormal lymph nodes were characterized by round shape with uniform or eccentric thickening, focal bulging or irregularity of the cortex displacement, obliteration of the hilum; or total loss of recognizable lymph node architecture. If suspicious ALN was identified, both ultrasound-guided FNAC and CNB were performed for the same designated ALN. The diameter in longitudinal section, transverse section and maximum cortical thickness of the target node was recorded. When more than one abnormal lymph node was present, the most abnormal-appearing node was sampled. The target tissue for biopsy was hypoechoic thickened cortex. Patients with a positive FNAC/CNB underwent ALND, and those with a negative FNAC and CNB biopsy or without suspicious ALN by AUS underwent SLNB. The paired parameters of FNAC and CNB were compared using McNemar’s exact test.

Results:
705 consecutive patients were screened and 558 patients (561 axillae) underwent AUS evaluation with confirmed ALN pathological results. 145 patients (146 axillae) with both FNAC and CNB were finally enrolled. Final histopathological results showed that 83.6% (122/146) were node positive (5 micro-metastases were considered negative). Sensitivity of FNAC and CNB was 67.2% (82/122) and 91.8% (112/122). Overall accuracy of FNAC and CNB was 72.6% (106/146) and 93.2% (136/146). Negative predictive value (NPV) of FNAC and CNB was 37.5% (24/64) and 70.6% (24/34). There was significant difference in sensitivity, overall accuracy and NPV between FNAC and CNB (p<0.001). 80.6% (29/36) FNAC negative and CNB positive patients have ALN cortical thickness of 3.3-7.2 mm.

Conclusion:
CNB is more sensitive and accurate than FNAC to stage the axilla under ultrasound guidance in operable breast cancer patients, especially in patients with ALN cortical thickness of 3.3-7.2 mm.
Usefulness of sentinel lymph node biopsy by indocyanine green fluorescence method for cN0 breast cancer patients

Yurina Maeshima¹, Sachiko Takahara¹, Akira Yamauchi¹, Kazuhiko Yamagami², Tomoharu Sugie³, Hiroyasu Yamashiro⁴, Hironori Kato⁵, Masae Torii⁶, Masahiro Takada⁶, and Masakazu Torii⁶. ¹Tazuke Kofukai Foundation, Medical Research Institute, Kitano Hospital, Osaka, Japan; ²Shinko Hospital, Kobe, Japan; ³Kansai Medical University Hospital, Osaka, Japan; ⁴Tenri Hospital, Nara, Japan; ⁵Kobe City Medical Center General Hospital, Kobe, Japan; and ⁶Kyoto University Hospital, Kyoto, Japan.

Background. Indocyanine green (ICG) fluorescence method (ICG-f) has been recently widely used in sentinel lymph node (SLN) detection. The advantages of ICG-f are no radiation exposure, no limitation to use in high-volume medical centers without radioactive facility, and to confirm lymph flow as a real-time image from outside the body. ICG-f identified an average of 2.3-3.4 SLNs and the detection rate was 99%, compared to 1.7-2 SLNs by RI methods. Long-term observation after SNB using ICG-f has not been reported, including arm lymphedema as the complication of this method. We evaluate the usefulness of SLN biopsy (SNB) for cN0 breast cancer patients from data of multicenter cohort study on long-term results after negative SNB by ICG-f.

Methods. Eleven hundred and thirty-two women were enrolled who had histologically proved clinical stage T1-4, pN0, M0 primary invasive breast cancer with SNB using ICG-f (ICG alone or combination of RI/blue dye method) sparing axillary lymph node dissection from May 2007 to December 2015. This study is retrospective, multicenter cohort study conducted at 6 centers in Japan. Primary endpoint is axillary recurrence rate. We analyzed the correlation with the axillary recurrence and adjuvant systemic therapy, adjuvant radiotherapy, and the clinicopathological characteristics. Secondary endpoint is lymphedema.

Results and Discussion. The median follow-up time was 41 (range 21-117) months, and axillary recurrence was found in 6 patients (0.53%). Five out of 6 patients were not received standard adjuvant systemic therapy or adjuvant radiation therapy after breast conserving surgery because of patient's preference or old age. Lymphedema was identified only 4 patients in 632 patients. It is reported that axillary recurrence after SNB was 0.3-1.65%, which was consistent with our result. Lymphedema was not frequent in patients received SNB using ICG-f, because SLNs are removed along with lymphatic ducts in the limited area of axillary adipose tissue.

Conclusion. Axillary recurrence after negative SNB using ICG-f was comparable to RI or blue dye method. It might be important to perform appropriate adjuvant medication or radiation therapy for preventing axillary recurrence after SNB using ICG-f. Next, ICG-f after neoadjuvant chemotherapy is to be investigated, because it is reported that removing more than 2 SLNs were associated with a lower likelihood of false negative ratio in patients with clinically node-positive disease converted to clinically node-negative after chemotherapy, and ICG-f might overcome this issue.
Prognostic impact of axillary lymph node status after neoadjuvant chemotherapy for patients with breast cancer

Rikiya Nakamura¹, Naohito Yamamoto¹, Tosihko Miyaki¹ and Makiko Itami¹. ¹Chiba Cancer Center, Chiba, Japan.

BACKGROUND:
Patients were stratified by final pathological axillary status: ypN0, ypN1, pN0 or pN1.
The prognostic impact of lymph node involvement after neoadjuvant chemotherapy (NAC) for breast cancer is not straightforward.
The aim of this study was to compare overall survival (OS) between pathologically node-positive T1,T2 T3 breast cancer patients treated with NAC, with ypN0 or ypN1 and those treated without NAC with pN0 or pN1.

METHODS:
A total of 3903 consecutive patients with operable breast cancer were prospectively identified at our institution between April 2006 and December 2017. Patients with suspicious axillary LN of breast cancer were assessed using preoperative imaging, underwent fine-needle aspiration cytology or core needle biopsy.
The patients in this study were divided into four groups as follows: the ER(+), the ER(+)/HER2(+) , the HER2(+) and the Triple negative (TN) group.
We evaluate the prognostic impact of the ypN0, ypN1 (with one to three positive lymph nodes after NAC), pN0 and pN1 with no NAC.
The main outcome measures DFS and OS were analyzed using Kaplan–Meier survival analysis.

Result
A number of 270 and 3633 patients were included for NAC and non NAC, respectively. Pathologic nodal status was ypN0 in 58%, ypN1 in 42% for NAC and pN0 in 76%, pN1 in 24% of patients for non NAC.
Overall, 10-year DFS and OS was 81%, 93% in ypN0, 67%, 80% in ypN1, in 90%, 97%, in pN0 and 83%, 94% in pN1 (p <0.001).
In subgroup analysis, 10-year DFS of ypN0, ypN1, pN0 and pN1 was 86%,77%,95% and 80% in the ER group, 91%,56%,93%,and 76% in the ER/HER2 group,89%,55%,91% and 80% in the HER2 group, 85%,59%,92% and 80% in the TN group.
10 years DFS for the ER group were significantly different between ypN0 and pN0 (HR, 2.42 (1.03–4.86, p = 0.04) but were not significantly different between ypN0 and pN0 for the ER/HER2 group (HR 3.58 (0.2–6.88, p = 0.66), for the HER2 group (HR 2.6 (0.78–7.65, p = 0.10) and for the TN group (HR 1.22(0.56–2.38, p = 0.58), respectively).
In all group, DFS for ypN1 was inferior to ypN0.

Conclusions
In the ER group treated with NAC, DFS for ypN0 be inferior to pN0 with adjuvant treatment. In the HER2, the ERHER2 and the TN group treated with NAC, ypN0 is similar to pN0 with adjuvant chemotherapy.
Axillary nodal status ypN1 in each subgroup is associated with a less favorable prognosis compared to ypN0. In conclusion, the HER2 or TN group is highest for predicting ypN0, shown to be most prognostic of long-term survival similar to the patients with pN0. They could be omitted the axillary dissection.
Which factor of metastatic lymph nodes—The number, tumor volume or anatomical location—is independently prognostic in breast cancer? - A prospective cohort study using molecular whole-node analysis of all removed axillary nodes

Tomo Osako¹,², Takuji Iwase¹, Masaru Ushijima¹, Akiko Ogiya¹, Takayuki Ueno¹, Shinji Ohno¹ and Futoshi Akiyama¹,². ¹The Cancer Institute Hospital of Japanese Foundation for Cancer Research, Tokyo, Japan and ²The Cancer Institute of Japanese Foundation for Cancer Research, Tokyo, Japan.

**Background:** Axillary lymph node status is one of the most powerful prognostic factors in breast cancer. However, it remains unknown which factor of metastatic lymph nodes—the number, tumor volume or anatomical location—is independently prognostic. Conventional pathological examinations of lymph nodes have limited ability to accurately measure metastatic tumor volume due to the partial evaluation of nodes. On the other hand, the one-step nucleic acid amplification (OSNA) assay, a novel molecular method, can quantify the tumor volume in a whole node based on cytokeratin 19 (CK19) mRNA copy number. In this prospective cohort study using the OSNA whole-node analysis, we aimed to elucidate the independent prognostic factor of lymph node metastasis in breast cancer.

**Patients and Methods:** The subjects consisted of 307 cN0 patients with invasive breast cancer, who underwent axillary dissection after a metastatic sentinel node (SN) biopsy and whose SNs and non-SNs were all examined using the OSNA whole-node assay between 2009 and 2012. The cut-off values of the OSNA assay for negative/positive results and micro/macrometastasis were defined at 250 and 5,000 copies/μL of CK19 mRNA, respectively. The total tumor volume in the SN or non-SN was defined as the sum of CK19 mRNA copy numbers from all samples in the SN or non-SN. The cut-off value for the total tumor volume in the SN was set at 2,810 copies/μL according to our previous study (Osako et al. Br J Cancer 2017). The anatomical location of metastasis was classified into Level I (confined to SN), Level I (spread to non-SN), or Level II/III. Predictive factors for distant disease-free survival (DDFS) were investigated using the univariate log-rank tests and multivariate Cox proportional hazards models. The median follow-up time was 6.1 years (range, 0.2–8.6).

**Results:** Of the 307 patients, 130 (42.3%) and 177 (57.7%) had the total tumor volume <2,810 and ≥2,810 copies/μL in the SN, respectively. Five-year DDFS was 96.0% in the entire cohort. In the univariate analysis, DDFS was significantly related to the pT classification, grade, hormone receptor status, triple-negative subtype, total tumor volume in the SN and cytotoxic chemotherapy. However, DDFS was not significantly related to the number of metastatic or macrometastatic nodes in the SN, non-SN, or all nodes (i.e. SN + non-SN); the total tumor volume in the non-SN or all nodes; the AJCC pN classification; or the anatomical location of metastasis. In the multivariate analysis, the total tumor volume in the SN (<2810 vs. ≥2810 copies/μL, hazard ratio 5.2, 95% confidence interval 1.2–23.2, P=0.03) and cytotoxic chemotherapy (- vs. +, hazard ratio 0.05, 95% confidence interval 0.02–0.17, P<0.001) remained significant.

**Conclusions:** The total tumor volume in the SN was the independent prognostic factor of lymph node metastasis in SN-positive invasive breast cancer. Accurate evaluation of metastatic tumor burden in the SN can be important for predicting prognosis and may help to guide the precise therapeutic decision making for breast cancer patients.
ABCSG 33 - A multi center registry to evaluate the affect of macro metastasis in sentinel lymph node on survival

Stephanie A Strobl¹, Peter Dubsky¹, Ruth Exner¹, Michael Gnant¹, Raimund Jakesz¹, Christoph Tausch², Viktor Wette⁵, Dietmar Heck⁵, Irmgard Luisser⁶, Vesna Bjelic-Radisic³, Peter Schrenk⁴, Clemens Poyssl⁹, Judith Mathis⁸ and Florian Fitzal¹. ¹Medical University of Vienna, Vienna, Austria; ²Brust Zentrum Zürich, Zürich, Switzerland; ³Medical University of Graz, Graz, Austria; ⁴General Hospital Linz, Linz, Austria; ⁵Brustzentrum Wette, St. Veit an der Glan, Austria; ⁶State Hospital Guessing, Guessing, Austria; ⁷Barmherzige Schwestern Linz, Linz, Austria; ⁸State Hospital Feldkirch, Feldkirch, Austria and ⁹State Hospital Dornbirn, Dornbirn, Austria.

Background:
Sentinel lymph node dissection identifies nodal positivity in early breast cancer. Trials like the ACOSOG Z0011 trial tried to show that the waiver of axillary dissection in nodal positive breast cancer (BC) has no effect on the oncologic outcome, however real world data are rare and the role of adjuvant regional radiotherapy is still disputed in this respect.

Objective:
We initiated a multicenter observational registry to investigate omission of axillary lymph node dissection in nodal positive early BC.

Design and Setting:
The 18 sites participating in Austria and Switzerland included from 2014 to 2017 178 patients in this trial.

Patients:
Women with unilateral invasive lymph node positive BC with one or two sentinel lymph node makrometastases, who did not undergo axillary lymph node dissection were included.

Results:
We had a median follow up time of 3.1 years (range between 0.5 and 10.5 years), the median patient age is 63.6 years (range between 33 – 93 years). In 16.9% women had a G1 Grading, 53.1% had G2 tumor and 29.9% had a G3 tumor. Multifocality was seen in 18.1% of the patients. Luminal A tumors were seen in 16 (8.9%) and Luminal B in 82 (46.1%). Fourteen (7.8%) patients in this cohort had HER2 positive BC. In one (0.5%) local recurrence of the axilla occurred. Three (1.7%) of 178 patients died due to BC recurrence.

Conclusion:
Patients with macro metastasis in the sentinel lymph node, treated with breast conserving surgery and whole breast radiation did not have an increased risk of BC recurrence. Therefore the authors assume that axillary dissection in patients with early stage BC and macro metastasis is not necessary in this patient cohort.
Quality of life and cost-effectiveness in patients undergoing level I versus level II and III axillary lymph node dissection for breast cancer: A double blind randomised controlled trial with non-inferiority hypothesis

Kaustubha S Gour¹, Kamal Kataria¹, Piyush Ranjan¹, Anita Dhar¹, Anurag Srivastava¹ and Kavindra Singh¹. ¹All India Institute of Medical Sciences, New Delhi, Delhi, India.

Background: Asian patients present with advanced breast cancer, necessitating full, level III axillary lymph node dissection (ALND). Full axillary dissection is associated with complications like seroma, surgical site infection, shoulder dysmobility and lymphedema. These complications lead to impaired activities of daily life and poor quality of life (QOL). Management of these morbidities escalates the cost of care. We designed this trial to ascertain and compare the quality of life and cumulative incidence and severity of complications of patients undergoing a level I vs level III axillary dissection.

Methods: In this two-group parallel design randomized trial with non-inferiority hypothesis, 70 patients were randomized. Patients were scheduled for level I axillary clearance. Those with no palpable nodes in the remaining axilla after level I clearance were randomized in OR to receive either complete ALND(level II,III clearance) or limit to level I only. Patients were followed for 3 months postoperatively(week 1,2,3,12). Baseline and postoperative quality of life scores calculated by EORTC-QLQ-C30 and BR23 module were compared between the two groups. Indirect cost for patients in each group was calculated based on the duration of OR time consumed and direct costs included the expenditure in the treatment of complications following surgery. Number of successfully managed patients was identified in each group(those patients not associated with incidence of seroma requiring aspiration and SSI). Cost effectiveness was calculated for each group by dividing the total cost of patient care in each group by the number of successfully managed patients.

Findings: There was a significant difference in the duration of procedure between the two groups[level I: 18.57 min vs level III: 32.48 min, p value = 0.000]. Significant differences with worse trend was found in level III patients for QOL[ Global Health Status/QOL- Level I: 77.25(8.92) vs Level III: 71.71(6.89), p value= 0.005; Physical functioning- Level I: 96.21(3.34) vs Level III: 92.92(2.32), p value= 0.000; Role functioning- Level I:91.44(8.44) vs Level III:78.78(11.23), p value= 0.000]. Significant differences were also found in symptom scales of fatigue, pain and arm symptoms. 72.9 % and 54.5 % of patients were successful in level I and level III groups, respectively(p value= 0.137), which yielded a cost-effectiveness ratio of Rs 2,240.46 for level I group and Rs 5.299.12 for level III group.

Conclusion: Level I dissection was associated with significantly better quality of life and was more cost-effective method of ALND as compared to level III ALND.

Challenging dual modality as the gold standard for sentinel lymph node biopsy in breast cancer: A systematic review and network meta-analysis of novel and conventional techniques

Chi Wei Mok¹, Qishi Zheng², Luming Shi² and Su-Ming Tan¹. ¹Changi General Hospital, Singapore, Singapore and ²Singapore Clinical Research Institute, Singapore, Singapore.

The current gold standard for sentinel lymph node biopsy in breast cancer patients is the dual modality technique (radioisotope and blue dye). Owing to the limitations inherent to the use of radioisotopes, the uptake of this method is limited to approximately 50-60% of breast cancer patients in developed countries. In most centers worldwide with no access to radioisotopes, blue dye is the most commonly employed technique as it is relatively cheap, easy to administer with no radiation exposure risk. However, the use of blue dye is associated with a high false negative rate. We performed a systematic review and network meta-analysis to compare the performance of blue dye and radioisotope against three novel techniques, namely indocyanine green fluorescence (ICG), superparamagnetic iron oxide (SPIO) nanoparticles and contrast enhanced ultrasound (CEUS) using microbubbles. This is the first network meta-analysis synthesizing direct as well as indirect comparisons of performance among different techniques in terms of sentinel lymph node detection and false negative rate, thereby allowing a more robust quantitative analysis. In comparison to a published systematic review on this topic in 2014, the current review had almost double the number of patients and trials included with a total of 35 cohort studies and 4,244 patients. Our systematic review suggested that two of the techniques, indocyanine green fluorescence (ICG) and superparamagnetic iron oxide (SPIO) nanoparticles have consistently performed better than the blue dye technique and similar to gold standard dual modality.

BD: Blue dye; CEUS: Contrast-enhanced ultrasound; ICG: Indocyanine green; SPIO: Superparamagnetic iron oxide; Tc: Technetium-99; Tc/BD: Combined used of Technetium-99 and blue dye Top right panel reported the pooled RRs of detection rate from network meta-analysis, and the technique name below each RR was the reference group; Bottom left panel reported the pooled RRs of false negative rate from network meta-analysis, and the technique name to the right of each RR was the reference group; *: Statistical significant with P value < 0.05

Hence, in centres where blue dye was used as a single modality, perhaps ICG and SPIO can offer a viable alternative with improved performance. Future research should focus on the economic evaluations of various techniques as well as to explore the cost-effectiveness and cost-utility of adopting new techniques in the clinical setting.
Can we select patients suitable for targeted axillary dissection after neoadjuvant chemotherapy who originally presented with involved axillary nodes?

Eva S Nagy¹, Lisa Whisker¹ and Kristjan Asgeirsson¹. 'Nottingham Breast Institute, Nottingham, United Kingdom.

Introduction:
The current recommended management for patients with involved lymph nodes at diagnosis of breast cancer is to perform an axillary node dissection after receiving neoadjuvant chemotherapy (NAC), regardless of response. A number of studies have proposed de-escalation of this practice by performing sentinel node biopsies and targeted axillary dissections in those with response to chemotherapy. We have audited our practice to assess the safety of introducing management change.

Methods:
Cancer data was collected between 2014 and 2018 for patients who had NAC and further selection criteria for those with lymph node involvement at diagnosis and subsequently underwent NAC. Assessment of radiological response at NAC completion, tumour hormone receptors and HER2 status along with axillary nodal response on final histopathology were reviewed to assess whether patients can be stratified to less extensive axillary management.

Results:
290 patients underwent NAC, 60 of whom had nodal involvement at diagnosis:
- All had USS axilla, MRI at baseline and completion of NAC
- All 60 node positive patients underwent axillary clearance, as per current local protocol
- Out of those 60 node positive patients, 39 had breast conserving surgery, whilst 21 patients had mastectomy
- 20 (33%) patients showed complete radiological response (CRR) on MRI in both breast and nodes
- 23 (38%) patients achieved pathological complete response (PCR) in their nodes
- 17 patients showed both CRR and PCR
- 4 patients showed CRR but did not achieve PCR:
  o patient 1: 1 macromet / 7 nodes - NEG/NEG/NEG
  o patient 2: 1 micromet / 14 nodes - POS/POS/POS
  o patient 3: 7 macromet / 10 nodes - POS/POS/NEG
  o patient 4: 5 macromet / 19 nodes - POS/POS/NEG
- Large volume of nodal disease remained in 2 patients with POS/POS/NEG despite CRR

Conclusion:
MRI can be safely and reliably used in patients who show CRR with TNBC and HER2+ cancers to select patients for de-escalating axillary surgery. Caution in those patients with POS/POS/NEG cancers as MRI may show CRR but large volume disease in nodes may still persist. Further prospective audit of de-escalating treatment will be essential to ensure locoregional control and long-term disease-free survival outcomes.
Evaluation of a direct reverse transcription loop-mediated isothermal amplification method without RNA extraction (direct RT-LAMP) for the detection of lymph node metastasis in early breast cancer

In Hee Lee¹, Jinhyang Jung¹, Soojung Lee¹, Jiyeon Lee¹, Ryu Kyung Lee¹, Hoyong Park¹, Jaehwan Jung², Jieun Kang² and Yeesoo Chae¹. ¹Kyungpook National Chilgok University Hospital, Daegu, Korea and ²Department of Cell and Matrix Research Institute, Kyungpook National Chilgok University Hospital, Daegu, Korea.

Background: The detection of lymph node metastasis by reverse transcription loop-mediated isothermal amplification method (RT-LAMP) had been studied previously. Even though, RT-LAMP method provides improved performance compared to intraoperative histology sentinel lymph node (SLN) evaluation, direct RT-LAMP method without RNA extraction can be more efficient and easily accessible process. Therefore, we evaluated the performance and efficacy of a direct reverse transcription loop-mediated isothermal amplification (direct RT-LAMP) assay for visual detection of CK19, CK20, and CEA mRNAs to identify lymph node metastasis in patients with early breast cancer.

Methods: A total of 92 lymph nodes dissected from 40 patients with breast cancer were collected at the breast cancer center of Kyungpook National University Chilgok Hospital between November 2015 and February 2016. All of the samples were analyzed by direct RT-LAMP assay and routine histopathology examination. Cutoff values to distinguish metastasis and nonmetastasis were determined by measuring cytokerain 19 (CK19) mRNA in histopathologically positive and negative lymph node using direct RT-LAMP.

Results: We set the cutoff value of direct RT-LAMP assay for CK 19 mRNA at 1ng to distinguish status of LN metastasis. The sensitivity and specificity of the RT-LAMP assay were 85.7% and 100%, respectively. The positive predictive value and negative predictive value were 100% and 94.4%.

Conclusion: Direct RT-LAMP assay can allow detection of SLN metastasis in breast cancer patients intraoperatively with a good sensitivity through cost-effective and time–saving manner.
Validity and safety of omission of axillary lymph node dissection among sentinel lymph node-positive breast cancer patients treated with mastectomy

Akiko Matsumoto¹, Yasuko Umemoto¹ and Hiromitsu Jinno¹. ¹Teikyo University School of Medicine, Tokyo, Japan.

Background: American College of Surgeons Oncology Group Z0011 trial showed that axillary lymph node dissection (ALND) had no impact on recurrence and survival in patients with positive sentinel lymph node (SLN) after breast-conserving surgery. However, it is still unknown if the omission of ALND can be applicable to patients treated with mastectomy. The aim of this study was to evaluate whether ALND could be safely omitted for patients with SLN-positive breast cancer after mastectomy.

Methods: From a prospective database of 296 patients with clinically node-negative breast cancer who underwent mastectomy and sentinel lymph node biopsy (SLNB) from March 2006 to December 2016, 81 patients who had positive SLNs were selected. Patient characteristics and prognosis were compared between SLN-positive patients with and without ALND. Patients treated with neoadjuvant chemotherapy were excluded from the analysis. Lymphatic mapping was performed using a combined method of blue dye and radioisotope.

Results: The median age of entire patients was 57.0 (range: 32-85) years and the median tumor size was 2.5 (range: 0.6-7.9) cm. Of 81 patients, 23 (28.4%) patients omitted ALND. Patients with SLNB alone were more likely to have smaller SLN involvements (p<0.001): micrometastasis was identified in 13 (56.5%) patients in SLNB-alone group and 9 (15.5%) patients in ALND group. The number of positive SLN was comparable between SLNB-alone (median: 1.0, range: 1-6) and ALND groups (median: 1.0, range: 1-5) (p=0.063). There was no significant difference in characteristics including age, tumor size and tumor subtypes between the two groups. Post-mastectomy radiotherapy was performed in 5 (21.7%) patients with SLNB alone and 16 (27.6%) patients with ALND (p=0.588). The majority of patients with macrometastatic SLN received adjuvant chemotherapy in both groups (83.3% vs. 75.5%, p=0.562). Twenty (87.0%) and 51 (87.9%) patients received adjuvant endocrine therapy in SLNB-alone and ALND group, respectively (p=0.584). After a median follow-up of 54.7 months, no axillary recurrence was observed in both groups and 5-year disease-free survival was not significantly different between the two groups (75.0% vs. 88.8%, p=0.489). Lymphedema was observed significantly more often after ALND than after SLNB (22.4% vs. 4.3%, p=0.045).

Conclusions: These data suggested that ALND could be safely omitted in SLN-positive breast cancer patients treated with mastectomy and appropriate systemic therapy.
Is sentinel lymph node biopsy necessary in all patients with early breast cancer?

Kwang Hyun Yoon¹, Kwan Beom Lee¹, Haemin Lee¹, Jeea Lee¹, Jee Ye Kim¹, Hyung Seok Park¹, Seho Park¹, Seung Il Kim¹, Young Up Cho¹ and Byeong-Woo Park¹. ¹Yonsei Cancer Center, Severance Hospital, Yonsei University College of Medicine, Seoul, Republic of Korea.

**Background and objectives**: Since the results of the American College of Surgeons Oncology Group Z0011 published, the criteria for applying axillary lymph node (ALN) dissection was relaxed among early breast cancer patients who were scheduled for breast conserving surgery, adjuvant chemotherapy therapy, and adjuvant radiation therapy. SLNB criteria may be established if pathologic nodal status can be predicted. The aim of this study was to develop a nomogram for preoperative prediction of axillary node metastasis.

**Methods**: The records of 1650 patients with T1, T2 primary invasive breast cancer who were treated between January 2013 and September 2016 were selected from the medical database of Yonsei University (Seoul, South Korea). Those whom a preoperative diagnosis of axillary node metastases were excluded. Two nomogram that predicted three or more axillary metastasis and one or more axillary metastasis were developed using a binary logistic regression model with a training cohort. Internal validation was carried out adopting bootstrap method by validation cohort 500 times resampling.

**Result**: A total of 82 (4.8%) patients had three or more ALNs metastasis. Three hundred seventy five (17.4%) patients had one or more ALNs metastasis. Axillary metastasis was associated with Preoperative ALN suspicious image findings, clinical tumor size, Number of neoplastic foci, estrogen receptor status, Ki-67 expression, tumor marker. The nomogram was developed based on the clinical and statistically significant predictors. It had good discrimination performance (AUC 0.79, 95% CI, 0.73–0.85), (AUC 0.71, 95% CI, 0.67–0.74) and calibration fit.

**Conclusion**: Our nomogram might help predict the ALN metastasis in breast cancer patients. Patients with a low probability of ALN metastasis could be spared SLNB.
Monocentric experience with the sentinel lymph node biopsy prior to neoadjuvant chemotherapy in clinically lymph node negative early breast cancer

Background
In patients with clinically lymph node negative (cN0) early breast cancer (EBC) treated with neoadjuvant chemotherapy (NACT), the sentinel lymph node biopsy (SLNB) can be performed before or after NACT. We report safety of axillary staging performing the SLNB prior to NACT in cN0 EBC and estimate NACT-induced downstaging to ypN0 in previously NACT-treated cN1 EBC, to make an assumption for avoiding axillary lymph node dissection (ALND) if SLNB was done after NACT.

Patients and Methods
Monocentric retrospective study of consecutive triple negative (TNBC) and HER-2 amplified BC patients treated with standard NACT. cN0 patients had SLNB before NACT followed by local therapy. Axillary lymph node dissection (ALND) post-NACT was performed in all cN1 and in cN0 cases with a positive or failed SLNB. Using descriptive statistics, we here report SLNB-detection and SLNB-positive rate, SLNB-operative complications, complete tumor regression in the breast (ypT0/is) and disease-free survival (DFS) for cN0 cases and NACT-induced downstaging to ypN0 in previously NACT-treated cN1 EBC.

Results
We included 245 NACT-treated patients; 119 cN0 and 126 cN1. SLNB-detection rate in cN0 cases was 99.2%; 25 or 21% had ≥ 1 involved SLN, 21.8% experienced SLNB related-complications (e.g. infection, seroma, hematoma) leading to NACT-delay in 3 and interruption in 1 patient. Median start of NACT after SLNB was 7 days (range 1-20 days). In patients with a positive SLNB, there were no additional involved nodes in the ALND. In 5 of these patients, therapy response in a lymph node was described. Complete tumor regression in the breast (ypT0/is) was 52% in SLNB-positive and 59.1% in SLNB-negative cN0 cases. NACT-induced ypN0 was 61% in cN1 cases. At 30 months of median follow-up (range 1-86 months), DFS was 93.2% (4.2% metastatic; no axillary relapse) in cN0 cases. Median DFS was better for patients with complete tumor regression in the breast as compared to those with partial response; 95.6% and 90% respectively.

Conclusion
In conclusion, performing SLNB before NACT in cN0 cases is a safe and accurate method. While some pN1(sn) could have avoid ALND by NACT-induced axillary down-staging, based on our assumption, long term follow-up is needed to conclude whether SLNB after NACT is safe.

Keywords: Breast cancer, neoadjuvant chemotherapy, timing sentinel lymph node biopsy
Sentinel lymph node biopsy is unnecessary in ductal carcinoma in situ patients diagnosed by biopsy

Yasuaki Uemoto, Naoto Kondo, Yumi Wanifuchi-Endo, Tomoka Hisada, Sayaka Nishikawa, Yusuke Katagiri, Hiroyuki Kato, Satoru Takahashi and Tatsuya Toyama. 1Nagoya City University Graduate School of Medical Sciences, Nagoya, Aichi, Japan and 2Nagoya City University Graduate School of Medical Sciences., Nagoya, Aichi, Japan.

Background: Japanese Breast Cancer Society Clinical Practice Guidelines for Breast Cancer 2018 state that sentinel lymph node (SN) biopsy is unnecessary for patients treated with breast-conserving therapy (BCT) and with an expected final pathological diagnosis of ductal carcinoma in situ (DCIS). Regardless of whether they were diagnosed with DCIS by biopsy before surgery, 78% of patients currently undergo axial procedures in Japan because invasive lesions may be detected in surgical specimens. This study examined whether SN biopsy can be omitted in DCIS patients diagnosed by biopsy and which factors are associated with invasion.

Methods: Patients who underwent definitive surgery for DCIS diagnosed by preoperative biopsy at our institution from May 2004 to January 2018 were investigated retrospectively. The factors associated with upstaging to invasive cancer from DCIS were examined with Fisher’s exact test and the t-test. (Age, Tumor size, Operation (Mastectomy or BCT), Biopsy method (Core Needle Biopsy or Vacuum-Assisted Biopsy), Mammography (detected or not-detected), Ultrasound (detected or not-detected, mass or non-mass), Comedo, ER, PgR, HER2)

Results: A total of 311 patients were enrolled in this study, of whom 277 (89.1%) underwent SN; six of these (2.2%) had SN metastasis. All six cases were upstaging to invasive cancer: five (1.8%) had micrometastasis and one had macrometastasis (0.4%). From a surgical viewpoint, SN metastasis were detected in 3/161 (1.9%) cases treated with mastectomy and 3/150 (2.4%) cases treated with BCT. Although all three cases treated with BCT had micrometastasis, one case treated with mastectomy had macrometastasis (the other two cases had micrometastasis). A total of 80/311 cases (25.7%) upstaged to invasive cancer and the only predictor of invasion was tumor size on images (p=0.0002). We could not determine the effective cut-off for tumor size because the area under the receiver operating characteristic curve was 0.63<0.70.

Table 1. Tumor size on images was the only predictor of invasion.

<table>
<thead>
<tr>
<th>Tumor size: mm (95% Confidence Interval)</th>
<th>Upstaging (N=80)</th>
<th>DCIS (N=231)</th>

<td>33.9 (30.5-37.3)</td>
<td>0.0002</td>
<td></td>
</tr>
</tbody>
</table>

Conclusion: Tumor size was found to be the only predictor of invasion. Only 2.2% of DCIS patients had SN metastasis despite the fact that 25.7% patients were upstaged to invasive cancer. We conclude that SN biopsy is not necessary for DCIS patients diagnosed by biopsy.
Prevalence and risk factors associated with development of lymphedema after axillary lymph node dissection among breast cancer patients: Single center retrospective study

YUKI Hara¹, Ryota Otsubo¹, Eiko Inamasu¹, Megumi Matsumoto¹, Hiroshi Yano¹, Chika Sakimura¹, Sayaka Kuba¹, Kosho Yamanouchi¹, Susumu Eguchi¹ and Takeshi Nagayasu¹. ¹Nagasaki University Hospital, Nagasaki, Japan.

Background: Lymphedema in breast cancer is one of the most important complications, and causes symptoms of arm swelling, heaviness and limited movement. Once lymphedema has occurred, it is difficult to cure. Nowadays, treatment with axillary lymph node dissection (ALND) has been decreasing among breast cancer patients as a result of the ACOSOG Z0011, AMAROS and IBCSG 23-01 trials. However, some cases require ALND for ALN metastasis. ALND increases the risk of lymphedema and detracts from quality of life, but the surgical procedure based on anatomical landmarks has not been changed for several decades. The upper borderline for ALND might cause injury to lymph ducts from arms, and incidence and risk factors for lymphedema after ALND are still unclear. Our aim was to identify prevalence and risk factors associated with development of lymphedema after ALND among breast cancer patients.

Methods: This retrospective study was based on data collected from 178 breast cancer patients who underwent ALND in Nagasaki University Hospital, Japan, between 2005 and 2017. Lymphedema was defined as symptomatic arm swelling with >2 cm difference in circumference of the arm compared with that of the contralateral arm. We classified the patients with and without lymphedema, and compared them regarding surgical and pathological findings. Univariate and multivariate analyses were performed to evaluate the risk factors, using the χ² test, Student's t-test and Cox logistic regression analysis.

Results: Prevalence of lymphedema was 16% (28/178 patients) and mean time interval from surgery to development of lymphedema was 463 days. In univariate analysis, there was a significant difference in postmastectomy radiation therapy (PMRT) (p = 0.02) and the number of patients with >18 dissected ALNs (p = 0.02). Body mass index (p = 0.6), administration of docetaxel (p = 0.2), and smoking (p = 0.07) did not significantly increase lymphedema. In multivariate analysis, PMRT (p = 0.01) and dissection of >18 ALNs (p = 0.001) significantly increased the risk of lymphedema, whereas smoking did not (p = 0.4).

Conclusion: Our study suggested that PMRT and number of dissected ALNs were risk factors for lymphedema. Aggressive and empiric ALND might be associated with axillary lymph duct damage. Therefore, we plan to introduce axillary reverse mapping using indocyanine green to reduce the risk of lymphedema in breast cancer patients who undergo ALND.
Extending ACOSOG Z0011 to encompass mastectomy patients: A retrospective review

Ruqayya Naheed Khan\(^1\), Mariam Baig\(^1\), Sameen Mohtasham\(^1\), Amina Khan\(^1\) and Asad Pervaiz\(^1\). \(^1\)Shaukat Khanam Memorial Cancer Hospital and Research Centre, Lahore, Pumjab, Pakistan.

INTRODUCTION: Axillary nodal status in breast cancer patients is a paramount prognosticator, next to primary tumor size and grade. It has been well established that patients with negative sentinel lymph node biopsy can safely avoid axillary lymph node dissection. A positive sentinel lymph node has traditionally required subsequent axillary dissection. The ACOSOG Z11 trial of sentinel lymph node positive patients undergoing breast-conserving surgery found no difference in Overall Survival (OS) and Disease Free Survival (DFS) in those patients who underwent subsequent Axillary Lymph Node Dissection (ALND) vs. observation. The Z11 trial excluded patients who underwent mastectomies. The purpose of this study is to determine whether Z0011 can be applied to mastectomy patients as well in 1-3 positive sentinel lymph nodes and avoid unnecessary ALND.

METHODS: A retrospective review was conducted at Shaukat Khanam Memorial Cancer Hospital Pakistan from Jan 2015 to Dec 2017 including patients who were treated for invasive breast cancer and required upfront mastectomy. They were clinically node negative so sentinel lymph node biopsy was performed. Patients underwent ALND with positive sentinel lymph node. A total of 156 breast cancer patients with mastectomies were reviewed.

RESULTS: 95% of the patients were female while 3% were male. Average age was 44 years. There was no difference in race, comorbidities, histology, T stage, N stage, overall stage, use of adjuvant chemotherapy and radiation therapy. 64 patients underwent ALND for positive lymph node while 92 patients were spared of axillary dissection due to negative SLNBx. Out of 64 patients 38 patients (59%) had only 1 lymph node positive which was the sentinel node. 18 patients (28%) had 2 lymph nodes positive including the sentinel node while only 8 patients (13%) had 3 or more positive nodes.

CONCLUSION: Keeping in mind the complications related to ALND, above results clearly show that ALND could have been avoided in 87% of patients in the setting of adjuvant radiation, possibly avoiding the morbidity associated with axillary lymphadenectomy although a prospective randomized trial needs to confirm these results.
A clinical evaluation of performing total axillary lymph node clearance in breast cancer patients after positive sentinel lymph node biopsy in light of the ZOO11 randomised control trial, based at one centre in the UK

Samerah Saeed¹, Shagayegh Javadzadeh¹, Stephanie Clark¹, Arun Kirupakaran¹, Mohammed Zaker Ullah¹, Shweta Aggarwal¹ and Peter B Frecker¹. ¹Whipps Cross University Hospital, Barts Health NHS Trust, London, United Kingdom.

Introduction
Axillary nodal involvement is a poor prognostic indicator in breast cancer¹. Sentinel lymph node biopsy (SLNB) is known to have a >95% rate for identification of nodal metastatic spread, its use has significantly reduced common complications of total axillary lymph node clearance (TALNC)¹. However, a recent large American study (ZOO11 RCT)² demonstrated that in cases of 1-2 positive sentinel lymph nodes (SLN) in patients with T1/T2 tumours, conservative management is non-inferior to TALNC and does not impact on the 10 year survival rate². In this retrospective study we have analysed a cohort of patients from our centre to clinically evaluate the need for TALNC in patients who have 1-2 positive SLN.

Methods
Retrospective analysis of histopathology data within our centre identified 1100 patients who had a breast surgery procedure recorded between 2012-2017. Patients were excluded from this original data set due to duplication of results, lack of electronic patient records as well as coding for non breast surgery related procedures. This left a total of 774 patients. A data collection tool was used to identify and record those patients who had SLNB performed. We recorded the number of nodes yielded as well as the number found to be positive for both SLNB and TALNC.

Results
From 774 patients 47.5% (368) patients had SLNB performed. The remaining 52.6% (407) patients had a core biopsy, no biopsy or radiological identification of lymphatic spread. A total of 82% (635) patients had TALNC. There were 30.4% patients who had a TALNC based on positive SLNB. The percentage of patients who had TALNC that yielded positive lymph nodes was 13.2%. There were 9.56% (74) patients with only 1-2 positive SLN excised that went on to have TALNC. There were 6.71% patients who had only 1 positive SLN (mean no. of nodes removed = 2.3) and 2.84% patients with 2 positive SLN (mean no. of nodes removed = 3.2). Interestingly there were 2 patients who had 0 positive SLN but had TALNC.

Conclusion
Our study demonstrates that the number of patients who had SLNB performed with only 1-2 positive nodes identified and then went on the have a TALNC, was very low (9.56%). It brings in to question whether performing a TALNC on this cohort of patients is a necessary routine procedure. Especially given that the ZOO11 RCT demonstrated no difference in 10 year survival (in a similar group of patients) between TALNC vs no TALNC, with both groups receiving radiotherapy post operatively. We could possibly suggest that a change in routine management for patients with only 1-2 positive SLN is that they do not undergo further operative TALNC but proceed straight to radiotherapy treatment.

Sentinel lymph node biopsy procedure: using surgical pliers eliminate radiation exposure risk

Christine Tunon de Lara, Marie Rois, Jerome Caron, Sébastien Herit, Philippe Stein, Barbara Lortal, Anne Laure Cazeau and Yann Godbert. 1Institut Bergonié, Bordeaux, France and 2Universite de Bordeaux, Bordeaux, France.

Introduction
The use of radioactive compounds for sentinel lymph node biopsy (SLNB) is now generally accepted for surgical treatment of breast cancer albeit the risk of radiation exposure to the surgeon. The purpose of our study was to compare the theoretical maximal radiation dose (TMRD) at the injection site of the breast versus fingers radiation dose (FRD) of the surgeon performing SLNB.

Patients, Material and Methods
This is a monocentric, prospective study on a single surgeon performing SLNB with different dosimetric measurements. Periareolar intradermal injections of technetium-99m colloidal rhenium sulphide (Nanocis® of Curium Laboratory) were administered in the nuclear medicine unit. For one and two day protocols, the activity was 25 MBq and 40 MBq ± 10%, respectively. During surgery, the nodes in the axilla were visualized with the injected blue dye and by a hand-held gamma probe. During surgery, the absorbed dose to the surgeon's right (dominant) and left hands were recorded using thermoluminescent dosimetry in a ring form From Landauer Laboratory. This lithium fluoride dosimeter enables monitoring equivalent skin dose “Hp007” with a minimum dose threshold of 0.1 mSv. On the hands, one ring was placed on each thumb under the surgical glove and another dosimeter on the nipple of the breast, covered in two thin surgical gloves. The radiation exposure to the hands of the surgeons (FRD) and injection site of the breast (TMRD) were measured by the rings' dosimeters from incision to the cutaneous stitch.

Results
Between 02-01-2018 and 04-30-2018, a total of 38 SLNBs were included in this study: 9 mastectomies, 28 lumpectomies and 1 sentinel node alone were performed by the same surgeon. The mean patient age was 57 years (range, 31-81). For one day protocol, 36 patients received 22.8 MBq (range, 15-26), and for the last two patients in the 2 day protocol, the activity was 39 and 40 MBq.

The mean exposure time was 57 min (range, 19-73) and the overall time of exposure was 33 h and 31 min. In our study, the TMRD is around 8.8 mSv for 3 months and represents approximately 35 mSv per year for a breast surgeon. The FRD is similar between right and left hand, 0.16 and 0.15, respectively for 3 months and about 0.6 mSv per year.

Discussion
It is evident that the surgeon received the highest radiadiodose in the operating theatre, the 3 months TMRD was 8-fold higher in injection site than the FRD, 35-fold per year. Nevertheless, the maximal dose at the injection site was below the critical dose (150 mSv) recommended by the French Nuclear Safety authority (ASN). Surgical techniques using tools such as pliers significantly decrease the dose on surgeon's finger (8.8 vs 0.15mSv for 3 months). According to a French Directive, workers exposed to radiations must be monitored if the effective extremity's annual dose is likely to exceed 50 mSv. Radioactivity in operating room is systematically monitored at our institute. We encourage young surgeons to perform surgery using surgical pliers to manipulate the radioactivity injection site of in the breast, to minimize exposure to radioactivity.
Sentinel lymph node biopsy after surgery with removal of the primary tumor

Elena Zhiltsova¹, Petr Krivorotko¹, Garik Dashayan¹, Alexander Emelyanov¹, Tengiz Tabagua¹, Alexander Bessonov¹, Olga Ivanova¹, Sergey Kanaev¹, Sergey Novikov¹, Pavel Krzivickiy¹, Alexander Komayachov¹, Kirill Nikolaev¹, Larisa Gigolaeva¹, Konstantin Zernov¹ and Vladimir Semiglazov¹. ¹Petrov’s National Medical Research Center of Oncology, Saint Petersburg, Russian Federation.

Nowadays, sentinel lymph node biopsy (SLNB) is one of the basic methods for diagnosing the lesion of regional lymph nodes (LN) and it is recommended by experts as a standard method in determining the prevalence of the disease in breast cancer patients (BC).

The aim of the study was the possibility of sentinel lymph node biopsy after surgery with removal of the primary tumor.

Materials and methods
The study was conducted in the N.N. Petrov’s National Medical Center of Oncology from 2013 to 2018. SLNB was performed in patients who had a primary tumorectomy in another medical institution. The study included patients with the stage cN0. Radionuclide imaging of the sentinel lymph nodes (SLN) was performed in 37 patients with breast cancer. The injection of radiopharmaceuticals in postoperative scar was performed before the biopsy. Median of the period between the operations was 21 days (14 to 30 days).

Results
After injection, the image of SLN was obtained in 91.9% (34 of 37) of patients. During the operation, 1-5 sentinel lymph nodes were visualized. The lesion of the sentinel lymph nodes (N+) was detected in 21.6% (8) patients, N0 in 78.4% (29) patients, respectively.

There is no data for locoregional relapse for the period of observation from 2014 to nowadays.

Conclusions
The obtained results are comparable with the results of sentinel lymph node biopsy in primary patients with breast cancer stage cN0. This indicates the possibility of biopsy after surgery with removal of the primary tumor.
A prospective two arm comparative study of indocyanine green (ICG) enhanced fluorescence imaging vs conventional methods (blue dye and radiocolloid/hand held gamma probe) for sentinel lymph node detection in breast cancer - Going beyond the horizon

SP Somashekhar¹, C Rohit Kumar¹, Shabber Zaveri¹, Ashwin Rajgopal¹, Susmita Rakshit¹ and Shaziya Hassan Ali¹. 'Manipal Comphrensive Cancer Center, Bangalore, Karnataka, India.

Background:
The dual technique with radio colloid and blue dye is the gold standard in sentinel lymph node biopsy (SLNB) to stage axilla in breast cancer. However due to cost & infrastructural demands of nuclear medicine department most of the oncology centers are not doing slnb or are doing SLNB with blue dye which is not a standard of care. Indocyanine green (ICG) has recently been used as a method of identifying sentinel lymph nodes. Studies have shown that ICG fluorescence imaging alone or in combination with the blue dye method or the radionuclide method is a safe and easy technique. The objective of the present study was to assess the diagnostic performance of sentinel lymph node (SLN) biopsy using the indocyanine green (ICG) fluorescence method compared with that using the conventional method in detection of sentinel lymph nodes.

Material & Methods:
60 patients diagnosed with early breast cancer underwent the SLNB procedure using technetium 99m radio colloid (R), methylene blue dye (MB), and ICG. Fluorescence imaging was done using an indigenously designed, very economical fluorescence imaging system, Irilic.nm fluorescence imaging along with Indocyanine green. All SLNs that were removed during surgery were labelled as hot, blue or/and fluorescent and sent for pathological examination. The detection rate of SLNs and positive SLNs, and the number of SLNs of ICG, MB+ R, ICG + MB, ICG + R were compared. Injection safety of ICG and MB was evaluated.

Results:
Sentinel Lymph Node was identified in all 60 cases. Total Sentinel lymph nodes removed was 145 (Mean=2, Range 2-5), ICG was able to identify more nodes than the dual dye technique. The identification rate with the dual dye technique was 95%, with blue dye alone 93.6% and with radioisotope alone 96.8% whereas with ICG alone was 100%, with ICG + MB was 96.6% & ICG + R was 96.6 %. 28(46.6%) out of 60 patients had positive nodes which was identified by both dual dye & ICG. None of the patients had any local or systemic reaction with ICG, 3 patients with blue dye had tattooing & staining of skin.

Conclusion:
ICG is as effective as the dual dye for SLNB. ICG is safe & reliable. In addition, as a near-infrared dye, it has the advantages of real-time visualization, lower cost, and wider availability. It can be a boon for developing countries & second tier referral centers of developed country where there is limited access to nuclear medicine department & radiocolloid and even if its accessible the cost involved is too high which comes with added radiation exposure to medical personnel handling them. A combination of blue dye and ICG is useful dual approach when radioisotope is unavailable.

Preoperative wirefree localization of positive axillary lymph nodes 31-365 days prior to surgery: A proposed practical approach to supplement SLN in neoadjuvant therapy patients

Mary K Hayes¹,², Heather R Wright¹ and Erica V Bloomquist¹. ¹Memorial Healthcare System, Hollywood, FL and ²Envision Physician Scientific Intelligence, Sunrise, FL.

The study objective was to evaluate preoperative Wirefree Localization (WFL) placement success rate and device stability 31-365 days prior to successful surgery in patients with node-positive breast cancer prior to neoadjuvant treatment (NAT).

**Background:** Wirefree nonradioactive Localization (WFL) has become a standard of care in over 40,000 breast cancer patients in 300 US sites. The radiologist/surgeon performs preoperative WFL of the positive breast or axillary lymph node (LN) using Mammography (MG), Ultrasound (US) or CT guidance.

In August 2018, the FDA expanded clearance of long-term breast WFL to soft tissue and LN. Results of this study further support the ACOSOG-Z1071 subset findings that selected patients with node-positive disease and NAT may be eligible for sentinel lymph node (SLN) surgery and may potentially require less extensive axillary surgery. Long-term (31-365 day) preoperative localization of the biopsy proven positive LN may represent a more practical approach to supplement SLN in NAT patients.

**Methods:** This prospective pilot study enrolled 33 breast cancer patients aged 28-74 (10 Caucasian, 12 African American, 11 Hispanic), with clinical T1-4, N0-2, M0 disease who planned NAT. WFL was performed prior to NAT response and 31 - 365 days preoperatively in the breast and/or positive axillary LN (19 LN only, 4 both breast and LN, 10 breast only). Descriptive statistics were used.

**Results:** This subset analysis showed 23/33 patients were node-positive (10-51 mm size). WFL placements were successful (0-10 mm from center) in all 23/23 patients via US guidance (22 patients, LN 8-35 mm deep to skin) and CT guidance (1 patient, LN 90 mm deep to skin).

WFL stability (0 mm migration) throughout NAT was documented on all standard of care (SOC) preoperative surveillance imaging MG, US, MRI, CT and specimen X-rays (0-222 days). Both the target LN and WFL were well visualized on 9/9 MRI and 8/8 PET/CT SOC imaging. WFL successfully supplemented SLN final surgery in 11/23 subjects to date.

**Conclusions:** WFL of positive LN may be successfully performed prior to NAT response, when the lesion is clearly visualized on imaging. Since successful NAT can result in a complete or partial imaging response, a simpler pre-NAT image-guided WFL may replace the more difficult and less reliable localization post-NAT response. The latter can contribute to incomplete removal of the targeted LN, and unintended larger, more disfiguring cancer surgery.

This subset analysis provides preliminary information to suggest that up front WFL of positive LN may be performed long-term prior to NAT response with no significant adverse events or device migration. Long-term (31-365 day) preoperative WFL of the biopsy proven positive LN may represent a more practical approach to supplement SLN in NAT patients. If larger scale studies confirm these findings, this may prove a clinically relevant paradigm shift for future LN positive patients to ensure that the targeted LN is successfully removed, potentially requiring fewer and/or less extensive radiology and surgical procedures.

ClinicalTrials.gov NCT03015649 accrual: 33/33
Prevention of lymphoedema after axillary clearance (ANC) by external compression sleeves randomised trial: Results of PLACE trial

Nigel J Bundred¹, Philip Foden¹, Katie Riches⁵, Julie Morris¹, Abigail Evans⁶, Chris Todd², Maria Bramley⁴, Anthony Skene⁷, Arnie Purushotham³ and Vaughan Keeley⁵. ¹University Manchester NHS Foundation Trust, Manchester, United Kingdom; ²School of Health Sciences, The University of Manchester, Manchester, United Kingdom; ³Guy's & St Thomas' NHS Foundation Trust, London, United Kingdom; ⁴Pennine Acute Hospitals NHS Trust, Greater Manchester, United Kingdom; ⁵Derby Hospitals NHS Foundation Trust, Derby, United Kingdom; ⁶Poole NHS Foundation Trust, Poole, United Kingdom and ⁷Royal Bournemouth NHS Foundation Trust, Bournemouth, United Kingdom.

Up to 30% of women with early arm swelling (RAVI 4-9%) develop lymphoedema by 24 months post ANC (based on a Relative Arm Volume Increase (RAVI) of >10% criterion). Intervention with a compression garment before arm swelling becomes chronic is claimed to prevent lymphoedema but there is no randomised evidence to support the value of compression garments in preventing lymphoedema after ANC.

Methods
The PLACE trial was a multicentre randomised open controlled trial testing (1) standard management (written advice, arm elevation, exercises and massage) versus (2) application of whole arm graduated compression garments (pressure 20-25mmHg: Sigvaris) to affected arm, and standard management for 1 year. Women randomised to compression garments were given 4 compression garments (type 2 20-25mmHg) for 12 months.

The aim was to compare the 1) Time to development of lymphoedema (>10% RAVI) from randomisation, 2) Quality of life in each group (TOI and FACT B+4 ARM sub-scale).

Women with node positive, early breast cancer (n=1300) undergoing ANC consented to pre and postoperative arm measurements with a perometer and those developing a 4-9% increase in arm volume up to 9 months post-surgery entered into the trial and had follow-up measurements.

Results
Between October 2010 and August 2016, 143 patients were randomised and 38 (27%) patients developed lymphoedema after randomisation. A total of 15 patients died during the study.

The lymphoedema rate by 24 months (as predefined by RAVI ≥10% after randomisation) for patients randomised to ‘no sleeve’ was 30% (21/71) compared to 26% in patients randomised to ‘sleeve’ (17/66: p=0.62). A total of 26 patients randomised to the ‘no sleeve’ group had a sleeve applied within 24 months; 13 (50%) of these patients subsequently developed RAVI≥10%.

Body Mass Index (BMI) pre-surgery predicted lymphoedema at any time point HR 1.08 (CI 1.02-1.14; p=0.011) with BMI >30 HR 3.09 (CI 1.11-8.54 compared to BMI ≤25) patients having the highest lymphoedema rate in both arms of the trial (sleeve: 10/23, 43.5%; no sleeve: 10/22, 45.5%).

There was no significant difference between patients in the two groups in their change in QoL (FACT-B, TOI and ARM subscale) from baseline to 12, 18 or 24 months.

Compression sleeves applied after development of Lymphoedema improved QoL scores (FACT-B p=0.007:TOI p=0.042).

**Conclusions**

Early intervention with Type 2 External Compression garments does not prevent lymphoedema, particularly in women with a BMI>30. The use of prophylactic compression garments in “subclinical” lymphoedema (RAVI<10%) is unwarranted.
Incorporation of MSKCC nomogram to guide the application of intra-operative sentinel lymph node frozen section evaluation in patients with early breast cancer

Houpu Yang¹, Shu Wang¹, Danhua Shen¹, Yingming Cao¹, Fuzhong Tong¹, Dingbao Chen¹, Peng Liu¹ and Yuan Peng¹. ¹Peking University People’s Hospital, Beijing, China.

Background and Objectives:
Although de-escalation of axillary surgery becomes more popular, axillary lymph node dissection (ALND) is still the standard care for sentinel lymph node (SLN) positive patients not meeting the criteria of ACOSOG Z0011 in many hospitals, and frozen section (FS) of SLN is one of the valuable intra-operative assessments to avoid axilla re-operation although it was controversial due to accuracy and efficiency concerns. This study was to assess the performance of selective use of frozen section evaluation guided by MSKCC lymph node metastasis risk prediction nomogram to optimize the procedure to be more accurate and cost effective.

Methods:
Surgical pathology records of consecutive 2582 biopsies in 2552 patients breast cancer patients from 2011 to 2017 were reviewed, intra-operative frozen section diagnosis were compared to post-operative paraffin reports. We calculated the sensitivity, specificity, accuracy and FNR for different MSKCC risk, the axilla re-operation rate with or without FS and the number needed to treat (NNT) to avoid second ALND was also analyzed.

Results:
The sensitivity, specificity, and FNR of FS were 84.7%, 99.9%, and 15.3% respectively. The axilla re-operation rates were significantly decreased if FS was done(4.7%±0.4% with FS versus 35.8%±5.8% without FS, P<0.001). The estimated axilla re-operation rate without FS was positively correlated with MSKCC risk(r=0.99, P<0.001), while NNT to avoid second ALND by FS were negatively correlated with MSKCC risk(r=-0.98, P<0.001). When patients were divided into four groups according to quartile MSKCC risk, the axilla re-excisional rates were 18.4%, 25.1%, 38.7%, 58.7% without FS, while 4.8%, 3.2%, 5.6%, 3.2% with FS, and NNT correspondingly decreased from 7.3, 4.5, 3.0 to 1.8. An decision-making algorithm for application of FS was proposed.

Conclusion:
Stratified decision-making algorithm based on MSKCC prediction model improved the efficiency of FS to avoid axilla re-operation in patients undergoing sentinel lymph node biopsy. We recommend FS be restricted to patients with MSKCC risk higher than 0.5 who do not meet ACOSOG Z0011 criteria.
The value of stereotactic vacuum-assisted biopsy in the investigation of microcalcifications in 1354 patients in public Brazilian hospital

Andre Mattar¹, Andressa Gonçalves Amorim¹, Marcellus do Nascimento Moreira Ramos¹, Jorge Yoshinori Shida¹, Guilherme Ribeiro Fonseca¹, Roberto Hegg¹ and Luiz Herique Gebrim¹. ¹Perola Byington Hospital, Sao Paulo, SP, Brazil.

Background: The gold standard for breast biopsy procedures is currently an open excision of the suspected lesion. However, an excisional biopsy inevitably makes a scar. The cost and morbidity associated with this procedure has prompted many physicians to evaluate less invasive, alternative procedures. More recently, image-guided percutaneous core-needle biopsy has become a frequently used method for diagnosing palpable and non-palpable breast lesions. Although sensitivity rates for core-needle biopsy are high, it has the disadvantage of histological underestimation, which renders the management of atypical ductal hyperplasia, papillary lesions, and fibroepithelial lesions somewhat difficult. Stereotactic vacuum assisted breast biopsy (VABB) was developed to overcome some of these negative aspects of core-needle biopsy. VABB allows for a sufficient specimen to be obtained with a single insertion and can provide a more accurate diagnosis and completely remove the lesion under real-time ultrasonic guidance. The advantage of complete lesion removal with VABB is to reduce or eliminate sampling error, to decrease the likelihood of a histological underestimation, to decrease imaging-histological discordance, to decrease the re-biopsy rate, and to diminish the likelihood of subsequent growth on follow-up, especially when stereotactic VABB is used to investigate microcalcifications. This method is expensive but cost effective when used to investigate microcalcifications classified as BI-RADS 4 and 5.

Methodology: We performed a review in 1,354 patients with suspicious mammography microcalcifications, classified as BI-RADS 4 or 5 that were seen in Perola Byington Hospital from July 2012 to July 2017 in São Paulo-Brazil. We have used aHologic Lorad Multicare Platinum Stereotactic Prone Breast Biopsy and a Surus Pearl (Hologic, Malbolrough, Massachusetts, USA), with gauge 9 probe. Four to eight fragments (median of 6) were obtained with the placement of a metal clip in the bed that the biopsy was performed, and histopathological analysis was made.

Results: The histopathological study of the lesions revealed benign alterations in 956 (68%) of our patients. The findings were positive for malignancy in 358 patients (29%) and the precursor lesions were diagnosed in 40 (3%). In 81 cases (5.9%) the findings were discordant. The sensitivity of the method was 84.4%, specificity was 96.1%, false negative rate was 4.5%, positive predictive value (PPV) was 89.8%, negative predictive value (NPV) was 93.8%. In literature review the sensitivity varies 91.5-100%, specificity 81.9-110%, false negative rate 0-3.3%, PPV 92.2-100% and NPV 80.5-99.5%. All patients with positive or discordant cases underwent surgical treatment to increase the margin or complete removal of the lesion. Conclusions: The VABB is an outpatient procedure that avoids hospital admissions for diagnostic elucidation in most of cases suspected of malignancy. It has high predictive value in both benign and malignant lesions, guiding therapeutic planning. In addition to presenting the cost lower than the surgical biopsy it indirect increases the supply of hospital beds for cancer treatment.
High ki67 increasing after core needle biopsy was associated with worse disease outcome in estrogen receptor negative breast cancer patients

Xiaosong Chen¹, Yiwei Tong¹, Weiguo Chen¹, Yafen Li¹ and Kunwei Shen¹. ¹Comprehensive Breast Health Center, Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China.

Ki67 level would increase after core needle biopsy (CNB) in invasive breast cancer. However, we don’t know whether this Ki67 increasing will influence disease outcome. In current study, we enrolled 2029 invasive breast cancer patients with paired CNB and surgical removed samples (SRS) between Jan-1st, 2009 and Jun-30th, 2016. Estrogen receptor (ER), progesterone receptor (PR), HER2, and Ki67 status were both tested in CNB and SRS samples. Ki67 change (ΔKi67) was calculated as Ki67 expression level in SRS minus CNB. Disease free survival (DFS) and overall survival (OS) were compared between patients with different ΔKi67. The concordance rate between CNB and SRS was 96.55%, 91.42%, 98.62%, and 81.62% for ER, PR, HER2, and Ki67, respectively. Mean Ki67 expression level was much higher in SRS compared with CNB samples: 30.37% vs. 26.55% (ΔKi67 = 3.82%, P < 0.001). High Ki67 increasing after CNB was defined as ΔKi67 > 3.82%. Both univariate and multivariate analysis found that surgery time interval after CNB, surgery type, pathological type and molecular subtype status were associated with ΔKi67 (P < 0.05). In whole population, there was no DFS (P = 0.679) or OS (P = 0.974) difference for patients with high or low ΔKi67 (ΔKi67 ≤ 3.82%). Moreover, ER status interacted with disease outcome and ΔKi67 value (P < 0.001). For patients with ER positive breast cancer, ΔKi67 level was still not related with DFS (P = 0.206) or OS (P = 0.112). However, in ER negative breast cancer patients, the 5-year DFS was 84.7% in the low ΔKi67 group, which was much higher than those in the high ΔKi67 group (77.5%, P = 0.025). The 5-year OS was 91.3% and 87.0% for ER negative patients with low or high ΔKi67, respectively (P = 0.079). Furthermore, multivariate analysis demonstrated that high ΔKi67 was associated with worse DFS (hazard ratio (HR) = 1.68, 95% confidence interval (CI): 1.06-2.65, P = 0.027) and OS (HR = 1.90, 95% CI: 0.97-3.73, P = 0.060) in ER negative patients. In conclusion, Ki67 value would increase after CNB for invasive breast cancer. High ΔKi67 didn’t influence disease outcome in ER positive breast cancer but was significantly associated with worse disease outcome in ER negative patients, which warrants further study.
Age-related methylation signals of breast cancer risk in blood

Erin W Hofstatter¹, Morgan Levine¹, Christos Hatzis¹ and Lajos Pusztai¹. ¹Yale School of Medicine, New Haven, CT.

BACKGROUND: Age is the biggest risk factor for developing breast cancer, which suggests that the biological aging process is a direct driver of cancer etiology. In all normal tissues, DNA methylation status changes systematically with age and is believed to mediate the biological consequences of aging. DNA methylation patterns, commonly referred to as 'Epigenetic Clocks', can be used as measures of aging. However, the chronologic and epigenetic ages can have subtle differences in different individuals. We hypothesize that accelerated epigenetic aging (i.e. DNA methylation indicating an older age than the chronologic age of the individual) is a risk factor for breast cancer development.

METHODS: We used DNA methylation data from blood samples and clinical data from n=2,107 participants in the Women's Health Initiative (WHI) and tested the association between breast cancer risk and two of the most commonly used epigenetic clocks by Horvath (based on 353 CpGs) and Hannum et al. (based on 71 CpGs). DNA methylation in whole blood was measured using the Illumina HumanMethylation450 BeadChip. We used Cox proportional hazard models to assess the association between two epigenetic age predictors (calculated using the algorithms by Horvath and Hannum et al.) and subsequent risk of breast cancer. The model was adjusted for several breast cancer risk factors including: chronologic age at the time of blood sampling, observational vs. clinical trial, clinical trial arm, race/ethnicity, education, BMI, waist-hip ratio, smoking, alcohol, age at menopause, age at menarche, number of pregnancies, age at first birth, previous mastectomy, months breastfed, and cell count estimates. Family history data and BRCA mutation status was incomplete in the WHI and therefore could not be included in our analysis.

RESULTS: Increased epigenetic age determined by the Horvath clock relative to chronological age was associated with increased future incidence of invasive breast cancer, even after adjusting for known risk factors (HR=1.04, P=0.03). Utilizing the Hannum clock, we found no significant association between epigenetic age and breast cancer risk (HR=1.01, P=0.568). When we included both age predictors as independent variables in a single model, the strength of the association between the Horvath epigenetic age and breast cancer risk increased (Horvath HR=1.09, P=6.3e-5; Hannum HR=0.95, p=0.077), such that every one year increase in epigenetic age relative to chronological age was associated with a 9% increased risk of future breast cancer. These results suggest that the aging signal in the Horvath clock that is unique from that captured by Hannum is what drives the specific association with breast cancer.

CONCLUSIONS: Our results support the hypothesis that “accelerated” epigenetic aging measured in the blood increases breast cancer risk. We also demonstrate that the two epigenetic clocks capture different aspects of aging, only some of which have implications for breast cancer risk. Epigenetic clocks may assist in targeting breast cancer screening to higher risk populations in the future, and understanding the biological mechanisms that are altered by the epigenetic changes may lead to new risk reduction strategies.
Epigenetic remodeling in response to BRCA2-crisis

Joshua J Gruber¹, Justin Chen¹, Benjamin Geller¹, Natalie Jager¹, Andrew M Lipchik¹ and Michael P Snyder¹. ¹Stanford University, Palo Alto, CA.

Individuals with a single functional copy of the BRCA2 tumor suppressor have elevated risks for breast, ovarian and other solid tumor malignancies. The exact mechanisms of carcinogenesis due to BRCA2 haploinsufficiency remain unclear, but one possibility is that at-risk cells are subject to acute periods of decreased BRCA2 availability and function (“BRCA2-crisis”), which may contribute to disease. Here we establish an in vitro model for BRCA2-crisis that demonstrates novel epigenetic remodeling and activation of an NF-κB survival pathway in response to transient BRCA2-depletion. Mechanistically, we identify BRCA2 chromatin binding, histone acetylation and associated transcriptional activity as critical determinants of the epigenetic response to BRCA2-crisis. These epigenetic alterations are reflected in transcriptional profiles of pre-malignant tissues from BRCA2-carriers and therefore may reflect natural steps in human disease. By modeling BRCA2-crisis in vitro we have derived insights into pre-neoplastic molecular alterations that may enhance the development of novel preventative therapies.
Identification of epigenetically silenced breast cancer driver genes

Shoghag Panjarian¹, Jozef Madzo¹, Carolyn Slater², Jaroslav Jelinek¹, Xiaowei Chen² and Jean-Pierre Issa¹. ¹Fels Institute, Temple University, Philadelphia, PA and ²Fox Chase Cancer Center (FCCC), Philadelphia, PA.

Breast cancer is clinically and molecularly complex disease driven by aberrant genetic and epigenetic alterations. Epigenetic alterations in particular DNA methylation changes are one of the most important events involved in breast cancer initiation and progression. Previous reports identified many aberrant DNA methylation signatures associated with molecular subtypes of breast cancer and over 100 candidate genes with promoter hypermethylation in breast cancer. However, it remains elusive which of these genes with promoter hypermethylation play “driver” role in tumorigenesis. In previous studies, the average gain of DNA methylation across all cancer samples compared to the average DNA methylation in normal samples has been the criterion to select for potential targets. However, known tumor suppressor driver genes regulated by methylation are relatively infrequently altered in target cancers. Therefore, we propose the paradoxical hypothesis that identifying hypermethylated cancer drivers require focusing on infrequent rather than frequent events. Hence, to identify these potential driver genes, we developed an algorithm with two unique properties. First, unlike previous studies we focused on targets that gained DNA methylation relatively infrequently (10-40%) and that lost expression in breast cancer. Second, using this algorithm, we distinguished cancer dependent gain of DNA methylation from age-dependent gain of methylation. To discern age dependent and independent DNA methylation changes, we generated DNA methylation sequencing data on 29 normal purified breast epithelium (age range 33-82 years old). Furthermore, to study the biological effects of the overexpression or downregulation of these genes, we generated DNA methylation sequencing data on 6 breast cancer cell lines. We also used DNA methylation and RNA expression datasets (675 cancer, 100 normal) available through the TCGA. Using our algorithm, we identified 53 genes with age independent promoter hypermethylation and loss of expression in TCGA tumor samples. To begin testing the biological effects of these driver genes, we performed canonical pathway enrichment analyses using Ingenuity Pathway Analysis software. We also investigated the mutational status of these genes and their molecular subtype enrichment. Based on these analyses, we picked 12 genes (C10orf125, RUNX3, YOD1, FXYD5, SMOC1, SLC16A5, RNLS, DKK1, PNPLA3, FZD10, RND2, and PLCB1) for further study. We stably overexpressed these potential driver genes in different breast cancer cell lines. Twelve genes out of the 12 tested, slowed cell proliferation and 9 decreased anchorage independent growth. We further validated these driver genes by knocking them out in normal human mammary epithelial cells using CRISPR/Cas9 tool. The loss of these genes, increased cell proliferation rate in normal human mammary epithelial cells compared to the control cells. In conclusion, based on our preliminary data, using bioinformatics tools as well as functional assays, we identified epigenetically altered breast cancer driver genes. Identifying and deciphering true epigenetic cancer drivers could potentially lead to the development of therapeutic drugs targeting these genes and/or targeting pathway dependence.
Clonal evolution and heterogeneity in breast tumors treated with neoadjuvant HER2-targeted therapy

Jennifer L Caswell-Jin¹, Katherine McNamara¹, Johannes G Reiter², Ruping Sun³, Zheng Hu³, Zhicheng Ma³, Carlos J Suarez¹, Susanne Tilk¹, Akshara Raghavendra², Victoria Forte³, Suet-Feung Chin⁴, Helen Bardwell⁴, Elena Provenzano⁵, Carlos Caldas⁴, Julie Lang⁴, Robert West¹, Debu Tripathy², Michael F Press³ and Christina Curtis¹. ¹Stanford University School of Medicine, Stanford, CA; ²The University of Texas MD Anderson Cancer Center, Houston, TX; ³Norris Comprehensive Cancer Center, Los Angeles, CA; ⁴Cancer Research UK Cambridge Institute, University of Cambridge, Cambridge, United Kingdom and ⁵Cambridge Experimental Cancer Medicine Centre and NIHR Cambridge Biomedical Research Centre, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom.

Background: Understanding to what extent a breast tumor’s genetic composition may change over the course of a few months of neoadjuvant therapy has implications for optimal therapeutic approach. However, genomic changes observed across treatment may result from either treatment-induced clonal evolution or geographically disparate sampling of a heterogeneous tumor. We sought to characterize the geographic heterogeneity in primary breast tumors, and to incorporate this information into analysis of clonal evolution with neoadjuvant therapy.

Methods: We assembled the largest cohort to date of multi-region (n=2-3) whole-exome sequenced (WES) or whole-genome sequenced untreated primary breast tumors with matched normal and adequate tumor purity for analysis: four tumors with data generated for this study and five tumors compiled from three previous studies. We also generated the first cohort of multi-region (n=2-6) WES breast tumors post-neoadjuvant HER2-targeted therapy and chemotherapy, sequencing one region from a pre-treatment diagnostic specimen, multiple regions from the post-treatment surgical specimen, and matched normal for five HER2+ breast tumors that did not achieve a pathologic complete response. We used an agent-based model of spatial tumor growth to investigate whether the mutational patterns we observed with treatment were consistent with pre-existing heterogeneity or treatment-induced selection.

Results: In untreated primary breast tumors, on average 30% (range 1-70%) of apparently clonal mutations from a single region were absent or rare in a second, spatially disparate region (high-frequency regional, or HFR). Intra-tumor heterogeneity was similar post-treatment (HFR 28%, range 10-54%), and was higher in breast tumors than in previously analyzed colon, brain, lung, and esophageal tumors. Simulation studies confirmed that with high heterogeneity as observed in breast tumors, analysis of one pre-treatment and one post-treatment region could not distinguish treatment-induced clonal evolution from pre-existing heterogeneity; however, obtaining at least two post-treatment regions allowed for detection of clonal shifts with treatment. Analysis of multi-region data revealed that clonal replacement occurred with neoadjuvant therapy in two of the five tumors. Candidate causes of therapeutic resistance included amplifications in \textit{CCND1}, \textit{ERBB4}, and \textit{MYC} in one subclone, and functional protein-altering mutations in \textit{ERCC2}, \textit{SMO}, and \textit{WT1} in another. Mathematical modeling suggested that these putative resistant subclones comprised 0.02-12.5% of the overall pre-treatment cell population, substantially larger than previous estimates of resistant tumor clone size.

Conclusions: WES data from multiple regions of untreated and treated primary breast tumors revealed considerable heterogeneity that remained present throughout treatment with chemotherapy and HER2-targeted therapy, even while major clonal sweeps took place in a minority of tumors. Obtaining at least two samples for analysis from breast tumors post-neoadjuvant therapy may reveal the tumor’s evolutionary path and, especially as increasing numbers of molecular and immune therapeutic targets are identified, inform new clinical strategies.
Imprint of parity and age at first pregnancy on the genomic landscape of subsequent breast cancer

Bastien Nguyen¹, David Venet¹, Matteo Lambertini¹, Christine Desmedt¹, Roberto Salgado², Hugo Mark Horlings³, Françoise Rothe¹ and Christos Sotiriou¹. ¹Institut Jules Bordet, Breast Cancer Translational Research Laboratory J.-C. Heuson, Brussels, Belgium; ²GZA-ZNA, Antwerp, Belgium and ³The Netherlands Cancer Institute, Amsterdam, Netherlands.

Background: Although parity and age at first pregnancy are among the most known extrinsic factors that modulates breast cancer risk, their impact on the biology of subsequent breast cancer has never been explored in depth. In this study, we investigated the imprint of parity and age at first pregnancy on the pattern of somatic mutations, somatic copy number alterations (SCNAs), transcriptomic profiles, and tumor immune microenvironment by assessing infiltrating lymphocytes (TILs) levels of subsequent breast cancer.

Methods: A total of 313 patients with primary breast cancer with available whole genome, RNA sequencing and TILs data were included in this study. We used a multivariate analysis adjusted for age at diagnosis, pathological stage, molecular subtypes and histological subtypes. We compared nulliparous vs. parous, late parous vs. early parous, and nulliparous vs. pregnancy associated breast cancer (PABC) patients. Late and early parous patients were grouped by using the median age at first pregnancy as a cut-off value. PABC was defined as patients diagnosed up to 10 years postpartum.

Results: Genomic alterations of breast cancer were associated with age at first pregnancy but not with parity status alone. Independently of clinicopathological features, early parous patients developed tumors characterized by a higher number of Indels (\( P_{adj} = 0.002 \)), a lower frequency of \( CDH1 \) mutations (1.2% vs. 12.7%; \( P_{adj} = 0.013 \)), a higher frequency of \( TP53 \) mutations (50% vs. 22.5%; \( P_{adj} = 0.010 \)), \( MYC \) amplification (28% vs. 7%; \( P_{adj} = 0.008 \)), and a lower prevalence of mutational signature 2, putatively associated with APOBEC activity. PABC were associated with increased TILs infiltration (\( P_{adj} = 0.0495 \)).

Conclusions: These findings highlight an unprecedented link between reproductive history and the genomic landscape of subsequent breast cancer. This work advocates that reproductive history should be routinely collected in future large scale genomic studies addressing the biology of female cancers.
Copy number analysis identifies ESR1 and MDM4 as drivers of progression in invasive lobular breast carcinoma

Jennifer M Atkinson\textsuperscript{1,3}, Lan Cao\textsuperscript{1,2}, Ahmed Basudan\textsuperscript{3,4}, Matthew J Sikora\textsuperscript{1,4}, Amir Bahreini\textsuperscript{1,5}, Nilgun Tasdemir\textsuperscript{1}, Rachel C Jankowitz\textsuperscript{6}, Priscilla F McAuliffe\textsuperscript{3,6}, David Dabbs\textsuperscript{3}, Sue Haupt\textsuperscript{7}, Ygal Haupt\textsuperscript{7}, Peter C Peter Lucas\textsuperscript{3}, Adrian V Lee\textsuperscript{1,3} and Steffi Oesterreich\textsuperscript{1,3}. \textsuperscript{1}Womens Cancer Research Center, University of Pittsburgh, Pittsburgh, PA; \textsuperscript{2}Third Xiangya Hospital, Central South University, Changsha, China; \textsuperscript{3}University of Pittsburgh, Pittsburgh, PA; \textsuperscript{4}University of Colorado Anschutz Medical Campus, Aurora, CO; \textsuperscript{5}School of Medicine, Isfahan University of Medical Sciences, Isfahan, Islamic Republic of Iran; \textsuperscript{6}UPMC Hillman Cancer Center, Pittsburgh, PA and \textsuperscript{7}Peter MacCallum Cancer Centre, Melbourne, Australia.

Background: Invasive lobular carcinoma (ILC) is the second most common histological subtype of breast cancer after invasive ductal carcinoma (IDC). While specific clinical and pathological features differ between ILC and IDC, both histologies are treated the same, due to a lack of knowledge of targetable pathways underlying the observed differences. To identify potential genetic drivers of ILC progression, we set out to identify genes with copy number (CN) alterations, comparing tumors with good outcome to those with poor outcome.

Method: We designed probes for a total of 67 genes known to be frequently altered in breast cancer and used sensitive nanoString technology to comprehensively investigate CN alterations of these genes in 70 well-curated primary ILCs. ILC cell lines MDA-MB-134-VI, SUM44PE, and BCK4 were used for functional studies including proliferation, apoptosis, colony formation, and analysis of gene expression.

Results: Our studies reveal that ESR1 is frequently amplified in primary ILC (14% gains and 10% amplification), and that tumors with amplified ESR1 are more likely to recur compared to those with normal CN. Our analysis also identified a subset of ILCs with HER2 amplification (19%) despite a negative clinical IHC score, and these tumors expressed high HER2 mRNA, protein, and demonstrated enrichment of a molecular HER2 signature. The other most frequently amplified genes included CCND1 (33%), MDM4 (17%), and MYC (17%), and most frequently lost genes were NCOR2 (7%), FGFR4 (6%) and TP53 (6%). MDM4, a negative regulator of p53, has previously been reported to play a role in breast cancer, though little is known about its role in ILC. We demonstrate that decreasing MDM4 levels in p53 wild type ILC cell lines results in increased apoptosis, decreased proliferation associated with cell cycle arrest, and activation of p53 target genes. Intriguingly, a similar induction of G0/G1 cell cycle arrest and increase in apoptosis was observed in p53 mutant ILC cells after MDM4 downregulation, suggesting a p53-independent function of MDM4.

Conclusion: Sensitive detection of CN changes identified amplifications of ESR1 and MDM4 as potential drivers of ILC. Functional studies demonstrate that MDM4 has both p53 dependent and independent functions that warrant further study.
Clonal evolution of non-malignant proliferative lesions into breast cancers

Tomomi Nishimura¹, Kenichi Yoshida¹, Yukiko Kawata¹, Yasuhide Takeuchi¹,², Nobuyuki Kakiuchi¹, Yusuke Shiozawa¹, Kosuke Aoki¹, Masahiro Hirata², Tatsuki R Kataoka², Takaki Sakurai², Satoko Baba³, Yuichi Shiraishi⁴, Kenich Chiba⁴, Kengo Takeuchi³, Hironori Haga², Satoru Miyano⁴, Masakazu Toi¹ and Seishi Ogawa¹. ¹Graduate School of Medicine, Kyoto University, Kyoto, Japan; ²Kyoto University Hospital, Kyoto, Japan; ³Pathology Project for Molecular Targets, Cancer Institute, Japanese Foundation for Cancer Research, Tokyo, Japan and ⁴Human Genome Center, The Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

[Introduction] Non-malignant proliferative lesions in the breast have been implicated in the development of invasive breast cancer. Previous studies showed that adjacent atypical proliferative lesions and breast cancers shared common genetic alterations, suggesting that these evolved from the same ancestral cell. However, the clonal structure of atypical proliferative lesions and their clonal dynamics during progression to cancer are poorly understood. In this study, we compared genetic profiles (with and without pathogenic germline mutations) of normal mammary ducts, non-malignant proliferative lesions, and cancer tissues from the same patients to illustrate the clonal evolution of cancer from a non-malignant epithelial cell.

[Methods] Multiple samples were collected from different proliferative lesions within the cancer-borne breast, including invasive cancers, using micro-dissection from formalin-fixed, paraffin-embedded surgical specimens. Somatic mutations and copy number alterations (CNAs) were then evaluated by whole exome sequencing.

[Results] We analyzed a total of 34 samples from 5 premenopausal females carrying estrogen receptor-positive cancers, where the samples were obtained from normal ducts (N = 6), non-atypical (N = 1) and atypical (N = 8) proliferative lesions, and non-invasive (N = 16) and invasive (N = 3) cancers. The number of somatic mutations per sample ranged from 1 to 276 and increased with disease progression, regardless of the germline mutation status. Two cases with bilateral cancers had a pathogenic germline mutation of either BRCA2 or TP53, where no somatic mutations or CNAs were shared by individual proliferative lesions, suggesting multifocal independent cancerous evolutions. By contrast, in the remaining three unilateral cases, no pathogenic germline mutations were detected, but all proliferative lesions, which were separated by a distance of 7-25 mm, shared one or more driver alterations, such as an AKT1 mutation (UID: KU01), concurrent 1q gain and 16q loss (der(1;16)) (UID: KU02), and a GATA3 mutation and der(1;16) (UID: KU03), while harboring private mutations and/or CNAs of their own. The phylogenetic analysis based on the number of shared mutations predicted an early origin of these founder mutations, which frequently predated decades before the onset of cancer.

[Conclusions] Our results suggest that early breast cancer development is shaped by the evolution of multiple precancerous clones. These clones are originated from a common ancestor that acquired a founder mutation long before the onset of cancer, followed by branching evolution of multiple clones that acquired additional driver mutations of their own, from which an invasive cancer ultimately develops. In hereditary cases, this process is thought to be substantially promoted multi-focally from within the entire breasts by a germline mutation shared by all mammary cells, frequently resulting in bilateral and/or multifocal breast cancers. Our findings provide unique insight into the early development of breast cancer.
Whole genome sequence analysis of 77 breast cancer patients reveal increased somatic transposable element insertions responsible for early onset of cancer

Robin Paul¹, Jeffrey P Solzak¹ and Milan Radovich¹. ¹Indiana University Purdue University Indianapolis, Indianapolis, IN.

More than 50% of the human genome consists of transposable elements (TE). However only certain classes of retrotransposons (ALU, SVA, ERV and L1) are believed to be active. They transpose using an RNA intermediate causing target-site duplications along with a poly-A tail. They can also insert into intronic regions and disrupt normal transcription of protein-coding genes. However, most TEs are repressed using various epigenetic mechanisms such as DNA methylation, histone modifications and RNA silencing. The piRNA pathway also plays an important role in retrotransposon silencing by establishing a repressive chromatin state. In this study, somatic and germline TE insertions in 77 TCGA breast cancer cases were characterized. These studies have revealed that somatic TEs can insert into intronic regions of tumor suppressor genes such as LRP1B, RAD51B and WNK2. Characterization of germline TE insertions, reveal insertions in intronic regions of predisposition genes such as CDH1 and BRCA2. Analysis of germline SNPs in high somatic TE patients reveals the presence of deleterious variants in genes such as NRDE2, RAD51C and DDX3X which are known to regulate TEs using RNA silencing via the piRNA pathway and other DNA-damage response mechanisms. Patients having high somatic TE insertions were found to have lower age of diagnosis suggesting a role in the early onset of cancer (median age of patients with high TE=43.37yrs; low TE=59.77yrs, Wilcoxon p=0.023). Further comparison of somatic TE insertion burden against somatic point-mutation burden revealed an inverse correlation suggesting analysis of TE insertions is indispensable to get the complete mutation profile of breast cancer genomes.
Novel breast cancer mutational signatures

Zexian Zeng1, Andy H Vo2, Yuan Luo1, Seema A Khan3 and Susan E Clare3. 1Northwestern University Feinberg School of Medicine, Chicago, IL; 2Committee on Developmental Biology and Regenerative Medicine, The University of Chicago, Chicago, IL and 3Feinberg School of Medicine, Northwestern University, Chicago, IL.

Background: Our understanding of the biological processes that generate somatic mutations in breast cancer has increased markedly over the past five years. Using the catalog of somatic mutations present in cancer genomes, over 30 “mutational signatures” have been produced. While these provide important insights into the processes responsible for somatic mutation, gaps remain, and the etiology of several signatures remains unknown.

Methods: We have developed a new method in which the specific nucleotide change (e.g., C>T), the codon that each mutation falls in (e.g., GCT), the position in the codon (e.g., 2), and the nucleotides immediately 5’ and 3’ of the mutation (e.g., 5’: C; 3’: G) are all considered. The summary of these mutation characteristics forms a mutational profile for each tissue sample. Putting multiple samples' profiles together forms a sparse matrix with the number of samples as rows and the mutation characteristics as columns. Nonsmooth nonnegative matrix factorization was then applied to enable the discovery of intrinsic patterns in this sparse matrix.

Results: Using somatic mutations identified in 1017 breast cancer tissues from The Cancer Genome Atlas (TCGA), we have identified four mutational signatures. Signature A correlates with the well-defined APOBEC signatures and signature B with the “aging” signature, which is the result 5-methylcytosine hydrolysis. Signature C and signature D are potentially new signatures. Signature D is enriched with C:G>A:T mutations; these mostly occur in the middle position of codons, and are enriched with GG(CC) either 5’ or 3’ of the mutation's sequence context. G>T mutations are known to occur as a consequence of oxidative damage that is not repaired. Guanines are vulnerable as they have the highest vertical oxidation potential of the nucleobases. The 5’ guanines in GG sites are especially reactive. We hypothesize that Signature D results from oxidative mutagenesis.

When correlated with clinical phenotypes, the basal subtype is clearly enriched for tumors with the Signature D mutation pattern (exposure level is in 169 basal tumors and in 797 non-basal tumors, p=<0.01), suggesting an etiologic link with basal-like breast cancer. G>T somatic mutations in breast cancer mainly take place during cell replication rather than during transcription. In the normal breast, epithelial cell replication occurs during the luteal phase of the menstrual cycle and during pregnancy, primarily under the direction of progesterone (P). P binds to its receptor (PR) in a subpopulation of PR positive cells where it initiates the transcription of genes including RANKL, with resultant paracrine stimulation (through RANK), of the NF-κB signaling pathway in neighboring cells. The four RANKL genes (TOP2A, MKI67, PBK, CDK1), defined by Nolan et al., are all positively associated with the signature D (P-values < 0.05), suggesting that this type of mutagenesis is associated with RANKL pathway upregulation.

Conclusions: We have identified a potentially new somatic mutational signature, which we have designated as Signature D, which appears to result from exposure of DNA to oxidative stress during replication. It is associated with the basal subtype of breast cancer as well as RANKL- NF-κB pathway upregulation.
Recurrent but not pathognomonic fusion genes in mucinous carcinomas of the breast

Fresia Pareja¹, Rodrigo Gularte-Merida¹, Arnaud Da Cruz Paula¹, David Brown¹, Felipe C Geyer¹, Salvatore Piscuoglio², Caterina Marchio³, Anne Vincent-Salomon⁴, Edi Brogi¹, Britta Weigelt¹ and Jorge S Reis-Filho¹. ¹Memorial Sloan Kettering Cancer Center, New York, NY; ²Institute of Pathology, University Hospital Basel, Basel, Switzerland; ³FPO-IRCS Candidolo Cancer Institute, University of Turin, Turin, Italy and ⁴Institute Curie, Paris, France.

Introduction: Mucinous carcinoma of the breast (MCB) is a rare histologic subtype of estrogen receptor (ER)-positive invasive carcinoma, and is characterized by tumor cells floating in pools of mucin. Despite their characteristic histology, MCBs are heterogeneous at the genetic level and no driver genetic alterations have been identified. Notably, MCBs lack the common genetic alterations found in ER-positive invasive ductal carcinomas (i.e. 16q losses, 1q gains and PIK3CA mutations). Fusion genes have been reported in breast cancer, including highly recurrent or pathognomonic fusions genes, such as the ETV6-NTRK3 and MYB/MYBL1 rearrangements in secretory carcinoma and adenoid cystic carcinoma, respectively. In this study we sought to define whether MCBs would be underpinned by a pathognomonic fusion gene.

Materials and methods: Seven pure mucinous A (hypocellular), seven pure mucinous B (hypercellular), and the mucinous component of a mixed MCB were microdissected, and subjected to RNA extraction followed by RNA-sequencing for fusion gene discovery. Read pairs supporting chimeric transcripts were identified using INTEGRATE, FusionCatcher and STARfusion. The Bayesian driver probability of the candidate fusion genes was annotated using OncoFuse. In-frame fusion gene candidates with a high driver probability were validated using orthogonal methods (RT-PCR and Sanger sequencing).

Results: Our analysis identified fusion genes in 47% (7/15) of the MCBs analyzed (29% (2/7) of type A MCBs, 57% (4/7) type B MCBs and in the mucinous component of one mixed MCB). The OAZ1-CSNK1G2 and RFC4-LPP fusion genes were identified in 20% (3/15) and 13% (2/15) of the cases, respectively. The OAZ1-CSNK1G2 chimeric transcript results in the truncation of the kinase domain of CSNK1G2, which represses ER transactivation. The RFC4-LPP chimeric transcript leads to the fusion of exons 1-3 of RFC4 and exons 5-11 of LPP, where the LIM domains of LPP are conserved. LPP is a known partner of fusion genes identified in mesenchymal tumors and reported to mediate TGF-β induced breast oncogenesis via its LIM domain. Additional validated, potentially pathogenic fusion genes identified in MCBs involved kinases, phosphatases or regulators of tyrosine kinase receptor signaling, such as IRAK3-PPM1H (n=1), GIGYF2–GFRA3 (n=1) and PHF20-FAM217B (n=1).

Conclusions: MCBs harbor fusion genes in almost half of the cases with two fusions being recurrent, involving primarily genes encoding kinases, phosphatases or receptor tyrosine kinase signaling regulators. Nevertheless, due to the lack of recurrence of a specific fusion gene, this special histologic type of breast cancer is unlikely to be underpinned by a highly recurrent/pathognomonic pathogenic fusion gene.
Mucinous and neuroendocrine breast cancers: A spectrum of genetically-related lesions distinct from common forms of estrogen receptor-positive breast cancers

Fresia Pareja¹, Arnaud Da Cruz Paula¹, Pier Selenica¹, Ju Youn Lee¹, Caterina Marchio², David Brown¹, Felipe C Geyer¹, Edi Brogi¹, Anne Vincent-Salomon³, Britta Weigelt¹ and Jorge S Reis-Filho¹. ¹Memorial Sloan Kettering Cancer Center, New York, NY; ²FPO-IRCCS Candiolo Cancer Institute, University of Turin, Turin, Italy and ³Institut Curie, Paris, France.

Introduction: Mucinous (MBCs) and neuroendocrine breast carcinomas (NBCs) are special histologic types of estrogen receptor (ER)-positive breast cancers. Together, MBCs and NBCs account for approximately 5% of invasive breast cancers. NBCs are defined by the expression of neuroendocrine markers (i.e., chromogranin and/or synaptophysin), whereas MBCs consist of nests of cancer cells floating in pools of extracellular mucin and can be either hypocellular/type A (MBC-A) or hypercellular/type B (MBC-B). MBC-B may display neuroendocrine differentiation. We compared the repertoire of somatic genetic alterations in MBCs-A and MBCs-B, and in NBCs, and evaluated whether they differ from ER-positive/HER2-negative invasive ductal carcinomas of no special type (IDC-NSTs).

Materials and methods: Reanalysis of the targeted capture or whole exome sequencing data of 22 MBCs (12 MBCs-A and 10 MBCs-B), and of 15 NBCs was performed. The BAM files were retrieved and somatic mutations were detected with MuTect, indels with Strelka, Varscan2, Scalpel and Lancet, and copy number alterations using FACETS. The mutational repertoire of MBCs-A and MBCs-B was compared to that of NBCs, and of ER-positive/HER2-negative IDC-NSTs from The Cancer Genome Atlas (TCGA) breast cancer study (n=310).

Results: The most frequently mutated genes in MBCs-A were SF3B1 and FRG1B (17%, each); in MBCs-B were GATA3 and KMT2C (30%, each), and in NBCs were FOXA1 and TBX3 (20%, each) and KMT2C (20%). No significant differences were observed in single gene comparisons between MBCs-A, MBCs-B and NBCs (Fisher’s exact tests, p>0.05). When compared with ER-positive/HER2-negative IDC-NSTs from TCGA, NBCs harbored a higher frequency of mutations targeting FOXA1 (20% vs 2.9%, Fisher’s exact test, p<0.05) and TBX3 (20% vs 2.9%, Fisher’s exact test, p<0.05), and a lower frequency of TP53 mutations (0% vs 23.9%; Fisher’s exact test, p<0.05). We observed a lower frequency of PIK3CA mutations in both MBCs-A (8.3% vs 40%, Fisher’s exact test, p<0.05) and MBCs-B (0% vs 40%; Fisher’s exact test, p<0.01) compared to ER-positive/HER2-negative IDC-NSTs. Although not statistically significant, PIK3CA mutations were numerically less frequent in NBCs than in ER+/HER2-IDC-NSTs (13.3% vs 40%; Fisher’s exact test, p>0.05). Concurrent 1q gains and 16q losses, the hallmark copy number alterations of ER-positive/HER2-negative breast cancer were found in 47% of the ER-positive/HER2-negative IDC-NSTs from TCGA, but only present in 20% of NBCs and in none of the MBCs-A or MBCs-B.

Conclusion: Type A MBCs, type B MBCs and NBCs harbor similar patterns of genetic alterations, including a low frequency of PIK3CA mutations and of concurrent 1q gains/16q deletions. Taken together, our data suggest that both MBCs and the vast majority of NBCs constitute a spectrum of histologically and genomically related subtypes, distinct from ER-positive/HER2-negative IDC-NSTs.
BRCA mutations and not type 1 tandem duplicator phenotypes are associated with pathological complete response in patients with triple negative breast cancer undergoing neoadjuvant carboplatin/nab-paclitaxel

Francesca Menghi¹, Yuan Yuan², George Somlo² and Edison T Liu³. ¹The Jackson Laboratory for Genomic Medicine, Farmington; ²City of Hope National Medical Center, Duarte and ³The Jackson Laboratory, Bar Harbor.

Background. We recently described six distinct genomic configurations characterized by large numbers of distributed somatic tandem duplications (TDs) known as Tandem Duplicator Phenotypes (TDPs). Different TDPs feature TDs of different span sizes, and are enriched in TNBC, ovarian, and uterine cancers. Type 1 TDPs (i.e. groups 1, 1/2mix and 1/3mix) feature short span TDs (~11Kb in size), invariably show abrogation of BRCA1 (via mutation or methylation) and of TP53, and affect ~40% of TNBCs. We had observed, in limited in vitro and preclinical PDX models, that TDP status correlates with platinum sensitivity (1). Here, we assess TDP status across a cohort of 42 TNBC patients (pts) undergoing neoadjuvant carboplatin and NAB-paclitaxel to test the hypothesis that type 1 TDP status may be predictive of optimal response to platinum-based therapy.

Methods. 42 pts with TNBC were enrolled in a phase II study of neoadjuvant carboplatin/nab-paclitaxel at the City of Hope National Medical Center (NCT01525966). Pathological complete response (pCR) was achieved in 50% of pts (21/42). WGS was performed using standard Illumina protocols. Structural variants were called using Crest, Delly and BreakDancer, and high confidence breakpoints were selected when called by at least two tools and by requiring split-read support. TDP status was ascertained as recently described (2). BRCA1 methylation was determined by methylation-specific PCR.

Results. 45% of the tumors classified as TDP (19/42). Consistent with our previous observation, the vast majority were type 1 TDPs with short span TDs (n=17) and were strongly associated with BRCA1 mutation or methylation (16/17, P = 1.4E-8). However, there was no correlation between TDP status and pCR (OR=1.1, NS). In a more detailed analysis, we found that BRCA1 mutation correlated with pCR rate (6/7 pCR, P=0.01), whereas promoter methylation did not (4/11 pCR, NS). Moreover, both pts with mutant BRCA2 achieved pCR. Thus, as a group, pts with BRCA1/2 mutations (but not BRCA1 methylation) were more likely to achieve pCR than those with wild type BRCA1/2 (OR=11.9, P=1.7E-2). Results were unchanged when using RCB 0 and 1 vs. RCB 2 and 3 as the response criteria.

Conclusions. This study confirmed that reduction of BRCA1 activity via either mutation or methylation robustly associates with type 1 TDPs in TNBC. However, TDP status did not predict good response, suggesting the separation of BRCA effects on genomic instability and platinum sensitivity. This indicates that genomic signature assessments, such as TDP and HRD, may not be sufficient in predicting pCR in TNBC. Importantly, we found that BRCA1/2 mutated TNBC pts were more likely to experience pCR (8/9) compared with pts with either BRCA1 methylation (4/11) or wild type BRCA1/2 (8/21). The exact genetic underpinnings of response in non-BRCA pts are currently under investigation.

References.
1) Menghi et al, The Tandem Duplicator Phenotype is a Prevalent Genome-Wide Cancer Configuration Driven by Distinct Gene Mutations, Cancer Cell (2018).
Introduction: The vast majority of cancer patients continue to receive treatments that are minimally informed by omics data. In the case of breast cancer, only ER and HER2 are routinely used for treatment selection. There is a particular need for personalized treatment in individuals with primary and secondary drug resistance or aggressive breast cancers. Emerging bioinformatics and statistical methods have made a fundamental impact on cancer research. However, challenges remain with regard to patient-centric data analysis and providing genomic data guidance to oncologists. There exists a large number of FDA approved anti-neoplastic drugs used to treat cancers other than breast and the development of innovative informatics methods and algorithms to repurpose those drugs should benefit breast cancer patients.

Methods and Results: We have developed precision care systems (such as PANOPLY and CORPUS) to identify personalized therapies for an individual patient and to deliver genomic reports in a standard, searchable format so that a researcher or an oncologist can quickly navigate through molecular data and obtain prioritized drugs and targets. The PANOPLY (Precision cancer genomics report: single sample inventory) algorithm applies machine learning and topology-based network analysis methods to integrate multi-omics profiles and clinical data; individual-specific molecular alterations are identified and compared with a set of matched-controls having similar clinical data. Since there is a lack of a “gold standard” dataset to test such algorithms, we simulated 500 case-control sets and evaluated drug predictions across multiple simulation scenarios. We applied the PANOPLY algorithm to the The Cancer Genome Atlas (TCGA) breast cancer cohort, which consists of multi-omics data and clinical data. In addition, PANOPLY was also applied to an in-house neoadjuvant breast cancer study (BEAUTY) that consists of multi-omics data, clinical data, and patient-derived xenografts (PDXs). In the TCGA breast cancer study we obtained survival data to determine the cases and matched-controls; and in the BEAUTY, we used pathologic complete response (pCR) as an outcome to determine responders and non-responders. Recurrent targetable alterations were not enriched in patients without pCR in the BEAUTY study. We have applied the PANOPLY to non-responder patients to identify individual specific alterations, dysregulated networks, drug targets, and drugs for each patient and stored them as case reports in CORPUS (Computational Oncology Reports and Precision therapeUticS), a web-based repository that allows clinicians to review genomic reports. Using comprehensive “omic” data derived from a triple negative breast cancer patient who had pre and post-neoadjuvant chemotherapy PDXs, PANOPLY prioritized the PARP inhibitors as the top class of drug. Using the PDX models available from this patient, we tested olaparib and confirmed the in vivo antitumor activity (more effective than vehicle with a p-value < 0.05 in the PDXs). Further studies to confirm PANOPLY findings are currently underway.

Conclusions: In summary, the PANOPLY and CORPUS systems incorporate molecular data together with clinical data to provide genomic reports with proposed drug targets to advance or enable precision breast cancer care.
Time-course DNA and RNA profiling of tumors from intra-patient cross-over trial of sequential use of aromatase inhibitors

Charles J Vaske¹, Rahul Parulkar¹, Nazli Bahrami², Torill Sauer³, Marie Loeng², Berit Gravdehaug², Belal Aljabri², Vahid Bemanian², Jonas Lindstrøm²,³, Torben Lüders⁴, Vessela Kristensen³,⁵ and Jürgen Geisler²,³. ¹NantOmics, Santa Cruz, CA; ²Akershus University Hospital, Lørenskog, Norway; ³Institute of Clinical Medicine, University of Oslo, Oslo, Norway; ⁴Health Services Research Unit, Akershus University Hospital, Lørenskog, Norway and ⁵EPIGEN Research Laboratory, Akershus University Hospital, Lørenskog, Norway.

Background. The NEO-LET-EXE trial examines the neoadjuvant use of sequential administration of the aromatase inhibitor letrozole (Femar / Femara) and the aromatase inactivator exemestane (Aromasin). Although both drugs nearly completely inhibit aromatase, resistance to both is developed with time. However, when used sequentially, in some patients after switching to the alternative drug and progressing on the first choice, new responses may appear. The mechanism behind this clinical observation is currently not known. The solution may lead to a novel strategy to re-sensitize tumors to hormonal treatment. Prior studies have examined genomics at the four month time point, but not at both two months and four months.

Material. Postmenopausal patients with estrogen receptor (ER) positive (>50%), HER-2 negative locally advanced breast cancer may be enrolled. Age: 18+ (no upper limit). Present accrual and target accrual: 49 out of planned 100 patients have been enrolled so far. The last patient is expected to enter the trial in Q4 2019.

Study design. In the neoadjuvant, randomized, open-label, intra-patient cross-over trial NEO-LET-EXE biopsies are taken before treatment, after two months on one aromatase inhibitor and swap to the other aromatase inhibitor, and at surgery at four months.

Results. In order to explain the phenomenon of a lack of cross-resistance between steroidal and non-steroidal aromatase inhibitors we profiled biopsies at three time points per patient by whole exome and whole transcriptome sequencing from FFPE from 25 patients. A total of 56 DNA whole exomes and 41 RNA seq transcriptomes were generated from FFPE samples available. When grouping both arms together, mutational burden decreased at two months, while clonality of mutations increased, providing evidence of selection. At four months, mutational burden increased from the two month timepoint. In particular, PIK3CA somatic variants present at the first time point were not detected at two months. However, these were detected again at significant variant allele fractions at four months after switch of treatment. The majority of gene expression changes happen in the initial two months, with fewer changes between two and four months. Instead, significant changes in alternative splicing at two months and four months were observed, for example for FGFR1, which does not experience a large fold change in expression between these two points. Our preliminary results show significant DNA and RNA changes in the first two months of aromatase inhibition leading to fewer, more clonal variants. Comparison of the four month to two month time point shows fewer RNA changes than the prior two months and an increase in the number of somatic variants compared to the two month timepoint.
Genetic heterogeneity of DCIS is a predictor of invasive cancer

Angelo Fortunato¹, Diego Mallo¹, Lorraine King², Timothy Hardman², Allison Hall², Jeffrey R Marks², Shelley Hwang² and Carlo C Maley¹. ¹The Biodesign Institute, Arizona State University, Tempe, AZ and ²Duke University, Durham, NC.

Background: Heterogeneity is a hallmark of human cancers that is apparent both between and within individual tumors. Intra-tumor heterogeneity provides the genetic fuel for natural selection in clonal evolution and cancer progression. Tumors with high levels of genetic heterogeneity are hypothesized to be more likely to progress to invasion and metastasis.

Methods: We measured the mutational loads from separate areas of pure DCIS and compared this to genetic heterogeneity in DCIS lesions that co-exist with invasive cancer, as a surrogate for progression. Cases of pure DCIS and DCIS diagnosed concurrent with invasive cancer were identified. Two areas of DCIS from each case a minimum of 0.8 cm apart and control tissues were macro-dissected and the DNA extracted from FFPE samples. To analyze the data, we developed new bioinformatics methods that allowed analysis of small amounts of degraded DNA extracted from FFPE samples across multiple regions. Our bioinformatics pipeline was optimized on a series of 28 independent technical replicates of the same DNA sample sequenced twice, as training tools to find the best filtering parameters.

Results: Whole exome sequencing was performed on two geospatially separated blocks for each case (41 pure DCIS and 30 DCIS adjacent to invasive disease). Minimum coverage for inclusion in this study was 40X over at least 50% of the exome. We used the ratio of private mutations (only in 1 area) to public (found in both areas) mutations as a measure of intra-tumor heterogeneity. Overall mutational load of DCIS was not a significant predictor to progression; however notably, DCIS adjacent to invasive disease patients had a higher ratio of private/public mutations (heterogeneity) in coding domains (Mann-Whitney p=0.016. Functional analysis of mutated coding genes (DAVID 6.8) shows a statistically significant enrichment in signal transduction, olfactory receptors (G-protein-coupled receptors) and cell-matrix interactions in both tumor types, after FDR correction. DCIS adjacent to invasive disease had an enrichment of mutated genes involved in additional cellular functions such as microtubule activity (fold enrichment =7.6, FDR=0.002), protein-protein interactions (fold enrichment =3.65, FDR=5.11E-04) and extracellular matrix remodeling (fold enrichment =8.3, FDR=0.02).

Conclusion: We present an approach to measure clonal heterogeneity using a bulk sequencing strategy applied to geospatially distinct foci of DCIS. Our findings suggest that functional heterogeneity may play an important evolutionary role as a driver for invasive progression.
Whole exome sequencing of HER2+ metastatic breast cancer (MBC) patients (pts) with extraordinary durable complete responses (ExdCR) to trastuzumab (T)

Naomi Walsh¹, Giuseppe Gullo², Cecily Quinn², Simon J Furney³ and John Crown². ¹National Institute for Cellular Biotechnology, Dublin City University, Dublin, Ireland; ²St. Vincent's University Hospital, Dublin, Ireland and ³Genomic Oncology Research Group, Royal College of Surgeons Ireland, Dublin, Ireland.

Background: Trastuzumab (T) has shown clinical efficacy in early-stage and MBC. However, within 1-year 40-50% develop resistance to T. The exact mechanism of the development of T resistance is not completely understood. Anecdotal observations suggest that a small fraction of patients with HER2+ MBC may be "extraordinary durable complete responders (ExdCR)". Indeed, we previously reported that 9% of MBC achieve dCR following T and chemotherapy. Understanding the genomic mechanisms underlying exceptional dCR to T may improve patient selection and treatment rationale to identify HER2+ MBC pts who are more likely to achieve dCR following T treatment.

Methods: Genomic DNA was extracted from paraffin embedded formalin fixed (FFPE) tissue. Whole exome sequencing (WES) on primary tumours from 9 MBC ExdCR > 60 mo (5 matched T:N) and 6 non-responders (NR) or PR < 6 mo (3 matched T:N). Tumours were analysed for single nucleotide variants (SNVs) point mutations, insertions/deletions (indels), copy number alterations (CNA), and tumour mutational burden. Detailed clinicopathologic data was collected for each patient and linked to the genomic information.

Results: WES of matched tumour:normal samples revealed differences in SNVs and indels between the ExdCR pts compared to NR. Mutations in TP53 were found in 2/5 ExdCR pts and in 0/3 NR. Initial analysis of CNA revealed that HER2 is significantly more amplified in ExdCR pts compared to NR, and this was also shown by IHC and FISH.

Conclusions: We present a genomic landscape of extraordinary durable complete responders compared to non-responders using WES. High variability exists in mutation profile of ExdCR pts with few overlapping genes. Further analysis into clinically relevant genomic and molecular alterations will be performed to potential aid in patient selection and choice of therapy, and novel drug targets.
Whole exome analysis of extreme long-term survivors with metastatic breast cancer

Rachel E Yan¹, Colin Longhurst², Kristy Lee³, Aidan D Gilbert¹, Roxana A Alexandridis², Stephanie M McGregor⁵, Jennifer J Laffin³, Gabrielle Rocque⁴ and Mark E Burkard¹. ¹UW Carbone Cancer Center and University of Wisconsin--Madison, Madison, WI; ²Biostatistics and Medical Informatics, Madison, WI; ³Wisconsin State Laboratory of Hygiene, University of Wisconsin--Madison, Madison, WI; ⁴UAB, Birmingham, AL and ⁵University of Wisconsin--Madison, Madison, WI.

**Background:** Metastatic breast cancer (MBC) is incurable, yet some extreme long-term survivors (ELTS) live for a decade or more. Mechanisms underlying extreme survival are incompletely known, yet are important to improve prognosis and treatment. Extreme survival also provides an opportunity for cancer cells to evolve over decades. To evaluate the genomic characteristics of ELTS, we identified a cohort representative of the extreme tail of the metastatic survival curve and performed genomic analysis of blood and matched metastatic tumor.

**Methods:** We identified a cohort of ELTS at our institution in an IRB-approved study. Eligible subjects had MBC and had lived a ≥10 years from the original breast cancer (BC) diagnosis with hormone receptor (HR)-positive disease or ≥5 years if HR-negative. Those with available archived tumor tissue were enrolled for genomic analyses. Archived samples were obtained from metastatic sites obtained late in the clinical course. Whole exome sequencing (WES) was performed on matched blood and tumor. Mutational profiles were qualitatively compared with publicly available reference somatic alterations in primary BC (Ctrl; cbioportal.org). Frequency of mutations is reported for known BC drivers. In an exploratory analysis to identify novel genes, the frequency of mutations in ELTS vs. Ctrl was compared for 15,659 well-covered genes. These were further evaluated for the ratio of non-synonymous to synonymous mutations, which is indicative of selective pressure.

**Results:** 53 ELTS were identified; 13 had available archived tumor tissue and consented. The median survival from original BC diagnosis was 22 years, which corresponds to 99.8th percentile for survival, benchmarked to a cohort of MBC patients identified from the Surveillance, Epidemiology, and End Results-Medicare linked database. The 13 subjects had lived with metastatic disease for a median of 9 years (range 4-23). One subject had HR-/HER2+ BC and had lived 16 years with MBC. Three additional subjects had HR+/HER2+ BC with survival ranging from 19-25 years from original BC diagnosis. The remaining 9 subjects had HR+/HER2- BC with survival of 13-40 years from original diagnosis. Matched tumor/somatic WES achieved a mean tumor read depth of ~600x and 96% coverage. Somatic mutations revealed near-expected rates of known driver alterations in commonly mutated genes such as PIK3CA, TP53, and CDH1 (Table). No mutations were found in PTEN or ESR1 in ELTS. Novel gene candidates were identified as having a high prevalence of mutations in this cohort including Androgen Receptor (10 of 13), MUC4 (12 of 13) MUC12 (10 of 13), and HRNR (12/13). Pathway analysis is ongoing.

**Conclusions:** ELTS tumors obtained late in the clinical course have mutations in known cancer drivers near rates expected from primary BC. However, we have identified additional genes with an increased number of mutations either related to distinct genetic features of these cancers, or due to accumulated mutations that occur over the extended time for tumor evolution.

Young breast cancer patients demonstrate worse survival associated with aggressive oncogene expression but not with mutation load, tumor heterogeneity or pro-tumor immune cell infiltrations

Jessica S Young¹, Mariko Asaoka¹, Eriko Katsuta¹, Tsutomu Kawaguchi¹, Qianya Qi¹, Song Liu¹, Li Yan¹ and Kazuaki Takabe¹.
¹Roswell Park Comprehensive Cancer Center, Buffalo, NY.

INTRODUCTION: Young breast cancer patients have more aggressive subtypes and higher mortality rates. This study investigates the biologic, immunologic, and oncogenic differences between Young (≤40 yo) and Non-Young (>40 yo) patients with breast cancer.

MATERIALS/METHODS: The Cancer Genome Atlas (TCGA; n=1095) and the Molecular Taxonomy of Breast Cancer International Consortium (METABRIC; n=1894) were used for analysis. Gene Set Enrichment Analysis (GSEA) was performed on breast cancer patients in TCGA. We calculated mutation load using both TCGA and METABRIC. We also calculated the Cytolytic Activity Score (CYT), Mutant-Allele Tumor Heterogeneity (MATH), T-Cell Receptor (TCR)-Richness, and Ki67 mRNA expression in TCGA.

RESULTS: There were 97 and 116 Young patients and 994 and 1788 Non-Young patients in the TCGA and METABRIC databases respectively. Young patients had a lower DFS (p=0.012) in TCGA. Young patients had a lower DSS (p<0.001) in METABRIC. There were less Stage I (13.5% vs 17.3%) and II (54.2% vs 58.3%) patients and more Stage III (31.2% vs 22.4%) patients in the Young group. There were more basal-like subtypes in the Young in TCGA (17.8% vs 16.1%) and METABRIC (28.4% vs 9.3%). Mutation load in TCGA was lower in the Young (p=0.030), but not significantly different in the METABRIC database. MATH, which reflects tumor heterogeneity, was not significantly different between the groups. These results were unexpected since Young patients have a higher proportion of basal-like subtype which is known to be rich in mutations and more immunogenic. In TCGA, Young patients were found to have higher amounts of activated dendritic cells (p=0.049). In METABRIC, Young patients had higher amounts of Plasma cells (p=0.016), CD4 memory-activated T-cells (p<0.001), NK resting cells (p=0.015), and M1 Macrophages (p=0.002). We also found that regulatory T-cells (p=0.029), activated NK cells (p=0.016), M2 Macrophages (p<0.001), and resting Mast cells (p=0.006) were lower in the Young. This unexpectedly showed that anti-tumor immune cells were more enriched in Young patients. Indeed, the CYT, which reflects tumor killing activity, and TCR-Richness, which reflects T-cell function, were both significantly higher in Young patients (p=0.034, p=0.004, respectively), which was opposite from what we expected due to its biological aggressiveness. GSEA was then used to analyze the TCGA database to clarify gene sets that are enriched in Young patients. Of the 50 Hallmark gene sets analyzed, 4 gene sets were found to be enriched in Young patients: G2M Checkpoint (p=0.002), Hallmark MYC Targets V1 (p=0.004), HALLMARK E2F Targets (p=0.035), and Hallmark Unfolded Protein Response (p=0.038). Ki67 which reflects cell proliferation was significantly higher in Young vs Non-Young patients (p=0.004).

CONCLUSIONS: Both TCGA and METABRIC cohorts demonstrated that Young patients have more basal-like subtype and significantly worse survival. Our results support the notion that Young patients have more aggressive cancer not because of mutations, tumor heterogeneity or immune cell infiltrations, but because of aggressive oncogene expressions.
The pattern of alpha- and beta- adrenergic receptor expression impacts breast cancer outcome

Ahmed Elkhanany¹, Eriko Katsuta¹, Elizabeth Repasky¹ and Kazuaki Takabe¹. ¹Roswell Park Comprehensive Cancer Center, Buffalo, NY.

BACKGROUND. Chronic stress promotes myriad of genomic changes collectively termed conserved transcriptional response to adversity (CTRA), contributing to a pro-tumorogenic and immunosuppressive tumor microenvironment (TME). Adrenergic stimulation is one mechanism of CTRA, and adrenergic receptor (AR) modulators are currently repurposed in cancer trials. However, the impact of AR expression on TME and overall survival outcome (OS) in breast cancer (BC) remains unclear. We asked whether AR expression in tumor samples predicts prognosis in BC patients (pts) and whether it correlated to expression in normal cells.

METHODS. Public RNA expression data accessed from The Cancer Genome Atlas (TCGA), and fed to deconvolutional algorithm CIBERSORT, estimating 22 immune cell proportions. Clinical and OS data were accessed from XENA. Differential gene expression obtained for 115 CTRA genes known to correlate with stress. Cytolytic activity (CY) appended from Rooney et al.

RESULTS. 1,211 pts had clinical and genomic data, including 114 pts with normal breast (BN) samples. When compared to BC, BN samples were enriched for ARG1, PTGS2, VCAM1, CSF1, as well as all ARs (ADR A1A, A1B, A1D, A2A, A2B, A2C, B1, B2, B3). There was significant correlation between BC and BN samples in A2A, B1, B2, IFN-γ, PTGS2 (Spearman ρ -0.2, -0.27, -0.2, 0.28, 0.29, P<0.01). On survival analysis, worse OS was associated with higher expression of A1B and A2C (HR 1.1[1-1.22], 1.1[1-1.17]), while higher B1 predicted better OS (HR 0.86[0.79-0.93]). OS impact persisted after quantile separation (HR for higher to lower quantiles of A1B, A2C and B1 were 1.47[1.1-2], 1.38[1.01-1.9], 0.69[0.49-0.0.95]). Co-expression of A1B and A2C predicted significantly worse OS than either alone (HR 1.53[1.1-2.2]). Results persisted after adjusting for age. For TME analysis between quantiles, higher A1B and A2C expression correlated with higher regulatory T (Treg) cells (OR 1.42[1.1-1.86]), fewer resting and activated dendritic cells (DCs) and memory CD4+ cells, and lower CY (OR 0.81[0.64-0.9]). In comparison, higher B1 correlated with higher tumor infiltrating lymphocytes (TILs), M1 macrophages (M1), M1/M2 ratio (OR 1.45[1.14-1.84], 3.64[1.03-12.8], 1.86[1.46-2.36]), lower M2 and Treg (0.42[0.33-0.53], 0.65[0.49-0.85]), and higher CY (OR 1.89[1.49-2.38]). CY also correlated with IFN-γ, MMP9 and CSF1 (Spearman ρ 0.75, 0.59, 0.3 p<0.001). Higher M2 and lower M1/M2 ratio were independently associated with a poorer OS, persisting after control for B1 (HR 1.78[1.27-2.47], 1.5[1.08-2.08]). T-cell exhaustion (Tex) genes CD274, PDCD1, CTLA4, IDO1, LAG3 and HAVCR2 were all lower in ADR-α (OR for A1B was 0.69, 0.73, 0.68, 0.87, 0.61, 0.69) and higher in ADR-β (OR for B1 was 1.46, 1.32, 1.29, 1.42, 1.26, 1.4).

CONCLUSIONS. AR genes were similarly expressed across normal and tumor samples from BC pts. Pts with higher ADR-α expression had worse OS (higher Treg, lower CY) while higher ADR-β expression pts had better OS (higher TILs, M1, M1/M2, lower Treg, M2). Tex genes were higher in ADR-β, likely due to higher TILs. These findings illustrate the potential impact of chronic stress on TME and clinical outcome, potentially helping to discern pts who can benefit most from AR modulation.
Unlocking the transcriptomic potential of formalin-fixed paraffin embedded breast cancer tissues for high-throughput genomic analysis

Arran K Turnbull¹, Cigdem Selli¹, Carlos Martinez-Perez¹, Anu Fernando¹, Lorna Renshaw², Jane Keys², Jonine D Figueroa¹, Xiaping He³, Maki Tanioka³, Alison Munro¹, Lee Murphy⁴, Angie Fawkes⁵, Richard Clark⁴, Audrey Coutts⁴, Charles M Perou³, Lisa A Carey³, J Michael Dixon² and Andrew H Sims¹.¹Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, United Kingdom; ²Edinburgh Breast Unit, Western General Hospital, Edinburgh, United Kingdom; ³Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill and ⁴Wellcome Trust Clinical Research Facility, Western General Hospital, Edinburgh, United Kingdom.

Background: Transcriptomic analyses of clinical samples can help improve our understanding of disease aetiology, drug effectiveness, assign molecular subtypes and derive prognostic signatures for clinical decision-making. The success of early microarray studies relied heavily on sample quality and predominantly fresh frozen (FF) tissues to generate reliably robust data. The emergence of next-generation microarray and sequencing-based technologies from formalin-fixed paraffin-embedded (FFPE) tissues provides an opportunity to study archival clinical tissues with long-term follow-up. Here we assess 9 technologies, which vary in resolution, cost and RNA requirements, with matched FF and FFPE tissues from the same patient.

Methods: Sequential tumour biopsies were taken pre-treatment and on-treatment (at 14-days and 3-months) from 11 postmenopausal patients with oestrogen receptor positive breast cancer treated with 3 months of neoadjuvant letrozole. Half of each sample was snap frozen in liquid nitrogen and half was FFPE, RNA was extracted from both. Transcriptomic analyses were performed using 9 technologies: Illumina Beadarray, Affymetrix U133A, Affymetrix Clariom S, NanoString nCounter, AmpliSeq Transcriptome, Lexogen QuantSeq and IonXpress RNAseq, Tempo-Seq BioSpyder and Qiagen UPX3

Results: Success rates for generating robust expression profiles from FFPE tissues were 100% all except the Illumina BeadChip (22%) and AmpliSeq Transcriptome (83%), which varied by the age of tissue. With the total number and position of probes/primers/counts varying widely between approaches, in total 7305 genes were represented across all of the whole-genome technologies tested.

Clear batch effects were evident when comparing data from FF and FFPE tissues and when comparing between different technologies. Standard batch correction approaches such as XPN and ComBat minimised technical bias effect and increased the correlations between matched samples (FF and FFPE) to R>0.9, irrespective of the technology used.

When analysed by multi-dimensional scaling following batch correction, samples clustered by treatment time-point. When ranked by expression of 60 proliferation genes, reported by us to change with letrozole treatment, samples ordered again by time-point, consistent with our previous findings, and paired samples clustered together.

Conclusions:
- Robust gene expression profiles can be reliably generated from FFPE tissues and are comparable to those derived from FF tissue using established transcriptomic approaches.
- A range of new technologies are available for the study of FFPE tissues; these vary in cost, resolution and RNA requirements to fit the user's needs.
- Gene expression data from biologically similar studies, generated using different technologies, can be reliably integrated for robust meta-analysis, subject to appropriate batch correction analysis.
Comprehensive genomic profiling of carcinosarcomas of the breast

Laurie M Gay¹, Julia A Elvin¹, Jo-Anne Vergilio¹, J Keith Killian¹, Shakti Ramkissoon¹, Eric Severson¹, Sugganth Daniel¹, Amanda Hammerich¹, Ethan Sokol¹, Garrett Frampton¹, Jon Chung¹, Sally Trabucco¹, Siraj Ali¹, Prasanth Reddy¹, Alexa B Schrock¹, Vincent A Miller¹ and Jeffrey S Ross². ¹Foundation Medicine, Inc., Cambridge, MA and ²Upstate Medical University, Syracuse, NY.

Background:
Carcinosarcomas of the breast (BCSC) are exceptionally rare and the underlying genomic drivers are still being elucidated. Comprehensive genomic profiling (CGP) determines the tumor mutation burden (TMB) and identifies all four classes of genomic alterations (GA) that have potential to direct personalized treatment strategies.

Methods:
CGP by hybridization capture of exons from up to 315 cancer-related genes and select introns of 28 genes commonly rearranged in cancer was applied to ≥ 50ng of DNA extracted from 9 consecutive BCSC and sequenced to high, uniform median coverage (>500X). Tumor mutational burden (TMB) was determined on 1.1 Mbp of sequenced DNA and microsatellite instability (MSI) was determined by principal components analysis of optimized loci.

Results:
The 9 BCSC patients had a median age of 57 yrs (range 49-78 yrs). CGP was performed on the primary BCSC in 4 cases and on metastasis biopsies in 5 cases (4 lung and 1 lymph node). The mean GA/tumor was 6.6 and clinically relevant GA (CRGA)/tumor was 1.3. The most frequent non-CRGA were in TP53 (89%), MYC (56%) and LYN (40%). The most frequent CRGA were in PIK3CA (33%), NF1, BRCA1, PTEN, RICTOR, FGFR1, AKT2 and STK11 (all at 11%). The median TMB for all BCSC was 2.4 mut/Mb with 1 (11%) tumor with a TMB > 20 mut/Mb and 8 BCSC (88%) with TMB < 5 mut/Mb. Five of 5 BCSC (100%) that were available for MSI status testing were microsatellite stable.

Conclusions:
On CGP, BCSC feature a high frequency of GA, but only a modest frequency of CRGA and high TMB. However, when the CRGA and TMB positive cases are combined (77.8% overall in this series), the opportunity for personalized targeted and immunotherapies are significant. Thus, further investigation of precision therapies for BCSC in the clinical trial setting appear warranted.
Breast cancer is a heterogeneous disease and accumulating evidence suggests that treatment failure may be driven by intra-tumour heterogeneity (ITH). Utilising the current protocol for neoadjuvant (pre-surgery) chemotherapy (NAC) provides the opportunity to study molecular genetic changes between pre- and post-therapy by assessing pre-therapy biopsies and post-therapy surgical resections.

Whole exome sequencing was performed on matched pre- and post-treatment cancer cells from 6 patients with oestrogen receptor positive breast cancers that showed partial responses to the chemotherapeutic epirubicin. Data analysis was performed to determine differences in genetic aberrations between pre- and post-NAC, and in particular to identify evidence of consistent selection by therapy of aberrations that therefore may define chemotherapy resistance or sensitivity.

There were extensive differences in the range of genetic aberrations between pre- and post-NAC. 48 genes were identified for further study based on evidence of mutations conferring a selective advantage or disadvantage during chemotherapeutic response. The relevance of these was screened using siRNA knock-down and assessment of response to chemotherapeutic drug using cell viability assays in vitro. Two genes were taken forward. Potential loss-of-function mutations in the MUC17 gene were selected against during therapy in patients, and in accordance with this MUC17 knock-down was associated with increased sensitivity in vitro. Potential loss-of-function mutations in the PCNX1 gene were selected for during therapy in patients, and in accordance with this PCNX1 knock-down was associated with resistance. Further work was done to investigate mechanisms by which these genes modify cellular chemotherapy response, by examining drug loading and ABC transporter expression levels.

Data indicate that both genes impact on drug loading, potentially through modulating ABC transporter activities. Using available transcriptomic datasets, expression of neither gene correlated with breast cancer outcomes in mixed cohorts that received a wide-range of therapies, however, analysis of correlations between protein expression and outcomes specifically after chemotherapy are ongoing. We conclude that MUC17 and PCNX1 are potential markers of response to chemotherapy in breast cancer, and therapeutic modulation of their activities could enhance chemotherapy responses.
Druggable genomic landscape of primary and metastatic breast cancers

Sam (Qiancheng) Sun. 'Baylor College of Medicine, Houston, TX.

Background: Several studies (e.g. The Pan-Cancer Atlas) have examined the druggable genomic landscape of breast cancers and other malignancies using The Cancer Genome Atlas (TCGA). However, TCGA is representative of newly-diagnosed, treatment-naïve breast cancers, whereas genomic profiling is typically used to inform therapy for metastatic and/or pre-treated breast cancers. Here, we characterize the druggable genomic landscape of breast cancers using AACR Genomics Evidence Neoplasia Information Exchange (GENIE), a multi-institutional pragmatic cancer genomics registry.

Methods: We obtained mutation, copy-number amplification (CNA), and fusion data from GENIE, which contains de-identified genomic records from 4506 breast carcinoma and carcinoma-in-situ (CIS) tumors. We used Clinical Interpretation of Variants in Cancer (CIViC) to label the potential druggability of these mutations, CNAs, and fusions. Further, we plan to assess variations in the druggable genomic landscape of breast tumors as a function of tumor characteristics (e.g. histology, tumor mutation burden), patient characteristics (age, sex, ethnicity), and genomics assay characteristics (e.g. PCR vs. hybridization capture).

Results: In GENIE, we identified 19932 mutations, 9334 copy number amplifications (CNA), and 987 fusions in 4506 breast tumors. CNAs suggesting potential druggability were relatively common (e.g. ERBB2 amplifications in 9.9% of tumors), whereas fusions suggesting potential druggability were relatively rare (e.g. NTRK fusions in 0.1% of tumors). Mutations suggesting potential druggability were identified in ERBB2 (3.5% of tumors) and mismatch repair genes [MLH1, MSH2, MSH3, MSH6, PMS1, PMS2] (3.7% of tumors).

Conclusion: GENIE can be used to infer druggability across a cohort of breast tumors likely to be considered for approved systemic therapy at tertiary academic centers. This may inform use of genomic assays and/or design of clinical trials for patients with breast tumors.

*The author would like to acknowledge the American Association for Cancer Research and its financial and material support in the development of the AACR Project GENIE registry, as well as members of the consortium for their commitment to data sharing. Interpretations are the responsibility of study authors.
Towards a therapeutically relevant subtyping scheme for triple-negative breast cancer (TNBC), profiling results from A Randomized, TNBC Enrolling trial to confirm Molecular profiling Improves Survival (ARTEMIS)

Sahil Seth1, Lei Huo1, Gaiane Rauch1, Rosanna Lau1, Mike Gilcrease1, Beatriz Adrada1, Helen Piwnica-Worms1, William F Symmans1, Giulio Draetta1, Andrew P Futreal1, Stacy Moulder1 and Jeffrey T Chang2. 1MD Anderson Cancer Center, Houston, TX and 2UT Health McGovern Medical School, Houston, TX.

Triple-negative breast cancer is a highly diverse group of cancers, with poor prognosis, and currently, there are no targeted drugs available in the clinic. In TNBC around 50% percent of the patients respond to chemotherapy, while, the other 50% percent relapse with poor prognosis. There is a need to understand better the targetable mechanisms driving TNBC via integrative analysis of gene-expression, copy-number, and mutational data.

Samples from 220 triple-negative breast cancer (TNBC) pts treated with NACT were prioritized for transcriptomic and genomic profiling. Non-negative matrix factorization was used on array-based profiling to identify six robust (ARTEMIS) subtypes. Comparing ARTEMIS subtypes with Vanderbilt subtypes, revealed significant overlap with 4/6 clusters while identifying two new clusters. Logistic regression on ssGSEA scores vs. subtypes revealed several pathways, selectively enriched specific subtypes. CL1/IM (Immune subtype), was enriched in INFg and INFa, while CL2 (MYC/mTOR), showed enrichment of several proliferation-related pathways. In addition, LAR and M (Mesenchymal) pts formed overlapping clusters, using either method. Two new subtypes did not associate significantly with any of the previous subtypes. The majority of the tumors from the Vanderbilt BL2 and MSL were reclassified into a CL5 (ANGIO) cluster, which was enriched in angiogenesis geneset, including targetable genes like VEGF and FGFR. Also, an MYO (CL3) subtype was identified, with myogenesis-related genes. Of note, TIL (tumor infiltrating lymphocytes) and LAR quantification using IHC were associated with respective ARTEMIS subtypes. Finally, the IM subtype was significantly associated with higher rates of RCB 0-I and the M (CL4) subtype was associated with higher rates of RCB II-III, irrespective of the neoadjuvant treatment regimen.

ARTEMIS subtypes are a novel classification system for TNBC that is focused on therapeutic translation. Further, we show a possibility to classify previously un-classified (UNS) tumors, which will be validated using additional cohorts (TCGA/METABRIC).
Metaplastic breast carcinomas and uterine carcinosarcomas are histologically and genetically related

Arnaud Da Cruz Paula¹, David Brown¹, Felipe C Geyer¹, Evan Smith¹, Fresia Pareja¹, Anastasios D Papanastasiou¹, Nicola Fusco¹, Caterina Marchio², Edi Brogi¹, Hannah Y Wen¹, Anne Vincent-Salomon³, Larry Norton¹, Britta Weigelt¹ and Jorge S Reis-Filho¹. ¹Memorial Sloan Kettering Cancer Center, New York, NY; ²FPO-IRCCS Candiolo Cancer Institute, University of Turin, Turin, Italy and ³Institute Curie, Paris, France.

Introduction: Metaplastic breast carcinomas (MBCs) and uterine carcinosarcomas (UCSs) are histologically similar, being often characterized by an admixture of adenocarcinoma areas with areas displaying sarcomatoid differentiation. We sought to investigate whether their histologic similarities would be paralleled by similar patterns of genetic alterations, and to determine whether the different histologic components of MBCs and UCSs would be clonally related.

Methods: Whole exome sequencing (WES) data from 35 MBCs previously analyzed by our group and 57 UCSs from The Cancer Genome Atlas (TCGA) study were reanalyzed. Somatic single nucleotide variants were detected with MuTect and indels with Strelka, Varscan2, Scalpel and Lancet. Copy number alterations were inferred using FACETS and functional annotation of the non-synonymous somatic mutations, amplifications or homozygous deletions was performed. We further microdissected the histologically distinct components of 11 MBCs and six UCSs and subjected each component to WES. Clonal decomposition was performed using PyClone.

Results: The most frequent somatic mutations identified in MBCs were *TP53* (69%), *PIK3CA* (29%), *FAT3* (26%) and *PTEN* (14%), whereas the most frequently mutated genes in UCSs were *TP53* (84%), *FBXW7* (35%), *PIK3CA* (29%), *PTEN* (15%) and *PPP2R1A* (15%). MBCs displayed a significantly higher frequency of mutations targeting *FAT3* (26% vs 4%, *P* <0.01), *FAT1* (11% vs 0%, *P*<0.05) and *CHERP* (11% vs 0%, *P*<0.05) than UCSs. UCSs more frequently harbored mutations affecting *FBXW7* (35% vs 0%; *P*<0.01) and *PPP2R1A* (15% vs 0%, *P*<0.05) than MBCs. MBCs and UCSs displayed similar copy number alteration profiles, with frequent gains/amplification of 8q, 3q and 1q, and losses of 8p. Pathway analysis based on the genes targeted by somatic genetic alterations revealed that both MBCs and UCSs were underpinned by genetic alterations resulting in activation of similar pathways, including PI3K, p53, Wnt and Notch signaling. Analysis of the separate components of MBCs and UCSs revealed that the histologically distinct components of MBCs and UCSs are clonally-related, with a median of 71% (range 26%-93%) and 78% (range 30%-93%) of somatic mutations being shared by the distinct components in MBCs and UCSs, respectively. In MBCs, clonal *TP53, NOTCH3, KMT2D, FAT4* and *PIK3CA* mutations and several copy number alterations were shared by the histologically distinct components. Mutations private to each of the histologically distinct components included *PIK3R1, CHERP* and *MAPK14* mutations. The carcinomatous and sarcomatous components of UCSs shared clonal *TP53, PIK3CA, CDKN2A, ITGB7* and *FGFR2* mutations. Private *KMT2B* mutations were identified in the UCS carcinomatous components. PyClone analysis revealed that the clonally-related histologically distinct components of each case harbored intra-component genetic heterogeneity coupled with parallel evolution.

Conclusions: Our findings support the contention that UCSs constitute the uterine counterpart of MBCs due to their similar histology and patterns of genetic alterations affecting the same signaling pathways (i.e. TP53, PI3K, Wnt and Notch). In each MBC and UCS analyzed here, the histologically distinct components were found to be clonally related.
Molecular characterization of mucinous breast cancers

Christine Desmedt¹, Isabelle Veys¹, Bastien Nguyen¹, Sophia Leduc¹, Yacine Bareche¹, Samira Majjaj¹, Bram Boeckx², Diether Lambrechts² and Christos Sotiriou¹. ¹Institut Jules Bordet- Université Libre de Bruxelles, Brussels, Belgium and ²VIB-KU Leuven Center for Cancer Biology, Leuven, Belgium.

Introduction
Mucinous carcinoma, a special histological subtype of breast cancer (BC) which accounts for ~2% of all invasive breast tumors, is characterized by the presence of extracellular mucin, typically expresses the estrogen receptor (ER), and lacks HER2 amplification. The majority of patients with mucinous BC are older at diagnosis, rarely present axillary lymph node metastases, and are associated with a better prognosis as compared to invasive ductal cancer patients (IDC, formally referred to as “breast cancer of no special type”). So far, it is unknown what is driving the mucinous phenotype of these tumors. Here we interrogated the genomics, transcriptomics, immune infiltration and epigenetics profiles of these tumors, using a retrospective institutional series and a publicly available dataset.

Patients and methods
After central pathology review and DNA extraction, a total of 31 pure mucinous cases from Institut J. Bordet Biobank were included (referred to as IJB cohort). Tumor infiltrating lymphocytes (TILs) were assessed on hematoxylin and eosin (H&E). Low pass whole genome sequencing was conducted to assess ploidy and to detect copy number aberrations (CNAs). A second cohort was analyzed from a publicly available dataset (referred to as BRCA560 cohort), with available centrally reviewed histology subtyping and DNA methylation profiles (Nik-Zainal et al. Nature 2016). 207 ER+ primary BC, 14 of which were mucinous, had HumanMethylation450K methylation profiles. RNAseq was available for a subset of 145 cancers, 13 of which were mucinous. DNA methylation data was processed in R using the minfi package. Beta-values were normalized (preprocessQuantile) and dmpFinder was used to identify differentially methylated positions.

Results
In the IJB cohort, whole genome sequencing revealed that all but two tumors were diploid. The most frequently deleted cancer genes were RB1 (38.1%), CDH1 (23.8%), BRCA2 (38.1%), TP53 (23.8%), MAP2K4 (23.8%), EGFR (28.6%) and PGR (23.8%). In terms of amplifications, only ZNF217 (19.4%) and FGFR1/ZNF703 (9.5%) were observed. These mucinous tumors generally displayed low TIL levels (median=5%). In the BRCA560 cohort, there was no significant difference in the clinico-pathological features of ER+ IDC vs mucinous subtypes. At the genomic level, we identified a lower frequency of PIK3CA mutations as compared to ER+ IDC from the same cohort. At the DNA methylation level, we identified 8013 differentially methylated CpGs (q-val < .05) between IDC and mucinous tumors. The top differentially methylated CpG mapped to MUC2, an extracellular mucin. MUC2 was significantly demethylated in mucinous tumors as compared to IDC (q-val <.001). There was a negative association between methylation level of this CpG and MUC2 expression (rho = - 0.27, p< .001). Finally, MUC2 expression was significantly increased in mucinous tumors as compared to IDC (p< .001).

Conclusion
To the best of our knowledge, this study is the first to report hypomethylation of MUC2 in mucinous carcinoma of the breast, as a possible mechanism of extracellular production of mucin in these tumors. Furthermore, it highlights the minor immune infiltration of these cancers, possibly prevented by the mucin, and sheds light on the few genomic alterations present in these overall stable cancer genomes.
Refined classification of triple negative breast cancers (TNBC) in women of african descent using the PAM50 NanoString platform

Ashley Hardeman¹, Tatyana Grushko¹, Wendy Clayton¹, Ian Hurley¹, Galina Khramtsova¹, Joel Parker², Charles Perou² and Olufunmilayo Olopade¹. ¹University of Chicago Medical Center, Chicago, IL and ²University of North Carolina Chapel Hill, Chapel Hill, NC.

**Introduction:** Wide-scale genomic studies of African and African American breast tumors are limited. In order to identify the most aggressive forms of breast cancer and associated molecular pathways within women of African descent we used the PAM50 NanoString platform to reclassify Nigerian (NG) and African American (AA) tumors previously subtyped by IHC.

**Methods:** Our study includes formalin-fixed, paraffin embedded (FFPE) tumors from 295 NG, 92 AA, and 74 Caucasian American (CA) breast cancer patients. These tumors were verified by two independent pathologists at our institution. RNAs were isolated from our FFPE tumors using the Roche High Pure Paraffin Kit (Roche) and assayed on NanoString nCounter. PAM50 intrinsic subtyping of 50 genes and gene-expression of an additional 60 cancer related genes were performed on NanoString's Digital Analyzer. The data was evaluated using Microsoft Excel and R statistical software. All study samples were previously annotated and subtyped by the ER/PR/HER2 IHC classifier.

**Results:** Within our NG cohort, the most prevalent subtype was basal-like (36%), followed by luminal A (24%), HER2-enriched (18%), normal-like (13%), and luminal B (9%). In our AA cohort, luminal A was the most prevalent subtype (40%) followed by basal-like (36%), luminal B (12%), normal-like (9%), and HER2-enriched (3%). Similarly, in our CA cohort, luminal A was the most prevalent subtype (54%) followed by basal-like (24%), luminal B (9%), normal-like (7%), and HER2-enriched (5%). Both NG and AA cohort have significantly more basal-like tumors compared to the CA cohort. We verified our subtype calls through ER/PR/HER2 IHC classifier and observed that 90% of our calls were concordant with IHC, suggesting that the NanoString platform can correctly classify our samples. Analysis of 110 genes across the NG cohort showed that approximately 20% of our samples highly expressed a majority of these 110 genes. These samples were classified as “normal-like” by the PAM50 classifier. We reconfirmed the morphology of these tumors to ensure this data was not due to technical error, suggesting these “normal-like” NG tumors may represent a unique class of tumors unclassifiable by the current PAM50 classifier. Lastly, risk of recurrence (ROR) scores based off of the sample’s subtype and proliferation scores across all cohorts were examined. Basal-like tumors in the CA had the highest proportion of high ROR scores (ROR >50), followed by AA, and NG. However, luminal A tumors from the NG cohort had a greater proportion of tumors with a medium ROR score (20<ROR<50) compared to luminal A tumors from CA cohort, which predominantly have low ROR scores (ROR<20).

**Conclusion:** Gene expression results of our PAM50 classifier and additional 60 cancer-related genes suggest a potential unique subtype existing in the NG population.
Evidence for tumor heterogeneity and clonal evolution during invasive progression in breast cancer

Yuantong Ding¹, Jeffery Marks¹, Lorraine King¹, Timothy Hardman¹, Allison Hall¹, Diego Mallo², Allen Rodrigo³, Carlo Maley² and Shelley Hwang¹. ¹Duke University Medical School, Durham, NC; ²Arizona State University, Tempe, AZ and ³Australian National University, Research School of Biology, Acton ACT, Australia.

Purpose: Intratumoral heterogeneity is well recognized to be an important driver of treatment resistance and metastasis. We undertook this N of three study to measure the degree of heterogeneity in three large preinvasive lesions, all with invasive components to determine the relationship between tumor heterogeneity, spatial distribution, clonal evolution, and invasive progression.

Methods: We identified patients A, B, C with extensive DCIS measuring 7.5 cm, 6 cm, and 7 cm associated with 0.3 cm, 3.8 cm, and 3.4 cm of an invasive component and 0, 7 and 1 positive lymph node, respectively. We sequenced the tumor sample for Case A from 32 unique blocks with precise geospatial localization; invasive cancer was identified in 3 of 32 blocks. Case B had 26 blocks sequenced with invasive cancer in 13 of 26 blocks. Case C had 23 blocks sequenced with invasive in 11 of 23 blocks. For germline reference, we sequenced DNA from an uninvolved tissue from each case. NGS libraries were made from FFPE derived DNA (20-40ng) for full exome sequencing. Variant calling was performed by GATK HaplotypeCaller, Platypus and MuTect. Identified somatic mutations were annotated with Oncotator and pathway enrichment analysis was performed with Bioconductor. To investigate the clonal evolution and progression history, phylogenetic trees were constructed in R and sub-clonal analysis was performed with Treeomics.

Results: The sequence data was analyzed with Platypus, MuTect and GATK HaplotypeCaller. The somatic mutation sites were concatenated into one sequence for each sample. Both neighbor-joining trees and maximum parsimony trees were built for each case. Phylogenetic analysis and sub-clonal analysis support the multi-clonal invasion model of invasive cells, in which invasive cancer can evolve from multiple clades, either early or late in the evolutionary history, independently. Dense sampling allowed reconstruction of the temporal order of mutations that accumulated in the cell lineage of the invasive cancers. Furthermore, phylogeny and sub-clone spatial analysis revealed that distant regions may be closely genetically related and showed a weak spatial sub-clone clustering pattern, which is consistent with the predictions of Big Bang model. For driver genes, we find that except for SETD2 in Case B, the majority of driver gene mutations are sub-clonal. Somatic mutations on ATP-binding cassette (ABC) transporter pathway was found in all cases.

Conclusions: Extensive sampling and sequencing of tumors yields important insights about tumor heterogeneity and tumor progression of DCIS to invasive cancer. Variable invasive propensity was identified, with foci of invasion were geospatially associated with preinvasive regions of progressively higher mutational load.
Multi-omic predictor of rapid and late relapse in primary triple negative breast cancer

Yiqing Zhang1, William Nock1, Sarah Asad1, Elizabeth Adams1, Jasneet Singh1, Adrienne Damicis1, Maryam B Lustberg2, Anne Noonan2, Raquel Reinbolt2, Sagar Sardesai2, Jeffrey VanDeusen2, Robert Wesolowski2, Nicole Williams2, Bhuvaneswari Ramaswamy2 and Daniel G Stover1. 1Ohio State University Comprehensive Cancer Center, Columbus, OH and 2Ohio State University Stefanie Spielman Comprehensive Breast Center, Columbus, OH.

Background: Triple-negative breast cancer (TNBC) is a heterogeneous disease. Clinically, we observe three distinct TNBC outcomes: 1) rapid relapse (rrTNBC) characterized by aggressive drug resistant disease; 2) late relapse (lrTNBC) characterized by indolent or treatment responsive disease; and 3) no relapse (NoRTNBC). We hypothesized that distinct clinical and genomic features of primary tumors define rapid versus late relapse in TNBC.

Approach: Using three publicly-available datasets (METABRIC, TCGA, and a prior gene expression meta-analysis), we identified 455 patients diagnosed with primary TNBC with adequate follow-up to be characterized as rrTNBC (relapse or death within 2 years of diagnosis), lrTNBC (relapse or death more than 2 years after diagnosis), or NoRTNBC (no relapse/death with at least 5 years follow-up). We compiled basic clinical (n=455 patients) and primary tumor multi-omic data, including whole transcriptome (n=455), whole genome copy number (n=317), and mutation data for 171 cancer-related genes (n=317). We evaluated intrinsic subtypes (PAM50, TNBCtype), 125 gene expression signatures, CIBERSORT immune subsets, copy number, and mutation frequency.

Results: We first evaluated patients with relapse (rrTNBC+lrTNBC) vs. NoRTNBC. There was no significant difference in age, grade, stage at diagnosis, or PAM50 or TNBC subtype proportion between relapse and NoRTNBC. Among 125 expression signatures, five immune signatures were significantly higher in NoRTNBCs (FDR p<0.05) suggesting increased immune activity in patients who do not relapse. Using CIBERSORT inferred immune subsets, anti-tumor CD8 T-cell, M1 macrophage, and gamma-delta T-cell subsets were all highly correlated to these immune signatures (all Pearson’s r >= 0.3, all p<1.2e-8). Among genomic features, patients who relapsed were significantly more likely to harbor a mutation in PIK3CA (Fisher exact FDR p=0.02) but there was no significant difference in tumor mutation burden or percent genome altered (Student’s t-test p=0.83 and p=0.99, respectively). We then evaluated primary TNBC genomic data in patients who ultimately developed rapid vs. late relapse. Patients with rrTNBC were more likely to be higher stage (p<0.0001) while lrTNBC were more likely to be non-basal PAM50 subtype (p=0.03). Among 11 significantly altered gene expression signatures (FDR p<0.05), 6 estrogen/luminal signatures were significantly higher in lrTNBC. Mutations in DNAH11 and PIK3CA were more common in lrTNBC (Fisher exact FDR p=0.04 and p=0.05, respectively) but there were no significant differences in tumor mutation burden or copy number burden (Student’s t-test p=0.13 and p=0.45, respectively). Using 317 cases with full genomic data divided into training and validation datasets, we will report a comparison of machine learning models for predicting relapse versus no relapse and rapid versus late relapse.

Conclusions: Primary TNBC tumors destined for rapid, late, or no relapse reflect distinct genomic features. Anti-tumor immune signatures and subsets are enriched in patients who do not relapse yet no difference in mutational or copy number burden. Relative to rapid relapse TNBCs, late relapse TNBCs are enriched for non-basal tumors, estrogen/luminal expression signatures, and mutations in DNAH11 and PIK3CA.
Tumour clonality in paired invasive breast carcinomas

Jana Biermann¹, Toshima Z Parris¹, Szilárd Nemes², Anna Danielsson¹, Hanna Engqvist¹, Elisabeth Werner Rönnerman¹,³, Eva Forssell-Aronsson¹, Anikó Kovács³, Per Karlsson¹ and Khalil Helou¹. ¹Institute of Clinical Sciences, Sahlgrenska Cancer Center, Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden; ²Swedish Hip Arthroplasty Register, Gothenburg, Sweden and ³Sahlgrenska University Hospital, Gothenburg, Sweden.

Background: Multiple invasive breast tumours may represent either independent primary tumours or clonal recurrences of the first tumour, where the same progenitor cell gives rise to all of the detected tumours. Consequently, the driver events for the progenitor cell need to have been identical in early tumour development. Molecular classification of tumour clonality is not currently evaluated in multiple invasive breast carcinomas, despite evidence suggesting common clonal origins. Furthermore, there is no consensus about which type of biological data (e.g. copy number, mutation, histology) and especially which statistical method is most suitable to distinguish clonal recurrences from independent primary tumours.

Methods: Thirty-seven invasive breast tumour pairs were stratified by laterality (bilateral vs. ipsilateral) and the time interval between the diagnoses of the first and second tumours (synchronous vs. metachronous). Both tumours from the same patient were analysed by integrating clinical characteristics (n = 37), DNA copy number (n = 37), DNA methylation (n = 8), gene expression microarray (n = 7), RNA sequencing (n = 3), and SNP genotyping data (n = 3). Different statistical methods, e.g. the diagnostic similarity index (SI), distance measure, shared segment analysis etc., were used to classify the tumours from the same patient as clonally related recurrences or independent primary tumours.

Results: The SI applied on DNA copy numbers derived from aCGH (array comparative genomic hybridization) data was determined as the strongest indicator of clonal relatedness as it showed the highest concordance with all other methods. The distance measure was the most conservative method and the shared segment analysis most liberal. Concordant evidence for tumour clonality was found in 46% (17/37) of the patients. Notably, no significant association was found between the clinical characteristics and molecular tumour features.

Conclusions: A more accurate classification of clonal relatedness between multiple breast tumours may help to mitigate treatment failure and relapse by integrating tumour-associated molecular features, clinical parameters, and statistical methods. In cases of extremely similar or different tumour pairs, the results showed consistency regardless of the method used. The SI can be easily integrated into clinical routine using FFPE samples to obtain copy number data. However, clinical guidelines with exact thresholds need to be defined to standardize clonality testing in a routine diagnostic setting.
Triple negative breast cancer subtyping by means of integrated transcriptome and proteome analyses

Mario Campone1, Catherine Guette2, Hamza Lasla3, Wilfried Gouraud4,5, Catherine Guérin-Charbonnel3,4,5 and Pascal Jézéquel3,4,5. 1Oncologie Médicale, Institut de Cancérologie de l'Ouest - René Gauducheau, Saint Herblain, France; 2Institut de Cancérologie de l'Ouest - Paul Papin, INSERM U892, CNRS 6299, Angers, France; 3Unité de Bioinformatique, Institut de Cancérologie de l'Ouest, Saint Herblain, France; 4Unité Mixte de Génomique du Cancer, Institut de Cancérologie de l'Ouest - René Gauducheau, Saint Herblain, France and 5INSERM U1232, IRS-UN, Nantes, France.

Background: Heterogeneity and lack of targeted therapies represent the two main impediments to precision treatment of triple-negative breast cancer (TNBC) and therefore, molecular subtyping and identification of therapeutic pathways are required to optimize medical care. The aim of the present work was to confirm unsupervised analysis of TNBC transcriptomic data by means of proteomics.

Methods: Transcriptome and proteome of 83 TNBC macrodissected tumors were screened in parallel. These patients were described in a previous study [Jézéquel, et al., Breast Cancer research (2015) 17, 43). Transcriptome screening was performed using Affymetrix Human Genome U133 Plus 2.0 Arrays (AffymetrixÒ, Santa Clara, CA). Proteome profiling was performed by means of iTRAQ-OFFGEL-LC-MS/MS approach [Campone, et al, Mol Cell Proteomics (2015) 14, 2936-2946].

Results: Unsupervised analysis of transcriptomic data identified three molecular clusters within TNBC: one molecular apocrine (C1: 20%) and two basal-like-enriched (C2: 47% and C3: 33%). C2 presented pro-tumorigenic immune response and C3 exhibited adaptive immune response.

iTRAQ-OFFGEL-LC-MS/MS screening identified 366 out of 1,929 unique proteins, which were quantified in at least 70% of TNBC tumors and therefore could be used for analysis. Principal component analysis (PCA) with projection of 83 TNBC onto the first principal plane showed inhomogeneous distribution: one largest group (n = 77) and two outlier groups composed of three tumors, which have been eliminated for the rest of the work. In order to look for the existence of a partition of 77 TNBC cohort based on proteomics data, we performed clustering analysis using fuzzy clustering. Gap statistic was used to estimate the optimal number of clusters. This number was equal to one, whatever the metric. PCA and estimation of the number of clusters results lead us to conclude that iTRAQ-OFFGEL-LC-MS/MS data could not be used alone to subtype our 77 TNBC cohort most probably due to insufficient information content of proteomics matrix.

TNBC cluster assignment, based on transcriptomics was applied to these tumors. Sixty-two out 366 ANOVA analyses were significant between the three clusters (p < 0.05). Twenty-two differentially expressed proteins between C1, C2 and C3 belonged to biological categories, which characterized these TNBC clusters

Table 1. Proteins found differentially expressed between TNBC cluster defined by means of transcriptomics

Gene Ontology enrichment analysis based on the set of proteins highly expressed in C2 compared to C1 and C3 (n = 21) displayed enrichment in genes coding for protein involved in extracellular matrix, wound response and RNA splicing.

Conclusion: Although iTRAQ-OFFGEL-LC-MS/MS screening did not contain enough information for cluster identification, 22
proteins, which were differentially expressed between the three clusters corroborate transcriptomic subtyping of TNBC.
Identification of luminal A-like subgroup among ER+/PR+/HER2+ breast cancers and its clinical implications

Shen Zhao\textsuperscript{1,2}, Xi Jin\textsuperscript{1,2}, Yi-Zhou Jiang\textsuperscript{1,2} and Zhi-Ming Shao\textsuperscript{1,2,3}. \textsuperscript{1}Fudan University Shanghai Cancer Center, Shanghai, China; \textsuperscript{2}Shanghai Medical College, Fudan University, Shanghai, China and \textsuperscript{3}Institutes of Biomedical Sciences, Fudan University, Shanghai, China.

\textbf{Background} Triple positive breast cancers (TPBCs), i.e. estrogen receptor-positive (ER+)/ progesterone receptor-positive (PR+)/ human epidermal growth factor receptor 2-positive (HER2+) breast cancers, constitute a therapeutic challenge due to the functional crosstalk between the hormone receptors and HER2 pathways. The intrinsic molecular subtyping of TPBCs has rarely been studied and may have implications for the prognostic evaluation and therapeutic decision-making.

\textbf{Methods} Our study included four cohorts of patients with TPBC. The first one consisted of 82 patients from The Cancer Genome Atlas (TCGA). The second and third ones were from two publicly available microarray datasets (GSE2603 and GSE2109) and included 37 and 30 patients respectively. The forth one comprised 165 patients from Fudan University Shanghai Cancer Center. First, we examined the PAM50 intrinsic subtypes of TPBCs in the first three cohorts. Then, we tried to find several differentially expressed genes (DEGs) between luminal A and the other subtypes. In cohort 1, we identified DEGs using LIMMA. In cohort 2 and 3, we further filtered and validated them using Wilcoxon's rank sum test. We also performed Receiver operating characteristic analyses to evaluate the accuracy of candidate DEGs in identifying TPBCs of luminal A subtype and determined the top 3 DEGs according to the area under the curve. Finally, in cohort 4, we detected the expression of these 3 genes by immunohistochemical (IHC) staining of tissue sections, defined a group of luminal A-like TPBCs and examined the prognosis and effect of adjuvant trastuzumab for them.

\textbf{Results} The distribution of PAM50 intrinsic subtypes of TPBCs was shown as follows.

The three genes that exhibited the highest accuracy in identifying TPBCs of luminal A subtype were STC2, BCL2 (highly expressed in luminal A subtype) and MKI67 (lowly expressed in luminal A subtype). In cohort 4, we defined a group of luminal A-like TPBCs with low expression of MKI67 as well as high expression of STC2 and/or BCL2. Compared with patients with non-luminal A-like TPBC (n = 110), those with luminal A-like TPBC (n = 55) had better disease-free survival (DFS) in both univariate (Log-rank $P = 0.029$) and multivariate analyses (hazard ratio = 0.25, $P = 0.025$). In the group with non-luminal A-like TPBCs, patients treated with trastuzumab (n = 67) showed better DFS than those not treated with it (n = 43) (Log-rank $P = 0.019$), while in the group with luminal A-like TPBCs, there is no difference in DFS between patients treated with trastuzumab (n = 22) and those not treated with it (n = 33) (Log-rank $P = 0.993$).

\textbf{Conclusions} TPBCs are heterogeneous in terms of intrinsic molecular subtype. Evaluating the expression of STC2, BCL2 and MKI67 by IHC staining can help us to conveniently identify a group of luminal A-like TPBCs. Patients with this group of TPBCs have relatively good prognosis and may only gain limited benefit from adjuvant trastuzumab.
Characteristics, outcomes and prognostic factors of luminal androgen receptor (LAR) triple-negative breast cancer (TNBC)

Roberto A Leon-Ferre¹, Mei-Yin Polley¹, Heshan Liu¹, Krishna R Kalari¹, Judy C Boughey¹, Minetta C Liu¹, Victoria Cafourek¹, Vivian Negron¹, James N Ingle¹, Kevin J Thompson¹, Xiaojia Tang¹, Poulami Barman¹, Erin Carlson¹, Daniel W Visscher¹, Jodi C Carter¹, Fergus J Couch¹, and Matthew P Goetz¹. ¹Mayo Clinic, Rochester, MN.

Background: The LAR subtype is a genomically distinct subset of TNBC. Using a large cohort of non-metastatic TNBC patients (pts) with long term follow-up, we sought to further characterize the clinicopathologic features and outcomes of LAR vs non-LAR TNBC.

Methods: From a cohort of 9982 women with surgically-treated non-metastatic breast cancer, 605 met criteria for TNBC (ER/PR<1% and HER2-negative) by central pathology. RNA extracted from 304 FFPE tumor specimens using the HighPure RNA extraction kit was subjected to TruSeq RNA Access library preparation and sequencing on a HiSeq2500. Adequate RNA was available for 283 pts. Tumors were classified as LAR or non-LAR using a shrunken centroid model, CABAL (Clustering Among Basal and Luminal androgen receptor). In addition to previously described analyses [Leon-Ferre et al, Breast Cancer Res Treat 2017], immunohistochemical (IHC) androgen receptor (AR) staining was performed and the impact of various parameters on invasive disease-free survival (IDFS) and overall survival (OS) was assessed using Cox proportional hazards models.

Results: 58 (20%) tumors were classified as LAR and 225 (80%) as non-LAR. Compared to non-LAR, LAR pts were older (mean age 65 vs 54) and more often postmenopausal (79%vs53%), both p=0.01. Apocrine histology was more common among LAR tumors (21%vs0%), which were also lower grade (grade3: 69%vs95%) and had lower Ki-67 (Ki-67>15%: 64%vs82%), all p<0.01. Additionally, LAR tumors had lower median stromal tumor infiltrating lymphocytes (TILs, 20%vs25%) and were less frequently lymphocyte-predominant [≥50% stromal or intratumoral TILs (19%vs32%)], although neither reached statistical significance. AR IHC was available for 223 of 283 tumors. Median AR IHC score in LAR was 65% (range 0-100%) vs 0% (range 0-90%) in non-LAR. T/N stage, surgery type, and receipt of adjuvant chemotherapy (AdjCT) or radiotherapy were similar between LAR and non-LAR. LAR pts had shorter IDFS and OS compared to non-LAR (5.6 vs 11.8 yrs and 10.8 vs 20.8 yrs, respectively), although this did not reach statistical significance. Test of proportional hazard assumption was not significant for IDFS or OS (p = 0.30 and 0.09). IDFS estimates were numerically higher in LAR vs non-LAR (80.2%vs70.5%,p = 0.92) at 3yrs post-diagnosis; whereas the opposite was true (40.9%vs55.6%,p = 0.07) after 10yrs. OS estimates at 3 and 5yrs were similar between LAR and non-LAR, but at 10yrs OS was inferior in LAR (40.9%vs66.4%,p = 0.24). In a univariate analysis including both LAR and non-LAR, older age, higher N stage, lower TILs and absence of AdjCT were associated with poorer IDFS and OS. In a multivariate analysis, higher N stage and absence of AdjCT remained associated with both poorer IDFS and OS; while lower stromal TILs were associated with poorer IDFS (p=0.01), and with a trend towards poorer OS (p=0.07).

Conclusions: LAR TNBCs occurred in older women, were lower grade, and had lower TIL density than non-LAR tumors. While significant differences in IDFS or OS were not demonstrated, LAR pts exhibited a numerically lower risk of a disease event at 3yrs, but higher risk by 10yrs compared to non-LAR pts. In the entire cohort, higher N stage, absence of AdjCT and lower TILs were independently associated with poorer outcomes.
Dissecting the heterogeneity of metaplastic breast cancer: A morphological, immunohistochemical and genomic analysis of a large cohort

Amy E McCart Reed¹, Emarene Kalaw¹, Katia Nones², Mark Bettington¹, Malcolm Lim¹, James Bennett¹,³, Kate Johnstone¹,³, Jamie R Kutasovic¹, Stephen Kazakoff², Qinying C Xu², Jodi M Saunus¹, Lynne E Reid¹, Debra Black¹, Colleen Niland¹, Kaltin Ferguson¹, Irma Gresshoff¹, Ashwini Raghavendra¹, John C Liu¹,³, Lauren Kalinowski¹,³, Andrew S Reid¹,³, Morgan Davidson¹,³, John V Pearson², Rin Yamaguchi⁴, Gavin Harris⁵, Gary Tse⁶, David Papadimos⁷, Rajadurai Pathmanathan⁸, Nirmala Pathmanathan⁹, Puay Hoon Tan¹⁰, Stephen Fox¹¹, Sandra O'Toole¹², Nicola Waddell¹, Peter T Simpson¹ and Sunil R Lakhani¹,³.

Although rare, Metaplastic Breast Carcinomas (MBC) account for significant global breast cancer mortality. This subgroup is extremely heterogeneous and by definition exhibits metaplastic change to squamous and/or mesenchymal elements, including but not limited to spindle, squamous, chondroid, osseous and rhabdomyoid elements. The WHO working group recognizes that the current classification is inadequate and in the interim, has suggested a purely descriptive classification. The mixed epithelial-mesenchymal morphology has led to speculation that MBC represent 'stem cell tumours'; in support of this, MBC have been shown to have a CD44⁺/CD24⁻/low phenotype. Clinically, patients present with tumours that are larger (higher stage), have increased likelihood of distant metastases at presentation and overall, have a reduced 5-year survival rate compared to Invasive Carcinoma-NST. Hence, this is a unique subtype with poor outcome but without a robust classification or understanding of the biology to aid clinical management. We present a detailed morphological, immunohistochemical and genomic analysis of a large series of MBC (n=347), as amassed through the Asia-Pacific MBC consortium. We consider our morphological dissection using the WHO subtyping guidelines and show that an increasing number of phenotypes in a mixed MBC (classified as WHO_1) significantly associates with a poor prognosis. Immunohistochemical analysis showed that a pure spindle (WHO_5) is significantly less likely to express vimentin, CK5/6, CK14, and CK19 than a mixed WHO_1 with spindle features. Similarly, a WHO_1 with chondroid features is less likely to express EGFR than WHO_1 with chondroid features and rhabdoid or osseous differentiation. Across the cohort, positivity for the AE1/3 antibody and a lack of EGFR expression both significantly associate with a better outcome. We report no significant association between patient age at diagnosis and breast cancer specific survival, nor between age and specific WHO MBC subtypes. We report a significant association between WHO_1 types and increasing tumour grade, and also between tumour size and grade, with tumour size being a highly significant prognostic indicator in this cohort. Our exome sequencing confirms a significant enrichment for TP53 and PTEN mutations in MBC, and intriguingly for concurrent mutations of TP53, PTEN and PIK3CA. A novel enrichment for NF1 mutations is also presented. In summary, we provide a thorough assessment of a large cohort of MBC, including morphology, survival, IHC and exome sequencing, and present our analysis contextualized by the WHO guidelines, extending the existing knowledge base of this rare tumour type.
Transient state change, but not permanent subtype change, after HER2-targeted therapy for HER2-positive breast cancer

Maki Tanioka1, Joel S Parker2, Lynn N Henry3, Sara Tolaney4, Chau Dang5, Ian E Krop4, Lyndsay Harris6, Mei Polley7, Donald A Berry8, Eric P Winer3, Lisa A Carey1 and Charles M Perou1. 1UNC Lineberger Comprehensive Cancer Center, Chapel Hill, NC; 2University of North Carolina, Chapel Hill; 3University of Utah, Salt Lake City; 4Dana-Farber/Partners CancerCare, Boston; 5Memorial Sloan Kettering Cancer Center, New York; 6National Cancer Institute, Washington; 7Alliance Statistics and Data Center, Mayo Clinic, Rochester and 8Alliance Statistics and Data Center, M.D. Anderson, Houston.

Background: In CALGB 40601 (Alliance, NCT00770809), a neoadjuvant phase III trial of paclitaxel and trastuzumab with or without lapatinib for 12 weeks for patients with HER2-positive breast cancer, 33% of pretreatment tumors were Luminal A subtype, however, 69% of post-treatment samples with residual disease were Luminal A subtype. In addition, 71% of Luminal B (12/17) and 67% of HER2-Enriched (6/9) tumors changed into Luminal A, while 80% of Luminal A (20/24) remained Luminal A (Carey et al. J Clin Oncol. 2016). It is not known whether this shift to Luminal A was transient or permanent.

Methods: We selected matched pairs of pre- and post-treatment 40601 samples with tumor purity >10% based upon DNA analyses to ensure all samples contained tumor. PAM50 intrinsic subtyping was applied to the 40601 samples gene expression data using a two-step normalization process based on The Genome Cancer Atlas, and PAM50 training set. In addition, a HER2-enriched expression subtype patient-derived xenograft (PDX) tumor called WHIM35, was studied and was either untreated (n=10), or treated with lapatinib at 220 mg/kg for 1 week (wk) (n=5), for 2 wks (n=8), or for 3 wks (n=4). We also treated WHIM35 tumors with lapatinib for 2 wks (on) and then removed lapatinib for 1 wk (off) (n=6), or for 2 wks on and 2-4 wk off (n=6), and finally for 3 wks on, and 1 wk off (n=3). PAM50 intrinsic subtyping was applied to the PDX gene expression data and subtype assessed as well as a genomic-based proliferation score. ANOVA p-values were calculated by comparing median values across all gene signature or correlation scores.

Results: We found 10 pairs of 40601 samples that kept their tumor purity values, however, their subtype changed to Luminal A after treatment (i.e., in the residual disease), and in these cases no minor tumor subclone became a dominant clone in the post treatment sample. Pretreatment subtypes were 6 Luminal B, 3 Luminal A, and 1 HER2-enriched. The tumor purity values did not change after the treatments, but correlation to Luminal A was significantly higher (p=0.01), while correlation to HER2-enriched (p=0.004) and proliferation signature scores (p=0.003) were significantly lower in the post-treatment samples. Among the WHIM35 PDX tumors, one sample changed its subtype from HER2-enriched to Luminal A after the lapatinib treatment and the rest remained HER2-enriched, suggesting environmental differences between patient samples and the PDX model. However, correlation to Luminal A was significantly higher in all lapatinib treated WHIM35 samples (p=8.3e-12), and notably went back to the initial low levels just one week after removing lapatinib. Likewise, correlation to HER2-enriched (p=1.2e-10) and proliferation signature scores (p=6.2e-12) also got lower while treated with lapatinib, but went back to the initial levels after cessation of treatment.

Conclusions: Our findings suggest that the apparent subtype change during HER2-targeting therapy is not permanent, but is more likely a transient state change from a HER2-enriched subtype into a more Luminal A-like state. When we plan additional treatment strategies using residual disease phenotypes, it may not be clear what is the true subtype of the sample due to this inherent plasticity.
High APOBEC3C-H gene expression in tumor associates with better survival in breast cancer

Mariko Asaoka¹,², Santosh K Patnaik², Eriko Katsuta³, Tsutomu Kawaguchi³, Takashi Ishikawa¹ and Kazuaki Takabe². ¹Tokyo Medical University Hospital, Tokyo, Japan; ²Roswell Park Comprehensive Cancer Center, Buffalo, NY and ³Kyoto Prefectural University of Medicine, Kyoto, Japan.

Background
APOBEC3 (A3) enzymes are strong mutagenic factors. A3B has been well described as an active mutator in breast cancer, whereas the roles of the other APOBEC3s (A3A, C-H) are unclear. While mutations may directly drive cancer progression, they can indirectly suppress cancer growth by generating neoantigens. To elucidate this, we comprehensively analyzed all APOBEC3s for their association with mutations and immune activity in breast cancer.

Methods
RNA seq.-based gene expression data for 1091 primary carcinomas and 113 adjacent normal tissues was from TCGA. Patients were divided into high and low groups by top and bottom gene expression terciles. Tumor immune features like cytolytic activity, T cell receptor (TCR) diversity, and cell fractions were quantified from gene expression data. Data for some of these features, mutation-related aspects, and survival outcomes were obtained from the Pan-Cancer Atlas. Gene expression data for 55 breast cancer cell-lines was from Cancer Cell Line Enycolpedia. Cox regression and Spearman methods were respectively used for survival and correlation analyses. Welch's t test was used for group comparison. P <0.05 was deemed significant. Hallmark gene-sets were used for enrichment analysis with recommended 25% FDR.

Results
A3B and A3C together represented most (91%) of A3 gene expression in breast cancer cell-lines. In TCGA patients, expression of only A3B was increased by 4.5x in tumors compared to normal tissue, whereas levels for other A3 genes were unchanged. Surprisingly, tumor A3B or A3A levels had no significant association with overall (OS) or disease-specific survival (DSS), whereas for each of A3C-H, higher expression was significantly associated with improved OS (hazard ratios of 0.45-0.66) or DSS (0.43-0.61). The prognostic benefit of high A3C-H expression was also seen in survival analyses of two meta-datasets of microarray-based gene expression (KMPlot and SurvExpress). A3A and A3B levels correlated with both mutation burden and neoantigen load (Spearman ρ = 0.28-0.34), which respectively were 2.0-2.9x higher in high compared to low expressors. But there was no association of expression with mutation burden or neoantigen load for A3C-H. On the other hand, A3C-H levels correlated positively with tumor leukocyte fraction (ρ = 0.29-0.70) and its lymphocyte subset (ρ = 0.20-0.50), whereas the correlation was poor for A3B (ρ = 0.10 & -0.01 respectively). Expression of genes of immune function like interferon response and complement activation was enriched in high A3C-H expressors. It was not so for A3B, for which enrichment was instead observed for cell proliferation. Both CD4 and CD8 T cells were significantly more (2.3-4.0x & 2.1-5.4x resp.), and TCR diversity significantly higher (1.3-2.1x) in A3C-H high expressors. Concordantly, for each of A3C-H, expression correlated with tumor immune cytolytic activity (ρ = 0.31-0.79), which was increased 3.1-7.9x in high compared to low expressors.

Conclusions
These findings suggest that in spite of A3C-H being known as DNA mutators, an increase in their expression confers a survival benefit in breast cancer. Their increased expression likely reflects a heightened anti-cancer immune response, and may be useful for disease prognosis and monitoring immunotherapy.
A novel integrated, clinical-pathologic and genomic classification method segregates early from late relapsing invasive ductal luminal breast cancers (IDLBC) of the METABRIC study

Wolfgang Hackl¹, Dominique Pinet² and David Demanse². ¹Novartis Institutes of Biomedical Research, Basel, Switzerland and ²Novartis Pharma AG, Basel, Switzerland.

Background and Objectives
Endocrine therapy is one of the most effective anti-cancer treatments for HR-positive breast cancers. However, in a significant proportion of patients the disease will relapse irrespective of the treatment modality (SERM, SERD, AI). Despite the progress made with multigene signatures for molecular classification of luminal breast cancers, predicting sensitivity towards endocrine modalities remains challenging. With the help of invasive ductal luminal breast cancers (IDLBC) from the METABRIC study we have developed an integrated clinical-pathologic and genomic classification method, identifying three distinct groups (IDLBC1, -2 and -3) [1, 2]. The 3 groups differ by DNA damage load, predominant lesion type, characteristic lesion patterns and oncogenic driver mechanisms [1, 3]. Here we present characteristic gene expression profiles of IDLBCs and discuss their biologic and clinical implications.

Methods
Gene expression profiles based on cDNA microarray data of 1.104 IDLBCs on the METABRIC study were examined (EGAS00000000083) [3]. To identify differentially expressed genes across IDLBC1-3 groups (52%, 23%, 25%), we compiled a gene list (N=2034) from 34 gene signatures reported to be predictive of ER, PR, GATA3, FOXA1 and/or AR signalling. A multiclass significance analysis of microarrays with 100 iterations and a false discovery rate of 0.05 was used to extract differentially expressed genes.

Results
Of 2034 steroid receptor signalling associated genes 36 exhibited differential expression in the IDLBC1/2 and -3 groups. The IDLBC1/2 specific set included 2 ER-associated genes (WLS, SPARCL1), 1 FOXA1-associated gene (NTN4) and 2 PR-associated genes (ZBTB16, CRY2). The IDLBC3 overexpressed set included 31 genes, amongst them regulators of mitotic fidelity, as well as effectors of centromere and kinetochore functioning. Eight of these genes have been reported as ER-associated (POLR2H, ECE2, SCL7A5, KIF11, FAM83D, GPSM2, MASTL, POLE2). Additional IDLBC3 hallmarks included high proliferation activity, defect apoptosis, epithelial-mesenchymal-transformation (EMT), BRCA-ness, multiple-drug resistance (MDR) and early relapse. The estimated relapse-free-survival rate at 5 years in the IDLBC3 group was 77% [95%CI 72; 82], significantly lower than in IDLBC1/2 tumours (91% [95%CI 89; 93]) and comparable to triple negative IDLBCs on the METABRIC study (70% [95%CI: 65; 76]).

Conclusions
We have shown that our integrated classification method has the potential to segregate early relapsing luminal breast cancers (IDLBC3) from tumours with favourable prognosis (IDLBC1/2). The data presented here and in the abstract by Demanse et al [4] provide also an intuitive hypothesis why IDLBC3 tumours are sensitive towards Letrozole but not Tamoxifen. Prospective clinical studies will be required to validate this hypothesis and to demonstrate the value of the IDLBC classification approach.

Distinct biological signatures describe differences in BRCA mutated subgroups

Jeremy Force¹, Jennifer Plichta¹, Ilona Stashko¹, Gretchen Kimmick¹, Kelly Westbrook¹, Sarah Sammons¹, Shelley Hwang¹, Terry Hyslop¹, Noah Kauff¹, Edgardo Castellar¹, Smita Nair¹, Kent Weinhold¹, Sarah Davis², Afshin Mashadi-Hossein², Heather Ann Brauer² and Paul Kelly Marcom¹. ¹Duke University Medical Center, Durham, NC and ²Nanostring Technologies, Seattle, WA.

**Background:** BRCA mutated (BRCA+) breast cancers are expected to have increased activation of Homologous Recombination Deficiency (HRD) and altered DNA damage repair pathways when compared to BRCA wildtype (BRCA-). To better understand differences in these populations, biological patterns and immune responses to BRCA+ breast cancers were evaluated. The primary aim of our study was to use novel gene expression tools to assess early stage breast cancers with and without germline BRCA mutations, and within distinct BRCA+ subgroups.

**Methods:** We identified 124 early stage untreated breast cancers with and without BRCA mutations (n = 62 and 62, respectively). Our BRCA- group was matched by hormone receptor (HR) status, age, and stage to the BRCA+ group. The NanoString Breast Cancer 360 panel was applied to RNA isolated from 80 breast tumors (BRCA+ = 39; BRCA- = 41). The BRCA+ group had a BRCA1+ subgroup (n=17) and a BRCA2+ subgroup (n=22).

**Results:** There was a significant increase in two BC360 signatures in both the BRCA1+ and BRCA2+ tumors compared with the BRCA- population: Prosigna™Risk of Recurrence (ROR) score [BRCA1+: HR: 1.142 (95% CI 1.019, 1.279), p=0.02; BRCA2+: HR: 1.321 (95% CI 1.190, 1.466), p<0.001] and HRD [BRCA1+: HR: 3.576 (95% CI 2.174, 5.880), p=0.02; BRCA2+: HR: 1.801 (95% CI 1.142, 2.840), p<0.001]. BRCA1+ tumors had lower expression of ESR1 [p=0.03], PGR [p=0.02], ER signaling [p<0.001], and differentiation [p=0.005]; while BRCA2+ tumors had lower expression of stroma markers [p=0.02] and inflammatory chemokines [p=0.001]. The two BRCA+ subgroups had distinct molecular subtype correlation trends that were highly significant. BRCA1+ tumors were positively associated with a basal subtype [p<0.001], whereas this association was not significant for BRCA2+ tumors. BRCA2+ tumors were associated with an increase in luminal B subtype [p=0.05]. All BRCA+ tumors had a decrease in luminal A subtype correlation [BRCA1+: p<0.001; BRCA2+: p=0.002]. In addition to the BC360 signatures, a differential analysis of all genes in the BC360 panel revealed more single gene differences in BRCA2+ than BRCA1+ tumors when compared to BRCA- tumors.

**Conclusions:** In early stage BRCA+ breast cancer, tumors have higher ROR and increased HRD signature scores compared to BRCA- tumors. Furthermore, BRCA1+ and BRCA2+ tumors have both signature and single gene expression differences when compared to BRCA- tumors, indicating distinct subgroup-related biology. The greater correlation of BRCA1+ tumors with basal-like biology and BRCA2+ tumors with aggressive hormonal biology confirms these trends. Distinctions in hormone receptor signaling, DNA-damage pathways, and microenvironment/inflammatory features between BRCA1 and BRCA2 associated cancers suggest a need for different prevention and therapeutic strategies for each of these breast cancer subtypes. The unique biological patterns identified here should be further evaluated as predictive or prognostic tools that could be translated into clinical care for early stage BRCA+ patients.
SOX11 is a potential prognostic marker of high-risk breast ductal carcinoma in situ

Farah A Ladha¹, Kazuharu Kai¹, Wei Lu¹, Fei Yang¹, Ximing Tang¹, Ignacio I Wistuba¹, Subrata Sen¹ and Alastair Thompson¹.
¹The University of Texas MD Anderson Cancer Center, Houston, TX.

Ductal carcinoma in situ (DCIS) comprises 20-25% of screen-detected breast cancers and, like invasive ductal carcinoma (IDC), is heterogenous in terms of the underlying biology, presentation, and outcome. While there are limited potential biomarkers of outcome for DCIS, estrogen receptor (ER)- positive, progesterone receptor (PR)- positive, and HER2- negative DCIS appears to have a better prognosis compared to ER- negative, PR- negative, and HER2- positive DCIS. The aim of this study was to identify additional clinically relevant markers to stratify DCIS according to risk of relapse or progression to invasive disease. In order to determine the driver genes involved in DCIS evolution, we utilized transcriptional data sets (GSE788, GSE16873), containing data from both normal mammary glands (NMG) and DCIS. Upon performing class comparison (NMG vs DCIS), we identified 297 over-expressed genes and 187 under-expressed genes. The over-expressed genes represented mitotic and proliferative features annotated as mitotic spindle and condensed chromosomes, while the under-expressed genes were associated with loss of epithelial features annotated as epithelial cell differentiation and development. The 484 differentially expressed genes were further correlated with recurrence events using Kessler’s breast cancer data set to identify genes contributing to the aggressive features across IDC and subsequently associated with DCIS. Genes correlating with recurrence events were selected. Of the 484 genes, 99 genes were found to be significantly associated with recurrence events of IDC (with P<0.003). Among these 99 genes, component genes of the Oncotype DCIS score and genes reported as relevant to DCIS biology were included for Nanostring transcriptomic analysis. The final number of genes-of-interest were 58, including 5 housekeeping genes. 40 DCIS lesions and 8 NMG tissue were macro- dissected from formalin- fix paraffin- embedded blocks (FFPE) and extracted transcripts were subjected for Nanostring analysis. Gene expression data was clustered in an unsupervised manner using R software. Two sample clusters were identified: an ER/PR- negative cluster and an ER/PR- positive cluster. Over-expression of transcription factor SOX11, along with HER2, was exclusively seen in the ER/PR- negative cluster. This cluster was further categorized into HER2-low/SOX11+ and HER2-high/SOX11+ groups. These RNA expression findings are undergoing confirmation by immunohistochemistry (IHC) of the FFPE tumor sections. An independent series of 15 DCIS cases that have recurred as DCIS or progressed to IDC were analyzed by IHC, revealing SOX11 expression only present in cases displaying a high proportion of HER2+ expression. SOX11 is exclusively expressed in ER/PR-negative DCIS and is a candidate clinical marker for recurrence of DCIS or progression to IDC.
The 21-gene recurrence score and chemotherapy use in triple negative breast cancer (TNBC) and HER2 positive breast cancer: A National Cancer Database study

Judy C Boughey¹, Tanya L Hoskin¹, Daniela Cocco², Courtney N Day¹, Roberto Leon-Ferre¹, Elizabeth B Habermann¹ and Matthew P Goetz¹. ¹Mayo Clinic, Rochester, MN and ²Maricopa Integrated Health, Phoenix, AZ.

Background
The 21-gene (Oncotype DX) Recurrence Score (RS) is a multi-gene expression assay that is both prognostic and predictive of adjuvant chemotherapy (AdjCT) benefit in estrogen receptor (ER) positive/HER2 negative breast cancer (BC). Use of the RS in TNBC and HER2+ BC is not recommended by national guidelines. Using the National Cancer Database (NCDB), we sought to evaluate whether oncologists use the RS in these subtypes. Additionally, we assessed the prognostic effects of the RS in node negative patients (pts) who did or did not receive adjuvant chemotherapy.

Methods
Pts with TN and HER2+ BC diagnosed from 2010-2015 in the NCDB were analyzed. Pts with neoadjuvant therapy or stage IV were excluded. Cases with RS testing were classified as low (RS 0-17), intermediate (RS 18-30) or high (RS 31+). Analysis was performed using multivariable logistic regression; overall survival (OS) was analyzed using the Kaplan-Meier method with log-rank tests.

Results
142,330 pts were evaluable: 64,830 TNBC and 77,500 HER2+ (21,768 ER-/HER2+ and 55,732 ER+/HER2+). In these subtypes, RS was performed in 5,369 (3.8%) pts as follows: 1,479 (2.3%) TNBC, 185 (0.8%) ER-/HER2+, and 3,705 (6.6%) ER+/HER2+.

In AdjCT untreated TNBC, 5 yr OS did not differ for low RS (96.5%) vs intermediate RS (95.2%, p=0.82). In contrast OS was significantly worse for high RS (76.7%) than the other two groups, each p≤0.04.

In AdjCT untreated ER+/HER2+, 5 yr OS was significantly better for low RS (96.7%) vs intermediate RS (92.5%, p=0.03) and vs high RS (92.1%, p=0.003), with no difference between intermediate RS vs high RS (p=0.32).

Conclusions
RS testing is being conducted in a small fraction of pts with TN and HER2+ BC with lower clinical risk features. The observation that RS is prognostic for survival in AdjCT untreated patients is hypothesis generating, and suggests that further evaluation of the RS and other multigene assays in ER negative and HER2+ BC is warranted.
A unique coding and non-coding benign breast transcriptome in post-menopausal ER+ breast cancer

Jodi M Carter¹, Asha A Nair¹, Jaime I Davila¹, Ethan P Heinzen¹, Tanya L Hoskin¹, Stacey J Winham¹, Derek C Radisky², Daniel W Visscher¹ and Amy C Degnim¹. ¹Mayo Clinic, Rochester, MN and ²Mayo Clinic, Jacksonville, FL.

Background: Differences in ER+ and ER- breast cancer tumor biology are well-documented, but little is known about the field of background benign breast in which those cancers arise. We evaluated the transcriptome of benign breast tissues from women with concurrent ipsilateral ER+ and ER- breast cancers (BC) to characterize coding and non-coding RNA profiles. This pilot study provides insight into the transcriptomic landscapes of benign breast tissues in patients with BC, and the microenvironment of the at-risk benign tissue.

Methods: With institutional approval, cryobanked breast tissues from patients with concurrent ipsilateral ER+ BC (benign ER+BC, N=14) or ER- BC (benign ER-BC, N=10), were selected for benign tissues with similar epithelial:stromal ratios and grouped into pre (preM) and post-menopausal (PM) groups. Following RNA sequencing (Illumina TruSeq Stranded mRNA kit & Illumina HiSeq 4000), reads were processed (MAP-RSeq v3.0.0) and aligned (STAR aligner; hg38). Differential expression (DE) analysis (edgeR 2.6.2) identified DE genes from normalized RPKM reads (absolute log2 fold change (FC) > 1 and false discovery rate (FDR) < 0.10), corrected for intra-group biases. Over-representation analysis [Ingenuity pathway analysis (IPA), Ingenuity® Systems] and gene set enrichment analysis [(GSEA), GeneTrail 2.0] identified significantly-enriched pathways.

Results: In the PM group, there were 144 DE transcripts between benign ER+BC and benign ER-BC, including coding RNAs (40%), antisense RNAs (35%) and lncRNAs (7%). In contrast, the preM group had no significantly DE genes between benign ER+BC and benign ER-BC. In the PM DE coding gene set, the top DE transcripts in benign ER+BC included many genes implicated in BC development or ER+ BC progression (* e.g. up-regulated: KAAG1*, DNAJB7/HSP40*, TMEM151B, ZBTB32 p < 0.001; down-regulated: CPB1*, FOS, TPPP3*, CLEC3B p < 0.001). Top canonical pathways altered in benign ER+BC included MAPK, PI3K, and acute phase response pathways (p<0.05). GSEA of the entire gene set (N=15,223; ranked in order of 144 DE genes) identified 72 altered pathways (P < 0.005); those with the highest normalization enrichment scores (NES) (> 0.4) functionally grouped as immune function-related (T cell function and antigen presentation). Depleted pathways with NES > 0.4, (N=6) functionally grouped into proteasome-related, fatty acid biosynthesis and mitochondrial energy metabolism. Among the non-coding DE gene set, notably, the entire DE antisense RNA gene set (N=51 transcripts) was up-regulated in benign ER+ BC compared to benign ER-BC (P< 0.001) with a subset (N=11) showing marked up-regulation (> 4 log2FC). Among the DE antisense RNAs, 70% have reported roles in carcinogenesis or BC progression (e.g. KRT7-AS, NAV2-AS2, CCDC144NL-AS1, RP11-66B24.4, HSA-MIR4454).

Conclusion: The benign breast transcriptome differs between postmenopausal women with ER+ vs ER- BC, with distinctive coding and non-coding RNA signatures. In postmenopausal women with ER+ BC, benign breast expresses a unique antisense RNA set and is enriched in genes implicated in BC development or progression. These data provide insight into at-risk benign breast and facilitate identification of potential biomarkers of carcinogenesis.
Multi-omics profiling reveals distinct molecular features in young and elderly triple negative breast cancer

Ding Ma1, Yi-Zhou Jiang1, Meng-Dan Xie1, Yi Xiao1, Shen Zhao1 and Zhi-Ming Shao1. 1Fudan University Shanghai Cancer Center, Shanghai, China.

Purpose
Age at breast cancer diagnosis not only predicts clinical outcome, but also indicates distinct molecular features thus we can choose the most appropriate treatment strategies. Yet little is known about the molecular profile of young and elderly triple negative breast cancers (TNBCs).

Methods
Clinical, genomic and transcriptome features of young (<40 year-olds) and elderly (≥65 year-olds) TNBC patients were studied in a cohort of 473 TNBCs from Fudan University Shanghai Cancer Center.

Results
In this study, 50, 354 and 69 patients were <40, 40–64 and ≥65 years of age, respectively. Young TNBCs had more relapse or metastasis within the first 2 years after surgery (P=0.036) which was also significant in the basal-like subgroup (P=0.004), while elderly TNBCs were more likely to be luminal androgen receptor (LAR) subtype (46%) harboring frequent PIK3CA and KMT2C/KMT2D somatic mutations, with more fibrosis or mesenchymal-like (MES) subtype (in the basal-like subgroup) and featured by significantly lower Ki-67 index. Gene set enrichment analyses revealed that young TNBCs showed elevated expression of genes involved in cell cycle, nucleotide metabolism and DNA damage repair. In further discussion on nucleotide metabolism, TYMS, a crucial gene encoding thymidylate synthase while is also the target of fluorouracil and capecitabine, were identified to be enriched in young TNBCs independent of molecular subtype in both our cohort (adjusted P<0.001) and METABRIC (adjusted P=0.027). We next studied DNA damage features and found that while TNBCs of different age groups had comparable somatic mutation load, their mutations had distinct generation mechanism that homologous recombination deficiency (HRD) related signature and Aging related signature tend to be enriched in younger and elder patients, respectively. We also observed higher germline BRCA1 mutation rate in young TNBCs (23%). Interestingly, while germline BRCA2 mutation rate was comparable among the groups, copy number (CN) loss of Chr13q13 (with BRCA2 in the 'peak') was almost exclusively found in young patients (adjusted P<0.05). We also found enriched CN loss at Chr15q13 (with FAN1 in the 'peak') and CN amplification at Chr1p34 (with KDM4A in the 'peak') in young patients. These two events significantly affected the expression levels of FAN1 and KDM4A, respectively, and were both corrected with genomic based HRD indexes.

Conclusions
TNBCs of different age had distinct clinical and molecular features. We should pay attention to that nearly half of the TNBCs diagnosed at 65 years-old or later were not basal-like cancers but a special group with positive AR staining. Taking together with the higher fibrosis/MES proportion in elderly TNBC, we should reconsider the benefit of specific treatment strategies (like neoadjuvant chemotherapy) in these patients. The young TNBCs were characterized by activated cell cycle, elevated nucleotide metabolism (especially TYMS expression and corresponding pyrimidine metabolism) and enhanced DNA damage (especially HRD). These molecular features supported the aggressive phenotypes of young TNBC, while also provide us with potential therapeutic strategies.
PIK3CA mutations in breast cancer: Mutational landscape and clinical implications in ER+/HER2- subtype

Hee Kyung Ahn¹, Seri Park², Seung Hyup Hyun³, Kyunghee Park³, Eunjin Lee⁴, Ji-Yeon Kim⁵, Seok Jin Nam⁵, Seok Won Kim⁵, Jeong Eon Lee⁵, Se Kyung Lee⁵, Jong Han Yu⁵, Jin Seok Ahn⁵, Young-Hyuck Im⁵ and Yeon Hee Park². ¹Gachon University Gil Medical Center, Incheon, Korea; ²Samsung Advanced Institute for Health Sciences & Technology, Seoul, Korea and ³Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea.

Introduction: PIK3CA mutation is one of the most frequent genomic alterations in breast cancer. We evaluated PIK3CA mutational status including spatial and temporal heterogeneity, clinical characteristics and prognostic impact focused on ER+/HER2- subtype.

Methods: We performed targeted ultra-deep sequencing (CancerSCAN™) of breast cancer tissue in a prospective cohort. Burden of disease was assessed by metabolic tumor volume(MTV) in 18F-FDG-PET scan. Association with clinical characteristics or survival were tested in ER+/HER2- subtype, using Chi square test or Kaplan-Meier method.

Results: PIK3CA analyses were performed in 1274 breast cancer specimens from 1091 patients. 957 patients had early breast cancer. PIK3CA alterations were found in 397 patients(36.3%), and frequency of PIK3CA mutation was significantly lower in triple negative breast cancer(19.0%), compared with 40.4% in ER+/HER2-, 40.9% in ER+/HER2+, and 45.2% in ER-/HER2+ subtype(p<0.0001). 158 patients had more than two biopsies. Among 92 patients with second biopsy within one month, 11%(10/92) had spatial heterogeneity of PIK3CA mutation. After neoadjuvant chemotherapy, 10%(3/30) of patients had change of PIK3CA mutational status. Serial biopsy at time of recurrence revealed loss or gain of PIK3CA mutation in 10 out of 59 patients (17%). In ER+/HER2- subtype, PIK3CA had a trend toward longer distant disease free survival without statistical significance. In patients with stage IV ER+/HER2- disease, PIK3CA hotspot mutations were associated with significant longer overall survival(OS) (71.0 vs. 37.8 months, p=0.048) and better progression free survival(PFS) at 1st line palliative treatment (37.7 vs. 9.4 months, p = 0.0004). Frequency of symptomatic recurrence, recurrence as oligometastases, and specific metastatic sites were not associated with PIK3CA mutational status, except that bone metastases at first distant metastases was less prevalent in patients with PIK3CA hotspot mutations(35.6% vs. 53.8% in PIK3CA wt, p=0.048). Metabolic tumor volume(MTV) at time of first distant metastases was not associated with presence of PIK3CA mutation.

Conclusion: We observed variations in PIK3CA mutational status in more than 10% of patients with >1 repeated biopsy. In stage IV ER+/HER2- disease, PIK3CA hotspot mutation seemed to be associated with longer PFS and OS, however metabolic tumor burden was not associated with PIK3CA alterations.
Exploring the role of ctDNA in triple negative breast cancer

Wendie D den Brok¹, Esther Kong², Cherie Bates³, Rosalia Aguirre-Hernandez³, Ruth R Miller³, Amy Lum², Adrian Wan³, Sohrab Shah⁴, Samuel Aparicio² and Karen A Gelmon¹. ¹BC Cancer, Vancouver, BC, Canada; ²BC Cancer Research Centre, Vancouver, BC, Canada and ³Contextual Genomics, Inc., Vancouver, BC, Canada.

BACKGROUND: Previously published work shows that triple negative (TNBC) is a heterogeneous disease with varying levels of genomic instability, where higher genomic instability is associated with poorer prognosis. Subgroups of TNBC patients with distinct patterns of genome aberrations may indicate pathologies in specific genome maintenance/repair processes. Circulating tumor DNA (ctDNA) as assessed by next generation sequencing (NGS) is a relatively non-invasive test that may provide prognostic and predictive information.

AIM OF STUDY: To analyze genomic alterations with serial plasma samples using NGS methods of ctDNA analysis and determine the utility for actionability and disease burden monitoring. We shall also determine whether TNBC subgroups differ in their ctDNA profiles. Shallow whole genome sequencing vs targeted capture at depth will be contrasted to determine sensitivity for relapse detection.

METHODS: Enrollment of a planned cohort of TNBC patients (N=300) with any stage, at diagnosis (dx) or within 2 years of dx, or at relapse of disease with ongoing plasma sampling every 3 - 6 months. Patient age, stage, grade, type of chemotherapy, date of relapse and date of last followup are collected. Tumor tissue (FFPE), saliva for germline mutations and serial blood draws for ctDNA are analyzed with two NGS sequencing methods: (i) a high sensitivity small hotspot gene panel (33 genes, 170 hotspots), directed purely at actionable findings (ii) capture sequencing directed at multiple regions of the genome or shallow whole genome sequencing.

RESULTS: Preliminary analysis in 20 patient cases using the targeted hotspot panel. Median followup 151 days. Two cases had plasma drawn at time of relapsed disease and 1 at the time of de novo metastatic disease; 12 had plasma samples drawn prior to neoadjuvant chemotherapy (clinical T1/T2N1, T3/T4Nany), and 5 had plasma draws after primary surgery (pathologic T1N0, T2N0). Of the neoadjuvant cases, 5 (42%) had a pathologic complete response (pCR); 4 with ctDNA mutations and 1 without. Six (58%) neoadjuvant cases did not achieve a pCR; 3 with ctDNA mutations, 3 without. One patient is awaiting surgery. Twelve (60%) cases had mutations in TP53, one case had 2 different TP53 mutations (no pCR) and one case had 3 mutations: TP53, PIK3CA, KRAS (achieved pCR). Of the cases treated with curative intent, with short followup (FU), there have been no relapses including the case of the sample containing 3 mutations.

CONCLUSION: TP53 mutations may be a marker of higher genomic alteration burden and may have prognostic value in patients with newly diagnosed, non-metastatic TNBC with longer FU. Ongoing analysis of serial plasma samples and FFPE analysis may provide further insight into the prognostic value of ctDNA. Full genome sequencing may be needed identify other mutations that have prognostic and/or predictive value. We have accrued over 200 patients with samples being analyzed and plan to present an interim analysis of the cohort at SABCS 2018.
Quantifying intrinsic subtype admixture in luminal A breast cancer and its relationship to clinical outcomes

Neeraj Kumar¹, Dan Zhao¹, Amit Sethi² and Peter H Gann¹. ¹University of Illinois at Chicago, Chicago, IL and ²Indian Institute of Technology Bombay, Mumbai, India.

**Background/Objectives:** PAM50 gene profiling assigns each cancer to a single intrinsic subtype. However, individual cancers vary in their adherence to a prototype, and some may exhibit expression patterns that indicate intra-tumor admixture of multiple subtypes. Our objective was to develop admixture metrics from PAM50 gene expression profiles in order to stratify Luminal A cases according to their degree of subtype admixture, and then relate such admixture to clinical and molecular variables.

**Methods:** We re-constructed scaled, normalized PAM50 profiles for 1,980 cases (674 LumA) in the METABRIC cohort and for each case we computed its Mahalanobis (M-) distance from its assigned centroid and its M-distance from all other centroids. We used t-SNE plots to visualize overlaps in subtype clustering. With Normal-like cases excluded, Median Distance Criteria (MDC) classified a case as Pure if it was located within the 50th percentile of the LumA centroid and >50th percentile from any other centroid. Distance Ratio Criteria (DRC) was computed as the ratio of M-distances from the LumA centroid to the nearest non-assigned centroid; cases were grouped by DRC tertile. Pure and admixed LumA cases were compared on clinical, molecular and survival traits. TCGA LumA cases (n=509) were used for independent validation.

**Results:** Compared to admixed cases in METABRIC, pure ones by MDC had younger age at diagnosis, smaller tumor size, lower grade and lower stage. Comparisons of the highest (T3, most admixed) to lowest tertile (T1) for DRC revealed even stronger associations. Admixed cases, by both metrics, were more likely to show HER2 gain, high proliferation by AURKA expression, higher PAM50 Risk of Recurrence scores, more frequent TP53 mutation, and less frequent mutation of PIK3CA and CBFB. Similar results were observed in the TCGA validation cohort. LumA-LumB confusion was predominant, but other combinations with LumA were also present. Degree of admixture was associated with overall survival in both cohorts, as was disease-free survival in TCGA, independent of age, grade and stage. (See table for adjusted hazard ratios).

**Conclusions:** Luminal A breast cancers subgrouped based on PAM50 subtype purity support the hypothesis that admixed cases have worse clinical features and survival. Future analyses will explore more extensive genomic metrics for admixture and their spatial significance within a single tumor.

Proteomic profile of PAM50 intermediate risk early breast cancers

Nawale Hajjaji1,2, Soulaimane Aboulouard2, Yves Marie Robin1,2, Delphine Bertin1, Isabelle Fournier2, Jacques Bonneterre1 and Michel Salzet2. 1Oscar Lambret Cancer Center, Lille, France and 2PRISM Laboratory U1192 - University of Lille, Lille, France.

Background
Breast cancer is a heterogeneous disease with a wide range of outcomes that are not fully predicted by routine clinical and pathologic features. The risk of recurrence of hormone receptor positive early-stage breast cancer, the most frequent tumor subtype, increases continuously over time. Genomic-based signatures have been developed to categorize patients according to their risk of recurrence and guide therapeutic decisions in this tumor subtype. However, the main genomic-based assays used in clinical practice classify up to 40% of the patients in an intermediate risk group. Many interrogations remain about the optimal strategy in this group. The aim of this study was to refine the molecular characterization of the intermediate risk group and determine the proportion of shared features with the low or high-risk groups using a mass spectrometry based proteomic approach.

Methods
Tumors with available routine PAM50 assay (PROSIGNA) results were selected from a cohort of breast cancer patients treated at Oscar Lambret Cancer Center (France). Fifteen tumors evenly split between PAM50 low, intermediate and high-risk groups were analyzed to determine the proteomic profiles of both cancer cells and stroma using MALDI mass spectrometry imaging combined with microproteomics, a spatially resolved proteomic technology.

Results
PAM50-Intermediate risk tumors had a distinctive proteomic profile compared to low and high-risk tumors. Heterogeneous nuclear ribonucleoproteins, 4-aminobutyrate aminotransferase, and pleckstrin homology-like domain family A member 1 are discriminating proteins between intermediate risk and low risk tumors. Differences were observed in expression of integrin beta-1, DNA replication licensing factors, splicing factors and interleukin enhancer-binding factor 2 between intermediate and high-risk tumors. Proteomic profiles of stroma according to tumor risk groups also showed differential protein expressions mainly between intermediate and high-risk groups. Breast cancer markers such as nuclear mitotic apparatus protein 1 (NUMA1), C-1-tetrahydrofolate synthase (MTHFD1), cystatin-C (CST3), and T-cell immune regulator 1 (TCIRG1) were identified in high-risk tumors. Specific protein profiles were identified in stroma versus tumor. Immunoglobulin kappa chain, IGHG1, IGHM, IGHM, MMP2, ORM1 & ORM2, podocan, asprorin, immunoglobulin superfamily containing leucine-rich repeat protein (ISLR) were detected in stroma. By contrast, squamous cell carcinoma antigen recognized by T-cells 3 (SART3), shootin-1, mitotic checkpoint protein BUB3, XRCC5 &XRCC6, membrane-associated progesterone receptor component 2 (PGRMC) and hepatocyte growth factor-regulated tyrosine kinase substrate (HGS) were specifically detected in tumor. Further analyses on an expanded cohort of patients will be presented.

Conclusion
MALDI mass spectrometry proteomics reveal distinctive tumor and microenvironment profiles in PAM50 intermediate risk early breast cancers.
Age's importance in early breast cancer: Oncotype Dx results in patients $\leq$ 40 years

Rossana Ruiz$^{1,2}$, Fernando Namuche$^1$, Zaida Morante$^{1,2}$, Alfredo Aguilar$^1$, Diego Urrunaga$^1$, Gonzalo Ziegler$^3$, Mariana Chavez Mac Gregor$^4$, Mauricio Leon$^3$ and Henry Gomez$^{1,2}$.  
$^1$OncoSalud, Lima, Peru; $^2$INEN, Lima, Peru; $^3$Clínica Ricardo Palma, Lima, Peru and $^4$MD Anderson, Houston, TX.

Background
The 21-gene recurrence score (RS) predicts the benefit of adjuvant chemotherapy (CT) in ER-positive HER2-negative breast cancer (BC) and has been validated in population where women under 40 are underrepresented. Young BC pts are more likely to receive adjuvant chemotherapy (CT) in addition to endocrine therapy (ET). Our objective was to assess the RS results in young ($\leq$ 40 yo) vs older (>40 yo) pts and evaluate the impact of age on clinical decision-making according to RS categories.

Methods
We retrospectively reviewed electronic medical files of all patients with early stage hormone receptor BC for whom RS was available between 2007 and 2017 in 3 specialized cancer centers. We used the Mann-Whitney and Chi-squared tests to assess differences between age group. Similarly, we evaluated the association between age groups and treatment, within each ODx category. To determine if age was associated with CT use in the low risk category, a logistic regression model was constructed.

Results
A total of 551 pts were included, 53 (9.6%) $\leq$ 40 yo and 498 (90.4%) >40 yo. No statistical differences were found between the younger and older groups in T (p=0.874), N (p=0.794), stage (p=0.188), or grade (p=0.791). Young patients underwent radical surgery more frequently than their older counterparts (41.5 vs 25.7%, p=0.014). Statistically significant differences were also observed in ER mean, which was lower in the younger group (80 vs 90%, p<0.001). The median RS result was significantly higher in the younger group (19 vs 16, p=0.009). Also, high-risk recurrence score category was significantly more frequent in the younger group (22.6 vs 9.2%, p=0.009). In the intermediate-risk category there were no differences in the proportion of patients who received CT according to age groups (p=0.484). In the low-risk category, 28.0% of patients $\leq$ 40 years vs 11.3% of patients >40 years received CT (p=0.037).

Conclusions
Our results indicate that RS tends to be higher in patients with BC $\leq$ 40 yo and that the frequency of high-risk RS is significantly higher in the younger group, suggesting biological differences between groups. 28% of young patients with low-risk RS from our cohort are overtreated. Based on these results, it should be considered to develop a test adjusted to the age of the patients.
Evaluation of Oncotype DX testing and subsequent treatment choices in the Latin American setting

Rossana Ruiz1,2, Zaida Morante1,2, Fernando Namuche2, Diego Urrunaga4, Alfredo Aguilar1, Jesus Schwarz1, Mauricio Leon3, Gonzalo Ziegler3, Mariana Chavez Mac Gregor5 and Henry Gomez1,2. 1ONCOSALUD - AUNA, Lima, Peru; 2Instituto Nacional de Enfermedades Neoplasicas, Lima, Peru; 3Clinica Ricardo Palma, Lima, Peru; 4Universidad de San Martin de Porres, Lima, Peru and 5MD Anderson Cancer Center, Houston, TX.

Background: The gene expression profiling assay OncotypeDx (ODx) prognosticates the risk of estrogen receptor positive (ER+) breast cancer (BC) recurrence and assesses the likely benefit from adjuvant chemotherapy in addition to endocrine therapy. Numerous clinical utility studies have shown that acknowledging the RS impacts on clinical decision making, leading to a decrease in chemotherapy (CT) use. However, the cost of the assay limits its widespread use, especially in low and middle-income countries. Our objective was to determine the patterns of use of ODx, its results and the subsequent treatment choices in a large Latin American cohort.

Methods: We retrospectively reviewed the electronic medical records of patients with early-stage ER+ BC for whom ODx recurrence score (RS) was available. Patients were diagnosed and treated at 3 specialized Peruvian cancer centers between 2007 and 2017. Descriptive results for numeric variables were presented as means with standard deviation (SD) or medians with interquartile range (IQR), depending on their distributions; otherwise, we expressed the qualitative variables as numbers with percentages. We evaluated the association between ODx RS category and treatment using the Chi-squared test.

Results: A total of 551 patients were included. Patients had a mean age of 56.2 ± 11.9 (SD) (range: 26-89). 9.6% (n=53) of patients were ≤40 years old. The size of the tumors ranged from 0.1 cm to 7.2 cm (median = 1.5 cm; IQR 1.0-2.2cm). 36 (6.5%) patients had tumors ≤0.5cm and 7 (1%) had tumors >5cm. A minority of patients had lymph node involvement (5.8%, n=32). ODx was ordered in 55 cases (10%) of lobular carcinoma and in 23 cases (4%) of favorable histology tumors (19 mucinous, 4 tubular). Most tumors exhibited an intermediate histological grade (71.6%, n=386). Ki67 was available in 58.8% patients (n= 324), with a median Ki67 of 20 (IQR 10-30). Using commercial cutoffs RS was distributed as follows: low (0–17) = 316 (57.4%), intermediate (18–30) = 177 (32.1%), and high (≥31) = 58 (10.5%). In general, 57.5% (n=317) of patients received endocrine therapy (ET) as their only systemic treatment and 42.5% (n=234), also received CT (ET + CT). In the low-risk category, 87.3% (n=276) of patients received ET and 12.7% (n=40), ET + CT. Within the intermediate-risk category, most patients received ET + CT (77.4%, n=137). Only one patient in the high-risk category did not receive CT. There was a significant association between the RS group and treatment choice (p<0.001)

Impact of ODx RS results on treatment recommendations

Conclusion: ODx significantly influenced treatment decisions in our cohort, however an overutilization of CT was found in low-risk patients. Further data analysis is needed to explain the higher than expected use of CT. Also, there is room for improvement in the selection of cases that undergo ODx testing.
Clinicopathological characteristics associated with intermediate and high-risk ODx RS

Rossana Ruiz1,2, Zaida Morante1,2, Fernando Namuche1, Diego Urrunaga4, Mauricio Leon3, Gonzalo Ziegler3, Alfredo Aguilar1, Mariana Chavez Mac Gregor5 and Henry Gomez1,2. 1ONCOSALUD - AUNA, Lima, Peru; 2Instituto Nacional de Enfermedades Neoplasicas, Lima, Peru; 3Clinica Ricardo Palma, Lima, Peru; 4Universidad San Martin de Porres, Lima, Peru and 5MD Anderson Cancer Center, Houston, TX.

**Background:** The gene expression profiling assay OncotypeDx (ODx) prognosticates the risk of estrogen receptor positive (ER+) breast cancer (BC) recurrence and assesses the likely benefit from adjuvant chemotherapy in addition to endocrine therapy. There have been several attempts to develop algorithms that provide similar outcome prediction to the ODx assay with the use of routine clinicopathological characteristics. These models appear to predict high-risk ODx RS but are unable to reliably rule out the presence of patients with intermediate-risk disease. Our objective was to identify the clinicopathological factors associated with intermediate and high-risk categories.

**Methods:** We retrospectively reviewed the electronic medical records of patients with early-stage ER+ BC for whom ODx recurrence score (RS) was available. Patients were diagnosed and treated at 3 specialized cancer centers between 2010 and 2017. Two multinomial logistic regression models (crude and adjusted) were constructed to assess the association between clinicopathological characteristics and ODx RS as a categorical variable. The adjusted model included the following variables: ODx RS, age, tumor size, node status, grade, lymphovascular invasion and hormonal receptors. The reported association measure was the relative prevalence ratio (RPR) with its respective 95%CI.

**Results:** A total of 551 patients were included. Patients had a mean age of 56.2 ± 11.9 (SD) (range: 26-89). 9.6% (n=53) of patients were ≤40 years old. The size of the tumors ranged from 0.1 cm to 7.2 cm (median = 1.5 cm; IQR 1.0-2.2cm). A minority of patients had lymph node involvement (5.8%, n=32). By subtype, carcinomas were mostly ductal (83.5%, n=460), followed by lobular (10.0%, n=55) and mucinous (3.5%, n=19). The majority of tumor exhibited an intermediate histological grade (71.6%, n=386). Ki 67 was available in 58.8% patients (n= 324), with a median Ki67 of 20 (IQR 10-30). In the adjusted multinomial logistic regression model, factors associated with ODx intermediate-risk category were grade 3 (RPR=4.78; 95%CI: 2.01-11.39) and having either ER or PR <50 (RPR=2.80; 95%CI: 1.83-4.27). Factors associated with ODx high-risk category were grade 3 (RPR=15.89; 95%CI: 3.23-78.19), having either ER or PR <50 (RPR=4.58; 95%CI: 2.37-8.87), age ≤40 (RPR=2.96; 95%CI: 1.20-7.29) and T2-3 (RPR=2.20; 95%CI: 1.13-4.32).

**Conclusion:** Grade 3, ER o PR <50, age ≤40 years and T2-3 are clinicopathological characteristics strongly associated with high-risk ODx RS. The associations with intermediate-risk ODx RS are weaker. The way these factors could be integrated into a clinicopathologic risk prediction model to identify high-risk patients needs further analysis.
Proteomic tracking of breast cancer metastasis progression

Nawale Hajjaji1,2, Soulaimane Aboulouard2, Yves Marie Robin1,2, Delphine Bertin1, Isabelle Fournier2, Jacques Bonneterre1 and Michel Salzet2. 1Oscar Lambret Cancer Center, Lille, France and 2PRISM Laboratory U1192 - University of Lille, Lille, France.

Background
Metastases from breast cancers have not yet reached curability mainly because of the continuous evolution of cancer cells leading to treatment resistance and tumor progression. Despite the identification of the main genomic drivers of breast cancer resistance, and the development of specific targeted therapies, resistance has not been eradicated. A deeper understanding of tumor biology underlying treatment escape and tumor progression is necessary to find new targets. The aim of this study was to determine whether mass spectrometry based imaging and microproteomics are able to capture changes in protein expression and pathways occurring during metastasis progression.

Methods
Ten tumor samples from five progressing metastatic breast cancer patients treated at Oscar Lambret Cancer Center (France) were selected based on the availability of paired metastasis biopsy performed at two time points during the evolution of the disease. The proteomic profiles of paired tumor samples were analyzed using MALDI mass spectrometry imaging combined with microproteomics, a spatially resolved proteomic technology.

Results
Comparison of paired samples showed gain and loss of proteins associated with tumor progression. However, few were shared between patients. The pathways and biological processes mainly represented during tumor progression, and which were found in at least two patients, were those involved in the negative regulation of leukocyte mediated cytotoxicity, the metabolism of carboxilic acid, peptides and nucleosides, in response to stress, oxidation-reduction process, endocytosis, catabolic processes, actin regulation, and extracellular matrix organization. During metastasis evolution, few shared proteins were identified in at least 3 patients such as SRPX2, CILP1, collagen alpha-2(V) chain, Ras-related C3 botulinum toxin substrate 1, filamin-C, PDZ and LIM domain protein 2 and chloride intracellular channel protein 4. The main proteins lost during progression and found in at least 2 patients were cell surface glycoprotein MUC18, collagen alpha-2(IV) chain, polyadenylate-binding protein 2, and latent-transforming growth factor beta-binding protein 4 (LTAGP4). Results from an expanded cohort will be presented at the meeting.

Conclusion
MALDI mass spectrometry proteomics identified private and shared changes in proteins and biological processes associated with breast cancer metastasis progression.
Clinical next-generation sequencing analysis in ER-positive HER2-negative metastatic breast cancer patients: Mutation frequency & clinical correlations

Janneke Goyens¹, Kevin Punie¹, Hans Wildiers¹, Ann Smeets¹, Sara Vander Borght¹, Guiseppe Floris², Ignace Vergote¹, Els Van Nieuwenhuysen¹, Sileny Han¹, Ines Nevelsteen¹, Patrick Neven¹ and Isabelle Vanden Bempt¹. ¹KU Leuven - University of Leuven, Leuven, Belgium and ²KU Leuven - University of Leuven, Laboratory of Translational Cell & Tissue Research and University Hospitals Leuven, Leuven, Belgium.

Background: Clinical next-generation sequencing (NGS) has opened new perspectives on genome-driven therapy for metastatic breast cancer (MBC) through the identification of recurrent driver mutations. However, therapeutic relevance of the detection of these mutations with a potential impact on disease outcome and treatment resistance remains unclear.

Patients and Methods: A monocentric retrospective study was performed to investigate mutation frequency and disease outcome in 86 metastatic breast cancers patients treated in UZ-Leuven and tested for the presence of mutations in representative formalin-fixed, paraffin-embedded tumor tissue using a routine diagnostic panel of 26 cancer genes (TruSight Tumor 26, Illumina, mean coverage 500X). It mainly concerned metastatic lesions (96.5%). Out of 86 patients, 63 had hormone receptor (HR) positive/HER2-negative disease; 8 were HER2-positive and 15 triple negative as determined by immunohistochemistry (IHC)/Fluorescence in situ hybridization (FISH). The 63 ER-positive/HER2-negative cases were selected for further investigation. Single-nucleotide variants and insertions/deletions were reported.

Results: Overall, mutations (> 5% allelic frequency) were found in 60.3% of the cases. As expected, mutations in PIK3CA and TP53 were being most frequently encountered (35% and 19% respectively); variants in AKT1, KRAS and PTEN were less common (5%, 3% and 2% respectively). Focusing on ER-positive/HER2-negative cases, 13 out of 63 had a single PIK3CA mutation, 6 had a single TP53 mutation and 21 cases had more than 1 mutation. In 23 out of 63 cases, no potentially actionable mutation could be identified using the 26 cancer gene panel. Interestingly, we found a clinically relevant and statistically significant difference in median progression-free survival between patients harboring a TP53 mutation only (19.8 months (m), range 12.1 – 27.4) and those harboring a PIK3CA mutation only (84m, range 7.4 – 215.1) or patients without any detected mutation (45.3m, range 5.8 – 225.8). Similarly, overall survival was significantly worse for TP53 mutated cases compared with patients with a PIK3CA or no mutation at all. Finally, a brief comparison of MBC-therapies used in these different subgroups showed the interesting finding that none of 7 PIK3CA-mutated tumors treated with fulvestrant monotherapy showed treatment response.

Conclusion: This small retrospective analysis showed that clinical sequencing using a small targeted NGS panel reveals mutations in 60.3% of MBC patients, with 40% being targetable. Besides predictive implications, detection of these mutations could also have major prognostic implications on distant metastasis free survival and overall survival.
Clinical Impact of HER-3 among patients with breast cancer – Molecular classification

Libor Stanek¹,², Petra Tesarova¹, Michal Vocka¹, Lubos Petruzela¹ and Zdenek Musil³. ¹Department of Oncology, Prague, Czech Republic; ²Department of Surgery, Prague, Czech Republic and ³Institute of Biology and Genetics, Prague, Czech Republic.

Receptors of HER family play an important role in breast cancer. Dimerization of HER2 with other members of HER (HER3) is the major driving mechanism for growth and survival of tumor cells. Numerous studies show that overexpression of HER3 gene correlates with bad prognosis. However, other studies show contrarily overexpression of HER3 as a positive prognostic factor. HER3 may provide resistance against certain therapeutics focusing on EGFR or HER2 receptor. The interesting fact is that the expression of HER3 might serve in imonotherapy as a marker among TNBC. It is suggested it participates not only on the cell survival and proliferation, but also on the regulation of expression of PD-L1.

The aim of the study was to monitor ERBB3 gene amplification (ZytoLight ® SPEC ERBB3 / CEN12 Dual Color Probe) and IHC expression of the HER-3 (HER-3 / c-erbB-3 RMab) in a cohort of 40 patients (20 HER-2 positive patients, 20 TNBC patients). Activation of tumor infiltrating lymphocytes (TIL) CD8 (clone C8 / 144B) CD4 (Clone 4B12) (Dako), expression of PD-L1 (Anti-PD-L1, Clone28-8, Dako) and TP53 mutation. Assess their clinical impact in relation to the HER-3 receptor.

20 patients were with a median age of 49.4 years (14 postmenopausal [46.7%] and 16 premenopausal [53.3%]) with detected HER-2 FISH amplification (histologically 18 patients with HER-2 subtype which means without hormone receptor positivity and 12 patients with luminal B subtype and thus hormone receptor positive). All patients were without evidence of distal metastases (6 in stage I, 13 in stage II and 11 in stage III).

20 patients subtype of TNBC were with a median age of 33.6/33.2 years (10/10 no relapse/relapse). All patients were without evidence of distal metastases (2/2 in stage I, 5/5 in stage II and 3/3 in stage III). Median follow-up (months) 59.8/23.3; median time to relapse (months) NR/15.9; median overal survival (months) NR/30.2.

The results demonstrated the amplification / expression of CERB3 / HER-3 in 2/20 (a group of TNBC patients), and 13/20 (a group of HER-2 positive patients). Expression of PD-L1 was demonstrated in 3/20 HER-2 positive and 2/20 TNBC. Expression of HER-3 correlated in 100% with PD-L1 expression. There was a strong correlation between positive expression of HER-3 and PD-L1 (p = <0.001). The TP53 mutation was found in 5 patients with HER-2 carcinoma and 6 TNBC and was always a HER-3-free patient (correlation was not found.) Activated antitumor immunity TIL (CD8 + positivity) in more than 15% (group TNBC) / 45% (group HER-2) of tumor and concurrently no expression (CD4-). There was a strong correlation between positive expression of HER-3 and activation of TIL (p = <0.001) in the HER-2 positive group.

However, the view of the HER-3 receptor will be far more complex, and it appears that overexpression of this receptor will have both negative and positive prognostic significance. Attention should be focused on the entire signaling pathway, including activation of the immune system. The significance of the current mutation of TP53 and HER-3 expression has not been demonstrated.
Oncotype Dx recurrence score risk groups according to Ki67, a predictor to be considered

Fernando Namuche¹, Rossana Ruiz¹,², Zaida Morante¹,², Alfredo Aguilar¹ and Henry Gomez¹,². ¹Oncosalud, Lima, Peru and ²INEN, Lima, Peru.

Background
The gene expression profiling assay OncotypeDx (ODx) prognosticates the risk of estrogen receptor positive (ER+) breast cancer (BC) recurrence and assesses the likely benefit from adjuvant chemotherapy in addition to endocrine therapy. There have been several attempts to develop algorithms that provide similar outcome prediction to the ODx assay with the use of routine clinicopathological characteristics. Ki67 is frequently incorporated into these assessments, although there is no standard cut-off for its use.

Methods
We retrospectively reviewed the electronic medical records of 330 patients with early stage ER+ BC for whom ODx recurrence score (RS) was available. Patients were diagnosed and treated at two specialized cancer centers between 2014 and 2017. Our objective was to determine the ki67's median differences between ODx risk groups.

We used Spearman rho for the correlation between Ki67 and ODx score and used Kruskal-Wallis test for compare medians, pairwise comparison for the intergroup relations.

Results
Mean age at diagnosis was 57.42 years (range 28-89). Mean tumor diameter was 15.67 mm. 78.9% were intermediate histologic grade and 9.7% patients had lymph node involvement. Median expression of ER and PR were 90% (5-100) and 70% (0-100), respectively. We assessed the correlation between Ki67 and ODx score, with a pearson r:0.31, p<0.001. The data showed a directly proportional trend between Ki67 and ODx score.

Median Ki67 was 20 (1-100). According to ODX RS, 61.5% of tumors were low risk, 30.3% were intermediate risk and, 8.2% were high risk. Median Ki67 within each category group is as follows: low: 15 (IQR:15), intermediate: 20 (IQR:18) and high: 40 (IQR:35), with a statistically significant difference between medians (p<0.001). In the Pairwise comparison intergroup the data showed: Low-Intermediate (p<0.05), Low-High (p<0.001), Intermediate-High (p<0.001).

Conclusions
The data showed directly proportional trend between Ki67 and ODx score. In our population there is a statistically significant difference between Ki67 medians according to ODx risk groups.
Prosigna assay for treatment decisions in early breast cancer: A single center, decision impact study

Ece Esin¹, Berna O Oksuzoglu¹, Fatma Markoc¹, Irem Bilgetekin¹, Fatih Yildiz¹, Sezen Guntekin², Fusun Yukruk¹ and Rengul Atalay². ¹University of Health Sciences Dr.A.Y. Ankara Oncology Hospital, Ankara, Turkey and ²Middle East Technical University, Ankara, Turkey.

Background: Therapeutic decisions in early breast cancer (EBC) are based on clinical and pathological features, which are subject to intra- and inter-observer variability. Hence, in the era of precision medicine, there is growing need for predictive biomarkers. The Prosigna assay utilizes Prediction Analysis of Microarray, a test based on the analysis of 50 intrinsic subtype-linked gene clusters. This single center decision impact study aimed to evaluate the effect of Prosigna test results on physicians’ adjuvant treatment choices.

Methods: Between September 2017 and February 2018, FFPE tumor samples from 53 newly diagnosed, postmenopausal, hormone receptor-positive, HER2-negative EBC (T1-T2; pN0-N1a) patients were analyzed. Pre-test clinical judgments and Prosigna test results were compared.

Results: Mean age was 59 (42-77). Invasive ductal carcinoma (79.2%), grade 2 (52.8%) and T1c-N0 tumors (43.4%) represented the majority. Before the Prosigna test, 65.4% of the patients were classified as luminal A and 34.6% as luminal B. Of the pre-test risk groups, 40.4% were low-risk, 40.4% were intermediate risk and 19.2% were high risk. Prosigna assay grouped 50% of patients as luminal A, 44.2% as luminal B, 3.8% as basal type and 1.9% as HER2-expressing. Post-test ROR score-based groups were distributed as 25% low-risk, 40.4% intermediate risk and 34.6% high risk. There was a statistically significant correlation between clinically defined and molecularly assessed intrinsic BC subtypes (kappa:0.334, p=0.007). Similarly, pre-test and post-test recurrence risk groups were correlated (kappa:0.397, p=0.001). Before the Prosigna test, endocrine treatment was physicians’ primary choice in 20 patients (39.2%), chemotherapy was recommended to 31 patients (60.8%). Overall, the Prosigna assay led to a change in choice of treatment for one patient (2%)
